FIGURE F13.3.1. Photomicrograph of an atheromatous plaque in the coronary artery. This low-magnification photomicrograph shows a cross section of the human coronary artery with chronic coronary heart disease. The specimen is stained with the Verhoeff van Gieson technique for elastic and connective tissue fibers. The *black strands* represent elastic lamellae; a distinct intact internal elastic membrane (*IEM*) is present between the *dark red*-stained tunica media (*TM*) containing smooth muscle cells and the pathologically changed tunica intima (*TI*). Variable shades of *pink* material represent collagen fibers deposited in a thick tunica intima, which contains an advanced atheromatous plaque with visible calcifications (*dark pink-orange*) and accumulation of extracellular lipids (cholesterol clefts). The *light pink* color surrounding the lumen of the vessel represents the most recent deposition of the pathologic material. Note that the lumen of the vessel is occluded almost 90%, which leads to inadequate coronary blood flow. Tunica adventitia (*TA*) represents the outermost layer of the vessel. $\times 34$. (Courtesy of Dr. William D. Edwards.)

FIGURE F13.3.2. Photomicrograph of the coronary artery with a mural thrombus. This photomicrograph shows a cross section of the coronary artery in a less advanced stage of atherosclerotic disease. The fibrofatty plaque is visible in the tunica intima (*TI*) and a thrombus is superimposed on a plaque, partially obstructing the arterial lumen. The *dashed line* indicates the border between the tunica intima and the tunica media (*TM*). The tunica adventitia (*TA*) forms the outermost layer of the vessel. $\times 40$. (Courtesy of Dr. William D. Edwards.)

- **Dural venous sinuses** represent venous channels in the cranial cavity. They are essentially broad spaces within the dura mater that are lined with endothelial cells and devoid of smooth muscles.
- The **great saphenous vein** represents a long subcutaneous vein of the lower limb that originates in the foot and drains into the femoral vein just below the inguinal ligament. This vein is often described as a **muscular vein** because of the presence of an unusual amount of smooth muscle (Fig. 13.28). In addition to

the thick circular arrangement of smooth muscle in its tunica media, the great saphenous vein possesses numerous longitudinal smooth muscle bundles in the intima and in the well-developed adventitia. A thin, poorly developed internal elastic membrane separates the tunica intima from the media. The great saphenous vein is frequently harvested from the lower limb and used for autotransplantation in coronary artery bypass graft (CABG) surgery when arterial grafts (usually taken from the internal thoracic artery) are not available or many grafts are required for multiple bypass anastomoses. CABG is the most common type of open-heart surgery performed in the United States.

FIGURE 13.28. Photomicrograph of the great saphenous vein. This photomicrograph shows a section through the wall of the great saphenous vein. The tunica intima is usually thicker than in the other medium-sized veins and is characterized by the presence of numerous longitudinal smooth muscle bundles (*SM*) separated by connective tissue fibers. The tunica media contains a relatively thick layer of circularly arranged smooth muscles. The tunica adventitia is well developed and contains additional layers of smooth muscle fibers arranged in spiral, oblique, and longitudinal bundles. $\times 380$. (Courtesy of Dr. Joseph J. Maleszewski.)

- The **central adrenomedullary vein** that passes through the adrenal medulla and its tributaries has an unusual tunica media. It contains several longitudinally oriented bundles of smooth muscle cells that vary in size and appearance (Fig. 13.29). These irregularly arranged smooth muscle bundles (also called **muscle cushions**) extend into larger tributaries of the central adrenomedullary vein. This unique eccentric arrangement of smooth muscle bundles results in irregularity of the thickness of the vascular wall. In areas where muscle bundles are absent, cells of the adrenal medulla or sometimes adrenal cortex are separated from the lumen of the vein by only a thin layer of the tunica intima (see Fig. 13.29). Contraction of the longitudinally arranged smooth muscles in the tunica media enhances the efflux of hormones from the adrenal medulla into the circulation.

FIGURE 13.29. Photomicrograph of the central adrenomedullary vein. This photomicrograph of the human adrenal gland shows a large central adrenomedullary vein with its tributary stained with hematoxylin and eosin (H&E). The wall of the vein is highly irregular, containing several longitudinally oriented bundles of smooth muscles (*SM*) that extend into the wall of a tributary. This unique eccentric arrangement of smooth muscles, sometimes called *muscle cushions*,

results in the irregularity of the thickness of the vascular wall. Note that in the cleft between two smooth muscle bundles (*asterisk*), the lumen of the vein is separated from the chromaffin cells of the adrenal medulla only by the tunica intima. On the opposite side of the wall, muscle bundles are absent (*arrowheads*) and the cells of the adrenal cortex are in direct contact with the tunica intima. $\times 120$. (Courtesy of Dr. Donald J. Lowrie Jr., University of Cincinnati College of Medicine.)

Veins in certain other locations (e.g., retina, placenta, trabeculae of the spleen) also have atypical walls and are discussed in the chapters that describe these organs.

■ LYMPHATIC VESSELS

Lymphatic vessels convey fluids from the tissues to the bloodstream and are important in the immunologic surveillance.

In addition to blood vessels, another set of vessels circulates fluid called **lymph** through most parts of the body. These lymph-carrying vessels serve as adjuncts to the blood vessels. Unlike the blood vessels, which convey blood to and from tissues, the **lymphatic vessels** are unidirectional, conveying fluid only from tissues. As mentioned earlier, approximately 90% of the extravasated fluid is reabsorbed at the venous side of the capillary network. Lymphatic vessels return the remaining 10% to the blood vascular system. In healthy adult individuals, the lymphatic system returns as much as 8 L of interstitial fluid with 20–30 g of protein per L to the blood circulation each day. In addition to this fluid **homeostasis function**, the lymphatic vessels are involved in the **immunologic surveillance** transporting antigens and antigen-presenting cells from the periphery to lymph nodes. In the gastrointestinal tract, lymphatics (lacteals) are crucial for **absorption of dietary fats** in the form of chylomicrons (an assembly of triglycerides, cholesterol, cholesteryl esters, phospholipids with apolipoprotein B). These processes all depend on the organized movement of fluid, solutes, and cells across the wall of the lymphatic vessel.

Defects affecting lymphatic vessels can lead to **lymphedema**, a clinical condition that is characterized by a localized

accumulation of interstitial fluid and tissue swelling. The most common presentations involve swelling of upper and lower limbs, tissue fibrosis, susceptibility to infections, and accumulation of adipose tissue. Primary lymphedema has origin from genetic defects that affect the development of the lymphatic vessels, whereas secondary lymphedema is most likely caused by surgery, radiation therapy, infection, or trauma.

The smallest lymphatic vessels are called **lymphatic capillaries**. They are especially numerous in the loose connective tissues under the epithelium of the skin and mucous membranes. The lymphatic capillaries begin as “blind-ended” tubes in the microcapillary beds (see Fig. 13.23). Lymphatic capillaries converge into increasingly larger **collecting vessels** called **lymphatic vessels**, and they connect with chains of **lymph nodes** where lymph is filtrated. They ultimately unite to form two large lymphatic vessels that empty into the blood vascular system by draining into the large veins in the base of the neck. Lymph enters the vascular system at the junctions of the internal jugular and subclavian veins. The largest lymphatic vessel, draining most of the body and emptying into the veins on the left side, is the **thoracic duct**. The other main channel is the **right lymphatic trunk**.

Lymphatic capillaries are more permeable than blood capillaries and collect excess protein-rich tissue fluid.

Lymphatic capillaries are a unique part of the circulatory system, forming a network of small vessels within the tissues. Because of their greater permeability, lymphatic capillaries are more effective than blood capillaries in removing protein-rich fluid from the intercellular spaces. They are also specialized in the uptake of inflammatory molecules, dietary lipids, and immune cells. Once the collected fluid enters the lymphatic vessel, it is called **lymph**. Lymphatic vessels also serve to convey proteins and lipids that are too large to cross the fenestrations of the absorptive capillaries in the small intestine.

Before lymph is returned to the blood, it passes through **lymph nodes**, where it is exposed to the cells of the immune system. Thus, the lymphatic vessels serve not only as an adjunct to the

blood vascular system but also as an integral component of the immune system.

Lymphatic capillaries have unique oak leaf-shaped endothelial cells with discontinuous basal lamina and button-like cell-to-cell junctions.

Lymphatic capillaries are essentially blind-ended tubes of endothelium that are approximately 30–80 μm in diameter. Unlike typical blood capillaries, they are not surrounded by pericytes or smooth muscle cells and **lack a continuous basal lamina** (Fig. 13.30). Lymphatic endothelial cells in lymphatic capillaries have a distinctive oak leaf shape. The overlapping flaps of adjacent endothelial cells interdigitate with one another (see Fig 13.30, inset). Lymphatic endothelial cells have characteristic **discontinuous** or **button-like cell-to-cell junctions** concentrated at the scalloped edges of the cells. These junctions are similar to **occluding (tight) junctions** in vascular epithelial cells composed of occludins, claudins, zonula occludens-1 (ZO-1), and junctional adhesion molecules (JAMs). They also contain **vascular endothelial cadherin** (VE-cadherin), which is found in the anchoring junctions. The gaps between tight junctions at the tip of the flaps express **platelet and endothelial cell adhesion molecule-1 (PECAM-1)**; also known as CD31). Homophilic interactions between leukocyte PECAM-1 and endothelial PECAM-1 are required for the migration of lymphocytes into the lymphatic capillary. Therefore, these areas provide the entry point for leukocytes, dendritic cells, and interstitial fluid into the vessels. The incomplete basal lamina and discontinuous cell-to-cell junctions are correlated with their high permeability, which enables optimal uptake of lymph components.

FIGURE 13.30. Diagrams and scanning electron microscope of a lymphatic capillary. Lymphatic capillaries are characterized by a discontinuous basal lamina and anchoring filaments that extend from endothelial cells to the extracellular matrix. Anchoring filaments consist of fibrillin microfibrils similar to those found in the elastic fibers. In the large figure on the *left*, note the overlapping flaps of adjacent endothelial cells that interdigitate with one another. The *lower inset* is an enlarged view of the basal domain of lymphatic endothelial cells containing discontinuous occluding junctions (button-like cell-to-cell adhesions). These junctions are concentrated at the overlapping edges of the cells. The gaps between tight junctions at the tip of the flaps express platelet and endothelial cell adhesion molecule-1 (PECAM-1). Interactions between leukocyte PECAM-1 and endothelial PECAM-1 are required for the migration of lymphocytes into the lymphatic capillary in the direction shown by the *yellow arrows*. The *upper inset* is a scanning electron micrograph showing the loosely apposed overlapping borders of lymphatic endothelial cells as they are visible from the basal domain of lymphatic endothelial cells following the removal of surrounding connective tissue. $\times 32,000$. (Reprinted with permission from Baluk P, McDonald DM. Buttons and zippers: endothelial junctions in lymphatic vessels. *Cold Spring Harb Perspect Med.* 2022,12:a041178.)

The lymphatic capillaries are connected to the surrounding extracellular matrix by **anchoring filaments** that extend between endothelial cells and their incomplete basal lamina and the

perivascular collagen (see Fig. 13.30). They consist of **fibrillin microfibrils** composed of **fibrillin-1** molecules and microfibril-associated protein **emilin-1**, which are similar to those found in elastic fibers of connective tissue. Anchoring filaments maintain the patency of the vessels during times of increased tissue pressure, such as in inflammation. **Deficiency in emilin-1 synthesis in animals is related to structural and functional defects of lymphatic capillaries.**

The lymphatic endothelial cells are terminally differentiated cells distinct from blood vascular endothelial cells. In the early embryo, under the influence of prospero-related homeobox transcription factor (**Prox-1**) or vascular endothelial growth factor C (**VEGF-C**), lymphatic endothelial cells bud from cardinal veins, giving rise to primitive lymph sacs. Lymphatic vessels subsequently sprout from lymphatic sacs, forming a separate vascular network with lymphatic vascular-specific molecules expressed on the surface of lymphatic endothelial cells. Markers used for identifying lymphatic vessels in tissues include **Prox-1**, the transmembrane glycoprotein **podoplanin (PDPN)**, vascular endothelial growth factor receptor-3 (**VEGFR-3**), and lymphatic vessel hyaluronan receptor-1 (**LYVE-1**). **Clinically, podoplanin is widely utilized as a marker for lymphatic differentiation in the evaluation of vascular tumors.**

In contrast to lymphatic capillaries, the lumens of **lymphatic vessels** exhibit features to prevent leakage of lymph. These include **continuous (zipper-like) tight junctions** between the endothelial cells and a continuous basal lamina that is surrounded by smooth muscle cells. As lymphatic vessels become larger, their walls thicken as more connective tissue and bundles of smooth muscle are added. Lymphatic vessels possess bileaflet **valves** that prevent backflow of the lymph, thus aiding unidirectional flow (Plate 13.4, page 480). There is no central pump in the lymphatic system. Lymph moves sluggishly, driven primarily by compression of the lymphatic vessels by adjacent skeletal muscles. In addition, contraction of the smooth muscle layer surrounding lymphatic vessels may help propel the lymph.

CARDIOVASCULAR SYSTEM

OVERVIEW OF THE CARDIOVASCULAR SYSTEM

- The **cardiovascular system** includes the heart, blood vessels, and lymphatic vessels. It carries blood and lymph to and from tissues of the body.
- The cardiovascular system consists of the **pulmonary circulation** (conveys arterial blood from the heart to the lungs and returns venous blood back to the heart) and **systemic circulation** (conveys arterial blood from the heart to all other tissues and returns venous blood back to the heart).

HEART

- The **heart** is a four-chambered muscular pump (two atria and two ventricles). It contains **cardiac muscle** (for contraction to propel blood), a **fibrous skeleton** (for attachment of valves and separation of atrial and ventricular musculature), a **conducting system** (for initiation and propagation of rhythmic contractions), and **coronary vasculature** (coronary arteries and cardiac veins).
- The wall of the heart is composed of three layers: epicardium, myocardium, and endocardium.
- **Epicardium** (visceral layer of serous pericardium) is the outer layer of the heart and consists of mesothelium with underlying connective and adipose tissue. It contains coronary vasculature.
- **Myocardium** is the middle layer and consists of cardiac muscle.
- **Endocardium** is the inner layer and consists of endothelium, subendothelial connective tissue, and a

subendocardial layer containing cells of the conducting system of the heart.

- Heart valves are composed of three layers: *fibrosa*, *spongiosa*, and either *ventricularis* (in semilunar valves) or *atrialis* (in atrioventricular valves).
- Contraction of the heart is initiated and synchronized by the *conducting system*, which consists of modified cardiac myocytes forming the *sinoatrial* (or *sinu-atrial*) (SA) node, *atrioventricular* (AV) node, *AV bundle* (of His), and *Purkinje fibers*.
- The heart rate is regulated by the sympathetic nerves (increase rate) and parasympathetic nerves (decrease rate) as well as by circulating hormones (*epinephrine* and *norepinephrine*) and other substances (Ca^{2+} , thyroid hormones, caffeine, etc.).

GENERAL FEATURES OF ARTERIES AND VEINS

- The walls of arteries and veins are composed of three layers called *tunics*.
- *Tunica intima*, the innermost layer of the vessel, consists of *endothelium*, a *subendothelial layer* of connective tissue, and an *internal elastic membrane*.
- *Tunica media*, the middle layer, consists of circumferentially arranged layers of vascular smooth muscle cells with elastic lamellae interposed between them. In arteries, tunica media is relatively thick and extends between the internal and external elastic membranes.
- *Tunica adventitia*, the outermost connective tissue layer, is composed primarily of collagen with few dispersed elastic fibers. It contains *vasa vasorum* and a network of autonomic nerves called *nervi vasorum* (*vascularis*).
- *Endothelial cells* actively interact with underlying vascular smooth muscle cells and connective tissue. In addition to maintaining a selective permeability barrier between blood and connective tissue, the endothelial cells prevent blood clotting (by secretion of anticoagulants and

antithrombogenic agents), modulate vascular resistance (by secretion of vasoconstrictors and vasodilators), and regulate immune responses.

ARTERIES

- **Arteries** are classified into three types based on the size and thickness of their tunica media: large arteries (elastic arteries), medium arteries (muscular arteries), and small arteries (including arterioles).
- **Elastic arteries** have a tunica media that consists of multiple layers of vascular smooth muscle cells separated by elastic lamellae. Fibroblasts are not present in the tunica media.
- **Muscular arteries** have a tunica media with more smooth muscle and less elastic lamellae than the elastic arteries. They also have a prominent internal elastic membrane in the tunica intima.
- **Small arteries** and arterioles are distinguished from one another by the number of smooth muscle cell layers in the tunica media.
- **Arterioles** have one to two layers of smooth muscles and regulate **vascular resistance**, thus controlling blood flow to capillary networks.
- **Arteriovenous shunts** allow blood to bypass capillaries by providing direct routes between the arteries and the veins. This pathway is regulated by contraction of precapillary sphincters on the **metarterioles**.

CAPILLARIES

- **Capillaries** are the smallest diameter blood vessels and are classified into three different types: **continuous** (characterized by uninterrupted vascular endothelium), **fenestrated** (characterized by numerous openings in the capillary wall and the continuous basal lamina), and **discontinuous** or **sinusoidal** capillaries (larger in

diameter with large openings, intercellular gaps, and a discontinuous basal lamina).

- Pericytes associated with capillaries represent a population of undifferentiated mesenchymal stem cells.

VEINS

- Veins are divided into four types based on their size (diameter): venules (<0.1 mm), small veins (<1 mm), medium veins (<10 mm), and large veins (>10 mm).
- Postcapillary venules collect blood from the capillary network and are characterized by the presence of pericytes. In lymphoid tissues, they are lined by cuboidal endothelium (high endothelial venules), which facilitates extensive lymphocyte migration from the blood.
- Small, medium, and large veins have a relatively thin layer of tunica media and a more pronounced tunica adventitia.
- Veins, especially of limbs, may contain valves preventing the backflow of blood.
- Large veins near the heart may contain myocardial sleeves in the tunica adventitia.

LYMPHATIC VESSELS

- Lymphatic vessels convey interstitial fluids from tissues to the bloodstream.
- The smallest and most permeable lymphatic vessels are called lymphatic capillaries. They drain lymph into larger collecting lymphatic vessels and then into the thoracic duct or right lymphatic trunk before emptying it into the venous system.
- All collecting lymphatic vessels possess valves that prevent the backflow of lymph.

PLATE 13.1 ■ HEART

The **cardiovascular system** is a transport system that carries blood and lymph to and from the tissues of the body. The cardiovascular system includes the heart, blood vessels, and lymphatic vessels. Blood vessels provide the route by which blood circulates to and from all parts of the body. The heart pumps the blood. Lymphatic vessels carry tissue-derived fluid, called *lymph*, back to the blood vascular system.

The **heart** is a four-chambered organ consisting of a right and left atrium and a right and left ventricle. Blood from the body is returned to the right atrium from which it enters the right ventricle. Blood is pumped from the right ventricle to the lungs for oxygenation and returns to the left atrium. Blood from the left atrium enters the left ventricle from which it is pumped to the rest of the body, that is, the systemic circulation.

The heart, which forms from a straight vascular tube in the embryo, has the same basic three-layered structure in its wall as do the blood vessels above the level of capillaries and postcapillary venules. In the blood vessels, the three layers are called the **tunica intima**, including the vascular endothelium and its underlying connective tissue; the **tunica media**, a muscular layer that varies in thickness in arteries and veins; and the **tunica adventitia**, the outermost layer of relatively dense connective tissue. In the heart, these layers are called the **endocardium**, the **myocardium**, and the **epicardium**, respectively.

Atrioventricular septum, heart, human,
hematoxylin and eosin (H&E) $\times 45$; inset $\times 125$.

This micrograph of the field shows portions of the atrial (*A*) and ventricular (*V*) walls at the level of the **atrioventricular septum** and the root of the mitral valve (*MV*). Both chambers and the valve are lined with squamous endothelium of the **endocardium** (*En*). **Purkinje fibers** (*PF*) of the cardiac conduction system are seen in the atrial wall between the relatively thin subendocardial connective tissue (*CT*) and the underlying modified **cardiac muscle cells** (*CM*) of the atrioventricular node (*AVN*). Dense fibrous connective tissue (*DCT*) that is continuous with that of the septum and the subendocardial layers of the atrium and ventricle extends from the root of the valve into the leaflet. Thin cardiac muscle fibers can also be seen extending from the wall of the atrium into the upper portion of the valve. **Inset.** This higher magnification view of the area outlined by the *rectangle* (turned $\sim 90^\circ$) shows more clearly the endothelial layer of the **endocardium** (*En*)

and the dense fibrous connective tissue of the endocardium (*DCT*) and subendocardial layer. A thin layer of smooth muscle (*SM*) appears between the more densely packed fibrous tissue immediately subjacent to the endothelium and the more loosely packed dense fibrous tissue of the subendocardium. Particularly evident are the longitudinally sectioned Purkinje fibers (*PF*) of the cardiac conduction system. These modified cardiac muscle cells contain the same fibrillar contractile system as their smaller counterparts in the myocardium, but the fibrils are fewer, more loosely packed, and often surround what appear to be vacuolated areas. **Intercalated discs** (*ID*), typical of cardiac muscle cell organization, are evident in some areas.

Coronary artery and cardiac vein, heart, human, H&E $\times 30$.

This micrograph shows cross sections of a coronary artery and cardiac vein in the coronary sulcus. The surrounding adipose tissue (*AT*) serves to cushion the blood vessels that run in the coronary sulcus. The **coronary artery** (*CA*) in the *lower left* of this micrograph is surrounded by small bundles of small cardiac muscle cells (*CM*) that are part of the atrioventricular node (*AVN*). A small lymph node (*LN*) and a loop of the conduction bundle (*CB*) containing **Purkinje fibers** are evident next to the artery. The darkly stained tunica intima (*TI*) is delimited by an internal elastic membrane (*IEM*) that is easily distinguished even at this relatively low magnification. The thick muscular tunica media (*TM*) is also easily distinguished from the thinner, fibrous tunica adventitia (*TA*). A smaller arterial vessel (*A'*) is visible in the *upper left* of the micrograph. The larger vessel, the cardiac vein (*CV*), has a large lumen and thin wall relative to its size, a feature typical of veins compared to arteries. The tunica intima (*TI*) of this vein again appears as a darker layer. At this magnification, it is not possible to distinguish the tunica media from the adventitia. Partial aggregates of blood (*B*) cellular elements are present in the lumens of the vessels.

A, atrium
A' , small artery
AT, adipose tissue
AVN, atrioventricular node
B, blood
CA, coronary artery
CB, conduction bundle
CM, cardiac muscle
CT, connective tissue
CV, cardiac vein

DCT, dense connective tissue
En, endothelium
ID, intercalated disc
IEM, internal elastic membrane
LN, lymph node
MV, mitral valve
PF, Purkinje fibers
SM, smooth muscle
TA, tunica adventitia
TI, tunica intima
TM, tunica media
V, ventricle

PLATE 13.2 ■ AORTA

The **aorta**, the main systemic artery of the body, is an elastic artery. The presence of numerous fenestrated elastic lamellae allows it to resist the pressure variations caused by a rhythmic contraction of the left ventricle. The **intima** is comparatively much thicker than that seen in muscular arteries. The subendothelial layer of the intima consists of connective tissue with both collagen and elastic fibers. The cellular component consists of smooth muscle cells and fibroblasts. The external border of the intima is bounded by an internal elastic membrane that represents the first layer of the many concentric fenestrated laminae in the media of the vessel. The **media** constitutes the bulk of the wall. Between the elastic laminae are collagen fibers and smooth muscle cells. The latter are responsible for the synthesis of collagen and elastic fibers. With increasing age, the number and thickness of elastic laminae in the wall increase. By the age 35 years, as many as 60 laminae are found in the thoracic aorta. At ~50 years of age, individual laminae begin to show signs of degeneration and gradually become replaced by collagen, leading to a gradual loss of elasticity of the aortic wall.

The **adventitia** consists of irregular dense connective tissue with intermixed elastic fibers that tend to be organized in a circumferential pattern. It also contains small blood vessels that supply the outer portion of the media. They are the vasa vasorum of the aorta. Also present in the adventitia are lymphatic capillaries.

ORIENTATION MICROGRAPHS: The *upper micrograph* shows a cross section of a hematoxylin and eosin (H&E)-stained human aorta from a child. The intima (*I*) stains considerably lighter than the adjacent media (*M*). The adventitia (*A*) contains an abundance of collagenous fibers and stains more densely than that of either the media or the intima. The *lower micrograph* is from an adult and has been stained to reveal the elastic component of the vessel wall. The intima (*I*) is very lightly stained, in this case, owing to the paucity of elastic material. The media (*M*) is heavily stained owing to the presence of large amounts of elastic laminae. The adventitia (*A*) contains, in addition to the dense connective tissue, a moderate amount of elastic fibers.

Aorta, human, H&E $\times 365$; inset $\times 700$.

This micrograph shows the layers of the aortic wall. The intima consists of an endothelium (*En*) overlying loose connective tissue (*LCT*). The thickest portion of the vessel wall is the media (*M*). The wavy eosinophilic material is the collagenous fibers. The eosin stain does not reveal the elastic laminae. The nuclei are those of smooth muscle cells. Fibroblasts are absent. The outer layer of the vessel wall is the adventitia (*A*). The eosinophilic material here consists of dense connective tissue. The nuclei that are evident belong to fibroblasts. Also note the small blood vessel (*BV*) in the adventitia.

The *inset* shows the intima at higher magnification and includes part of the media. Note the endothelium (*En*). The eosinophilic material in the intima consists of collagenous fibers (*CF*). The main cell type here is the smooth muscle cell (*SMC*).

Aorta, human, iron hematoxylin and aniline blue
×255; inset ×350.

The specimen shown here has been stained to distinguish collagen from elastic material. The intima (*I*) consists mostly of collagenous fibers. The endothelium (*En*) represented by several nuclei is just barely evident. The media (*M*) contains numerous elastic lamellae that appear as the *black wavy lines*. The intervening *blue*-stained material consists of collagen fibers. Careful examination of the media reveals nuclei of smooth muscle cells dispersed between the elastic lamellae. The *inset* shows the intima at higher magnification. Note the nuclei of the endothelial cells (*EnC*) at the luminal surface. The remainder of the intima consists mostly of collagenous fibers (stained *blue*) with occasional elastic fibers (*EF*) identified by their *darker coloration*. The nuclei of the fibroblasts and occasional smooth muscle cells (*SMC*) appear randomly arranged.

Aorta, human, iron hematoxylin and aniline blue
×255.

This micrograph shows the outer portion of the media (*M*) with its elastic lamellae. The major portion of the micrograph is the adventitia (*A*). Here, the thick collagenous fibers (*CF*) are readily recognized. The outer portion of the adventitia contains numerous elastic fibers that appear as *black, dot-like* structures. These elastic fibers are arranged in a circumferential pattern, thus when sectioned, they appear as *black, dot-like* structures.

A, adventitia
BV, blood vessel
CF, collagenous fibers
EF, elastic fibers
En, endothelium
EnC, endothelial cells
I, intima
LCT, loose connective tissue
M, media

SMC, smooth muscle cells

PLATE 13.3 ■ MUSCULAR ARTERIES AND MEDIUM VEINS

Muscular arteries have more smooth muscle and less elastin in the tunica media than do elastic arteries. Thus, as the arterial tree is traced further from the heart, the elastic tissue is considerably reduced, and smooth muscle becomes the predominant component of the tunica media. The muscular arteries are characterized, however, by a refractile **internal elastic membrane** separating the tunica intima from the tunica media and usually by an **external elastic membrane** separating the tunica media from the tunica adventitia. Muscular arteries, or arteries of medium caliber, constitute the majority of the named arteries in the body. Veins usually accompany arteries as they travel in the loose connective tissue. The veins have the same three layers in their walls, but the tunica media is thinner than in the accompanying artery, and the tunica adventitia is the predominant layer in the wall. The veins usually have the same name as the artery they accompany.

Muscular artery and medium vein, monkey, hematoxylin and eosin (H&E) $\times 365$.

In this photomicrograph, the lumen of the artery is at the *left* and the lumen of the vein is at the *right*. Both vessels are joined by their outermost layers of tunica adventitia in the *middle* of this image. The arterial endothelium (*AEn*) is clearly seen on the corrugated surface of the tunica intima, whereas the venous endothelium (*VEn*) is somewhat harder to distinguish. The internal elastic membrane (*IEM*) of the artery is seen as a corrugated thin clear ribbon immediately beneath the endothelial layer, separating the tunica intima from the underlying smooth muscle (*SM*) layer of the tunica media (*TM*). The external elastic membrane containing elastic fibers (*EF*) separates the tunica media (*TM*) from the tunica adventitia of the artery (*TA'*). It is evident here that the tunica media is almost twice as thick as the tunica adventitia (*TA'*). The tunica media of the vein at the *right* is thin and difficult to detect. It contains a layer of small smooth muscles (*SSm*) that is adjacent to thick tunica adventitia (*TA*), which is about twice as thick as the tunica media in the vein. Tunica adventitia represents the outermost connective tissue layer containing bundles of collagen fibers with visible nuclei (*N*) of fibroblasts.

Muscular artery, monkey, H&E $\times 545$.

This is a higher magnification micrograph of the portion of the previous figure outlined by the *rectangle* turned 90 degree. At this magnification, it is evident that the flattened endothelial cells (*EN*) follow the contours of the refractile, corrugated internal elastic

membrane (*IEM*), which rests directly on the most luminal layer of smooth muscle cells (*SM*) of the thick tunica media (*TM*). The *lower portion* of the micrograph is occupied by the tunica adventitia (*TA'*), which is ~3 times thinner than that of the tunica media. Nuclei (*N*) of fibroblasts are visible among bundles of collagen fibers (*C*) and elastic fibers (*EF*) at the intersection between the tunica media (*TM*) and the tunica adventitia (*TA'*) of the artery.

Medium vein, monkey, H&E $\times 600$.

In this higher magnification view of a portion of the wall of the vein in the previous figure, the endothelial cells (*EN*) are more easily recognized and are seen to be plumper than those of the arterial endothelium. The margin between the tunica intima (*TI*) and the thin tunica media (*TM*) is difficult to discern, but the smooth muscle cells (*SM*) in the thin media are more easily recognized than in the previous figure because of the shape of their nuclei and the slight basophilia of their cytoplasm. The tunica adventitia (*TA*) is about twice as thick as the tunica media and appears to contain only bundles of collagen fibers and fibroblasts, with the latter recognizable by their nuclei (*N*). The collagen bundles of the loose connective tissue beneath the tunica adventitia are larger than those of the adventitia, and there are fewer cells in this portion of the specimen.

AEn, arterial endothelium
C, collagen bundles
EF, elastic fibers
EN, endothelial cells
IEM, internal elastic membrane
N, nuclei
SM, smooth muscle
SSm, small smooth muscle
TA, tunica adventitia of accompanying vein
TA', tunica adventitia of artery
TI, tunica intima
TM, tunica media
VEn, venous endothelium

PLATE 13.4 ■ ARTERIOLES, VENULES, AND LYMPHATIC VESSELS

The terminal components of the arterial tree just before a capillary bed or an arteriovenous shunt are the **arterioles**. Arterioles have an endothelial lining and smooth muscle in the wall, but the smooth muscle is limited in thickness to one or two cells. There may or may not be an internal elastic membrane, according to the size of the vessel. Arterioles control blood flow into capillary networks. In the normal relationship between an arteriole and a capillary network, contraction of the smooth muscle of the arteriole wall reduces or shuts off the blood going to the capillaries. A **precapillary sphincter** is formed by a slight thickening of the smooth muscle at the origin of a capillary bed from an arteriole. Nerve impulses and hormonal stimulation can cause the muscle cells to contract, directing blood into capillary beds where it is most needed.

Arteriole, venule, and small nerve,
fingertip, human, hematoxylin and eosin (H&E) $\times 600$.

This micrograph shows two cross-sectioned arterioles (*A*) and a venule (*V*). The **arteriole** on the *left* is identified as a large arteriole, based on the presence of two discrete layers of smooth muscle cells that form the tunica media of the vessel. The nuclei of the muscle cells appear in longitudinal profile as a result of the circumferential arrangement of the cells. The endothelial cell nuclei of the vessel appear as small round profiles surrounding the lumen. These cells are elongated and oriented with their long axis in the direction of flow. Thus, their nuclei are seen here as cross-sectioned profiles. The arteriole on the *right* is a very small arteriole, having only a single layer of smooth muscle. Again, the muscle cell nuclei are seen in longitudinal profile. The endothelial cell nuclei appear as *small round* profiles at the luminal surface. A venule is seen in proximity to the larger arteriole, and a cross section of peripheral nerve (*N*) is seen in proximity to the smaller arteriole. Compare the wall of the **venule**, consisting only of endothelium and a thin layer of connective tissue, with the arterioles. Also, note the relatively large lumen of the venule.

Arteriole, fingertip, human, H&E $\times 350$.

This micrograph shows a longitudinal section of an **arteriole**. Because of its twisting path through the section, its wall has been cut such that the single layer of muscle cells of the tunica media is seen in different planes along its length. In segment numbered 1, at the *left*, the vessel wall has been cut tangentially. Thus, the vessel lumen is not included in the plane of section, but the smooth muscle cell nuclei of the tunica media are seen in longitudinal profile. After the arteriole makes an acute turn (segment numbered 2), the vessel wall is cut to reveal the lumen. Here, the smooth muscle nuclei appear as round profiles, and the nuclei of the endothelial cells lining the lumen appear in longitudinal profile. In segment numbered 3, the vessel wall is again only grazed. In segment numbered 4, the cut is deeper, again showing the lumen and some of the endothelial cells in face view (*arrowheads*). The washed-out area above segment numbered 4 represents adipose tissue (*AT*). The area below the vessel is occupied by dense irregular connective tissue (*DCT*) and contains an encapsulated nerve ending known as a Pacinian corpuscle (*P*) that detects pressure and vibration applied to the skin surface.

Lymphatic vessel, fingertip, human, H&E $\times 175$.

The **lymphatic vessel** shown in this figure shows a region where the vessel is making a U-shaped turn in the plane of the section, thus disappearing at the *top* and *bottom* of the micrograph. The wall of the vessel consists of an endothelial lining and a small amount of connective tissue, with one being indistinguishable from the other. A **valve** (*Val*), which is characteristic of lymphatic vessels, is seen within the vessel. It is formed from a minuscule layer of connective tissue that is covered on both sides by endothelium. The *arrows* indicate nuclei that are just barely visible at this magnification; most of them belong to endothelial cells. Typically, the lumen contains precipitated lymph material (*L*); sometimes, lymphocytes may be present. Adjacent to the vessel, on the *right*, is adipose tissue (*AT*), and on the *upper left* is dense irregular connective tissue (*DCT*).

Lymphatic vessel, fingertip, human, Mallory trichrome $\times 375$.

The **lymphatic vessel** shown here is contained within dense irregular connective tissue (*DCT*). The lumen is irregular, appearing relatively narrow below the valve (*Val*). A few endothelial cell nuclei are evident (*arrows*). A thin layer of connective tissue that is present outside the endothelium blends with the dense connective tissue beyond the wall of the vessel. A venule (*V*) and arteriole (*A*) are also present; they can

readily be distinguished from the lymphatic vessel by thicker walls and by the presence of red blood cells in the lumen. Also at the *bottom left*, note a single adipocyte (*Ad*) from which a lipid droplet has been removed during slide preparation. In contrast to the lumen of the lymphatic vessel, which contains precipitated lymph material (*L*), the space occupied by the lipid droplet is borderless and clear.

A, arteriole
Ad, adipocyte
AT, adipose tissue
DCT, dense irregular connective tissue
L, lymph material
N, nerve
P, Pacinian corpuscle
V, venule
Val, valve
arrowheads, endothelial cells
arrows, endothelial cell nuclei

HISTOLOGY

■ OVERVIEW OF THE IMMUNE AND LYMPHATIC SYSTEMS

The physiologic role of the **immune system** is to defend the body against infectious microorganisms and pathogenic agents as well as noninfectious foreign substances and transformed cells and their products. The **lymphatic system** is a morphologic counterpart of the immune system and consists of groups of cells, tissues, and organs that monitor body surfaces and internal fluid compartments (Fig. 14.1). Thus, the term *immune system* reflects the physiologic role (i.e., defense mechanisms) of the lymphatic system. Included in the lymphatic system are primary and secondary lymphatic organs connected by lymphatic vessels that terminate in the blood vascular system. The two systems are so closely associated that they are virtually indistinguishable from each other. Throughout history, it has been noted that individuals who recover from certain diseases such as chickenpox, measles, and mumps become resistant or immune [*Lat., immūnis, free, exempt*] to the same disease. Another long-standing observation is that immunity is specific—that is, immunity to chickenpox does not prevent infection with measles. It is also recognized that the immune system can react against the body's own tissues, causing autoimmune diseases such as lupus erythematosus, autoimmune hemolytic anemia, some forms of diabetes mellitus, and autoimmune thyroiditis (Hashimoto thyroiditis).

FIGURE 14.1. Overview of the structures constituting the lymphatic system. The lymphatic system consists of a group of cells, tissues, and organs that are responsible for monitoring body surfaces and internal compartments in order to combat foreign microorganisms, transformed cells, and other harmful substances. Lymphocytes are the most important cells of

the lymphatic system. They differentiate and mature in the primary lymphatic organs, which for B lymphocytes is the bone marrow and for T lymphocytes is the thymus. Lymphocytes then enter into the blood or lymphatic vessels to colonize secondary lymphatic organs and tissues, where they undergo the final stages of antigen-dependent activation. Secondary lymphatic tissues consist of the spleen; various groups of lymph nodes and aggregations of lymphatic nodules, such as tonsils; conjunctiva-associated lymphatic tissue (*CALT*) in eyelids; bronchus-associated lymphatic tissue (*BALT*) in lungs; gut-associated lymphatic tissues (*GALT*) in the gastrointestinal tract; and mucosa-associated lymphatic tissue (*MALT*) throughout the genitourinary system (i.e., shown here is the mucosa of the bladder). Lymph is the fluid that is removed from the extracellular spaces of the connective tissues. It flows in lymphatic vessels into the lymph nodes, which are interspersed along the superficial lymphatic vessels (associated with the skin and superficial fascia) and deep lymphatic vessels (associated with main arteries). Ultimately, the lymphatic vessels empty into the bloodstream by joining the large veins at the base of the neck. The thoracic duct is the largest lymphatic vessel.

Almost all **cells of the immune system** are derived from **hemopoietic stem cells (HSCs)** in the bone marrow. Based on their progenitor stem cells (see pages 321–323), immune cells are derived from either the myeloid lineage (monocytes, macrophages, granulocytes, and dendritic cells) or lymphoid lineage (all lymphocytes). **Lymphocytes** are the definitive cell type of the immune system and the effector cells in the response of the immune system to harmful substances. Lymphatic tissues serve as primary sites where lymphocytes proliferate, differentiate, and mature. The **thymus** and **bone marrow** are the **primary lymphatic organs** in mammals (see Fig. 14.1) where lymphocytes are “born and educated” and equipped with diverse antigen receptors to recognize and destroy specific antigens. After undergoing maturation and a careful selection process in the primary lymphatic organs, lymphocytes migrate to the **secondary lymphatic organs** and tissues, including the spleen, lymph nodes, appendix, lymphatic nodules, and diffuse lymphatic tissues (see Fig. 14.1). Within these secondary lymphatic tissues in the presence of antigen, lymphocytes interact with each other and with nonlymphoid cells to become activated, such as **immunocompetent effector T and B cells**. These cells are able to distinguish between “self” (molecules normally present within an organism) and “nonself” (foreign molecules—i.e., those not normally present) and initiate an appropriate immune response.

An antigen is any substance that can induce a specific immune response.

The body is constantly exposed to pathogenic (disease-causing) organisms and hazardous substances from the external environment (infectious microorganisms, toxins, and foreign cells). In addition, changes may occur in cells (such as transformation of normal cells into cancerous cells) that give them characteristics of foreign cells. An immune response is generated against a specific **antigen**, which can be a soluble substance (e.g., a foreign protein, polysaccharide, or toxin) or an infectious organism, foreign tissue, or transformed (e.g., virus-infected or malignant) tissue. It is important to note that the term “antigen” refers to a molecule that can be recognized by the cells of the immune system and does not necessarily imply pathogenic origin. Most antigens must be “processed” by cells of the immune system before other cells can mount the immune response.

Historically, the term **antigen** has been used to refer to any substance that is able to induce the **specific (adaptive) immune response** culminating with the production of **antibodies** to which the antigen is capable of binding. However, it is now known that some antigens are too small (typically under 20 kDa) or too difficult to be detected by cells of immune system, and they are thus unable to trigger an immune response. For this reason, the term **immunogen** was introduced to describe a specific type of antigen that is always able to elicit an immune response. Therefore, all immunogens are antigens, but not all antigens are necessarily immunogens. The terms *antigen* and *immunogen* are often used interchangeably. In this chapter, because the difference between an immunogen and an antigen is not relevant, the term “antigen” is used exclusively.

The immune responses can be divided into nonspecific (innate) and specific (adaptive) defenses.

The body has two lines of immune defenses against foreign invaders and transformed cells: nonspecific immunity and specific immunity.

- **Nonspecific (innate) immunity**, comprising preexisting, nonspecific defenses, represents the first line of defense against microbial invasion. It consists of (1) **physical barriers** (e.g., the skin and mucous membranes) that prevent foreign organisms from invading the tissues; (2) **chemical defenses** (e.g., low pH in the stomach and vagina) that destroy many invading microorganisms; (3) various **secretory substances** (e.g., thiocyanate in saliva, lysozymes, interferons, fibronectin, and complement in serum) that neutralize foreign microorganisms; and (4) **cells** of the innate

immune system, including phagocytic cells (e.g., **neutrophils**, **monocytes**, and **macrophages**), natural killer (NK) cells, mast cells, basophils, eosinophils, and dendritic cells (Fig. 14.2). In addition, a specific **type of gamma/delta (γ/δ) T lymphocytes** that reside in various epithelial tissues (e.g., the skin, oral mucosa, respiratory mucosa, intestines, and vagina) can be considered a part of these first-line defense mechanisms. For example, **neutrophils** can recognize invading bacteria via **pattern recognition receptors (PRRs)** such as **toll-like receptors (TLRs)**. These receptors recognize various pathogen-associated molecules commonly expressed on the bacterial surface (but not on the surface of its own cells), triggering an immune response (see page 309). PRRs are a key element of the innate immune system. In the case of **viral infection**, infected cells produce a pathogen-nonspecific antiviral agent, **interferon**, that inhibits the replication of viruses in neighboring cells by decreasing protein synthesis.

FIGURE 14.2. Nonspecific (innate) and specific (adaptive) immunity. The body has two lines of immune defenses against foreign invaders and transformed cells. Nonspecific (innate) immunity represents the first line of defense against microorganisms (microbial invasion). It consists of physical barriers, chemical defenses, various secretory substances, and a variety of cells that support the innate immune system. Specific (adaptive) immunity provides defenses that can precisely target antigens specific to invaders. Initial contact with foreign microorganisms activates specialized antigen-presenting cells (*APCs*) and initiates a chain of events involving effector cells. During an adaptive immune response, specific B and T lymphocytes become activated in secondary lymphatic organs and tissues to destroy invading organisms. *Ag*, antigen; *NK*, natural killer.

- **Specific (adaptive) immunity**, activated when nonspecific defenses fail, precisely targets antigens specific to the invader. **B lymphocytes** and **T lymphocytes** provide both the **specificity** and **immune memory** characteristics of the adaptive immune response (see Fig. 14.2). Initial contact with an antigen or foreign agent activates specialized antigen-presenting cells and initiates a chain of reactions that involve effector cells of the immune system and may eventually lead to a state of immune memory. Adaptive immunity is possible due to acquired resistance against microbial aggression through random somatic rearrangements of genes that encode membrane-bound forms of immunoglobulin on B lymphocytes (i.e., B-cell receptors or BCRs) and specific receptors on T lymphocytes (i.e., T-cell receptors or TCRs). This rearrangement occurs in the thymus for T cells and bone marrow for B cells. During an adaptive immune response, specific B and T lymphocytes become activated in secondary lymphatic organs and tissues to destroy invading organisms.

Both nonspecific (innate) and specific (adaptive) immunity systems are interconnected and overlapping. In most cases, innate immunity is activated first. Shortly after invasion by a pathogenic agent, the innate immune system activates an **inflammatory response** to destroy infectious agents. **Neutrophils** are the main cell types that are recruited in the initial phases of the inflammatory response. As discussed earlier, neutrophils possess PRRs and complement receptors that trigger phagocytosis and destruction of invading pathogenic agents. The influx of neutrophils is followed by the influx of **monocytes** that differentiate into **macrophages**. Both macrophages and neutrophils are, therefore, also known as *inflammatory cells*. Because the inflammation site is drained by lymphatic vessels, the pathogenic agents (and antigens) flow with

the lymph to neighboring lymph nodes, resulting in the activation of T and B lymphocytes. They generate a specific (adaptive) immune response that may produce long-term memory against pathogens.

Specific (adaptive) immunity can be divided into humoral and cell-mediated immunity.

Adaptive immunity is induced by innate immunity and is generally activated if innate immunity (i.e., the inflammatory response) fails. Adaptive immunity is activated by the presence of antigen. The longer the innate system takes to clear a pathogen, the more antigens are accumulated and the more robust the adaptive response is. In general, an encounter with a given antigen triggers a response characterized as either a humoral immune response (antibody production by B lymphocytes) or a cell-mediated immune response (mediated by T lymphocytes) (see Fig. 14.2). Typically, however, both cellular and humoral immune systems are involved, although one system generally predominates, depending on the stimulus.

- The **humoral response (humoral immunity)** is mediated by secretion of proteins called **antibodies** that coat and neutralize invaders (e.g., toxins, viruses, and bacteria) and mark them for destruction by other immune cells. **B lymphocytes** are the primary effector cells in this system. A B lymphocyte recognizes a pathogen using its surface BCR, which is specific to a single corresponding (cognate) antigen. Interaction of the BCR with its cognate antigen induces the proliferation of the B cell. Different populations of the B-cell clones then differentiate into **memory B cells** and **plasma cells**. Plasma cells can secrete soluble forms of the BCR as **antibodies** (see Fig. 14.2). Humoral immunity represents the major defense mechanism against pathogenic microorganisms and their toxins located outside cells (e.g., on cell surfaces and within the lumens of the gastrointestinal [GI], respiratory, and urogenital tracts) and within extracellular fluids (e.g., blood, lymph, and other body secretions). Humoral immunity promotes their elimination by macrophages and by activation of complement system, which consists of circulating small proteins that enhance the function of antibodies and macrophages. In some diseases (e.g., tetanus, rabies, COVID-19), antibodies are so critical and effective that a nonimmune person can be rendered “immune” by receiving an injection of antibody purified from the blood of an immune person (or animal). The effectiveness of this passive

transfer proves that it is the antibody that is responsible for the protection.

- **Cell-mediated response (cellular immunity)** is mediated by **T lymphocytes** and their products (e.g., cytokines) that target cancer-transformed and virus-infected cells for destruction by specific “killer” cells. Cytotoxic CD8⁺ lymphocytes are involved in direct killing of infected cells. Cellular immunity also promotes the destruction of infectious microorganisms inside phagocytic cells as well as foreign (transplanted) cells. T lymphocytes do not produce antibodies but possess specialized **antigen receptors** that recognize peptide-derived antigens (see Fig. 14.2). Unlike B lymphocytes, T lymphocytes cannot recognize antigen on their own. T lymphocytes require antigen to be presented to them on major histocompatibility complex (MHC) molecules (see pages 492–493) that are expressed on the surface of other antigen-presenting cells (APCs). **Cell-mediated immunity is important in the defense against viral, fungal, and mycobacterial infections as well as tumor cells. Cell-mediated immunity is also responsible for transplant rejection.**

■ CELLS OF THE IMMUNE SYSTEM

Overview

Cells of the immune system include lymphocytes and various supporting cells.

Lymphocytes and various supporting cells comprise the cells of the immune system. Three major types of **lymphocytes** are recognized: B cells, T cells, and NK cells. Supporting cells interact with lymphocytes and play important roles in the presentation of antigen to lymphocytes and the regulation of immune responses. These cells include **monocytes, macrophages, neutrophils, basophils, mast cells, eosinophils, reticular cells, dendritic cells, follicular dendritic cells, Langerhans cells, and epithelioreticular cells.** In addition, a series of specialized epithelial and stromal cells provide the environment for many immune reactions to occur by secreting specific substances that regulate growth, migration, and the activation of effector and supporting cells.

Supporting cells in the lymphatic organs are organized into loose meshworks.

In lymph nodules, lymph nodes, and the spleen, **reticular cells** and the **reticular fibers** produced by these cells form elaborate meshworks. Lymphocytes, macrophages, dendritic cells, follicular dendritic cells, and other cells of the immune system reside in these meshworks and in the loose connective tissue of the body; Langerhans cells are found only in the middle layers of the epidermis. At these sites, they carry out their mission of surveillance and defense. In the thymus, **epithelioreticular cells** form the structural meshwork within the tissue. Despite their name, these cells neither produce nor are related to reticular fibers.

Different types of cells in lymphatic tissue are identified by a specific cluster of differentiation (CD) molecules on their surfaces.

Different lymphatic and hematopoietic tissue cells possess unique cell surface molecules. Until the early 1980s, the various names of these surface molecules used in the scientific literature were inconsistent and confusing. The First International Workshop on Human Leucocyte Differentiation Antigens held in Paris in 1982 proposed a new nomenclature system that linked different antibodies with clusters of corresponding molecules. The specific markers, now called **cluster of differentiation (CD) molecules**, became designated by numbers that related them to antigens expressed at different stages of cell differentiation. For example, CD4 is a protein complex specific to T lymphocytes, whereas the CD4 antibody is the monoclonal antibody reacting to the CD4 molecule. CD molecules can be visualized by immunohistochemical or immunofluorescent methods using monoclonal antibodies and are useful in identifying specific subtypes of lymphatic or hematopoietic cells. Some CD markers are expressed by cells throughout their entire life span; others are expressed only during one phase of differentiation or cell activation. To date, there are more than 400 identified CD markers.

CD markers are useful in the diagnosis and treatment of many hematopoietic tissue disorders. For instance, the absence (or presence in large quantities) of one particular CD marker in lymphocytes in a biopsy sample may indicate that the patient has a disorder related to the production and differentiation of a specific lymphocyte expressing this marker. CD markers are also useful in distinguishing between T-cell and B-cell leukemia (cancer of white blood cell-forming tissues) and other hematopoietic tissue disorders. Table 14.1 lists the most clinically useful markers.

TABLE 14.1

Most Common Cluster of Differentiation Markers Used in Clinical Practice

Marker	Main Cellular Expression	Function/Identity	Molecular Weight (kDa)
CD1	T cells in the midstage of development, Langerhans cells, dendritic cells	Presentation of lipid antigen to T cells MHC I-like molecules associated with β_2 microglobulin Developmental markers for T cells and Langerhans cells of the skin	49
CD2	T cells, NK cells	Adhesion molecules Used as clinical markers for T-cell activation	50
CD3	T cells	Form complex with T-cell receptor (TCR)	25 – 28
CD4	Helper T cells, monocytes, macrophages	Members of Ig superfamily Interact with MHC II molecules Bind viral protein gp120 of HIV-1 and HIV-2	56
CD5	T cells, some B cells	Costimulatory molecules that appear on mature T and B cells Required for Th2 and Th17 cells differentiation High levels in chronic lymphocytic leukemia	67
CD7	T cells, pluripotential hematopoietic cells	Members of Ig superfamily Bind the PI-3 kinase Useful clinical markers for T-cell acute lymphocytic leukemia and stem cell leukemia	40
CD8	Cytotoxic T cells	Members of Ig superfamily Interact with MHC I molecules	34
CD9	B cells, T cells, monocytes, eosinophils, basophils, platelets, endothelial cells, exosomes	Facilitate aggregation of platelets, cell adhesion, and cell migration. General exosome marker	24

Marker	Main Cellular Expression	Function/Identity	Molecular Weight (kDa)
CD10	Pre - B cells, pre - T cells, monocytes, eosinophils	Zinc metalloprotease Common markers for acute lymphoblastic leukemia	100
CD16a	NK cells also mast cells, macrophages	Clinical markers for NK cells Function as F _c receptors for aggregated IgG Mediate phagocytosis and antibody-dependent cell - mediated cytotoxicity	50 - 70
CD16b	Neutrophils	Function as F _c receptors for aggregated IgG Mediate neutrophil activation (degranulation, phagocytosis oxidative burst reaction)	50 - 70
CD19	B cells, dendritic cells	Co-receptors with CD21 and CD81 Clinical markers for all stages of B-cell development	95
CD20	B cells	Form Ca ²⁺ channels Role in B-cell activation and plasma cell development Markers for late stage of B-cell development Monoclonal antibodies to CD20 are used to achieve B cell depletion in chronic lymphocytic leukemia	35 - 37
CD21	B cells, follicular dendritic cells	Receptors for C3d complement protein and for Epstein - Barr virus	145
CD22	B cells	B-lymphocyte cell adhesion molecules Mediate B-cell to T-cell adhesion	130 - 140

Marker	Main Cellular Expression	Function/Identity	Molecular Weight (kDa)
CD23	B cells, monocytes, macrophages, eosinophils, platelets, dendritic cells	Low-affinity receptor for the F _c portion of IgE that mediates IgE-dependent cytotoxicity and phagocytosis by macrophages and eosinophils	45
CD24	B cells, granulocytes, epithelial cells	Sialoglycoprotein at the cell surface Expressed in late stage of B-cell differentiation	41
CD25	Activated T cells and B cells	Binds to IL-2 (IL-2 receptor α -chain)	55
CD28	T cells (all CD4 ⁺ and >50% of CD8 ⁺ in humans)	T-cell costimulatory molecule interacts with CD80 (B7-1) and CD86 (B7-2); the costimulatory signal induces T-cell activation and IL-2 production.	44
CD31	Lymphatic endothelial cells, platelets, macrophages, leukocytes, megakaryocytes	Also known as platelet and endothelial cell adhesion molecule-1 (PECAM-1A) involved in leukocyte migration into lymphatic capillaries	130
CD34	Hemopoietic stem cells (HSCs)	Clinical markers for HSCs and ligand for CD62L Mediate attachment of stem cells to bone marrow extracellular matrix	105 - 120
CD35	T cells, B cells, monocytes, dendritic cells, granulocytes, erythrocytes	Complement receptor 1 Promote phagocytosis of complement-coated particles Bind C3b and C4b complement proteins	250
CD38	Early B and T cells, activated T cells	NAD glycohydrolase Used as markers for T-cell activation and proliferation	45

Marker	Main Cellular Expression	Function/Identity	Molecular Weight (kDa)
CD40	B cells, macrophages, follicular dendritic cells, dendritic cells, activated monocytes, endothelial and vascular smooth muscle cells	Active in proliferating B cells Costimulatory molecules for CD40L (CD154) Facilitate cytokine production in macrophages and dendritic cells	48
CD40L	Activated CD4 ⁺ T cells; known as CD154	Facilitate interaction between T and B cells Regulate B-cell function Costimulatory molecules for CD40	39
CD45	All human leukocytes	Tyrosine phosphatase Leukocyte common antigen Required for T- and B-cell receptor signal transduction	220
CD45RO, CD45RA	Memory T cells (CD45RO), naïve T cells (CD45RA), some B cells, monocytes, macrophages	Tyrosine phosphatase Isoforms of CD45 Regulate T- and B-cell activation	180
CD49a	Tissue resident memory CD8 ⁺ cells (Trm)	$\alpha 1 \beta 1$ integrin, a receptor associated with adhesion of lymphocytes to collagen IV	200
CD56	NK cells	Clinical markers for NK cells Isoforms of neural adhesion molecules (N-CAM)	135 - 220
CD62E	Endothelial cells (only)	Represent ELAM-1 Binds to Sialyl-Lewis ^x (s-Le ^x) carbohydrates on leukocytes	140
CD62L	Leukocytes	Bind CD34 Represent L-selectins, a leukocyte adhesion molecules that allow lymphocytes to roll along the endothelial surface	150

Marker	Main Cellular Expression	Function/Identity	Molecular Weight (kDa)
CD63	All cells, activated platelets, exosomes	LAMP-3 protein associated with lysosomes and membranes of intracellular vesicles General exosome marker	30 - 60
CD69	Tissue resident memory CD8 ⁺ cells (Trm), γ/δ T cells	Represent a membrane-bound, type II C-lectin receptor Considered as marker of lymphocyte tissue retention	28 - 32
CD80	B cells, macrophages, dendritic cells, monocytes; known as B7-1 receptor	APC costimulatory molecule interacts with CD28 and CTLA-4	60
CD86	Activated B cells, macrophages, monocytes, dendritic cells, endothelial cells; known as B7-2 receptor	APC costimulatory molecule interacts with CD28 and CTLA-4	80
CD94	NK cells	Regulate function of NK cells Clinical markers for NK cells	43
CD103	Tissue resident memory CD8 ⁺ cells (Trm) in skin, lungs, and GI tract	Represent $\alpha 4\beta 7$ integrin and directs lymphocytes to its ligand E-cadherin Considered as marker of lymphocyte tissue retention	175

APC, antigen-presenting cell; *CTLA-4*, cytotoxic T-lymphocyte - associated protein 4; *ELAM-1*, endothelial - leukocyte adhesion molecule 1; *GI*, gastrointestinal; *HIV-1*, human immunodeficiency virus-1; *Ig*, immunoglobulin; *LAMP*, lysosome-associated membrane protein, *MHC*, major histocompatibility complex; *NAD*, nicotinamide adenine dinucleotide; *N-CAM*, neural cell adhesion molecule; *NK*, natural killer; *PECAM-1A*, platelet and endothelial cell adhesion molecule-1A; *PI-3 kinase*, phosphatidylinositol-3 kinase.

Lymphocytes

Circulating lymphocytes are the chief cellular constituents of lymphatic tissue.

To understand the function of **lymphocytes**, it is important to recognize that most lymphocytes (~70%) in blood or lymph represent a **circulating pool** of immunocompetent cells. These cells participate in a cycle during which they exit the systemic circulation to enter the lymphatic tissue. While there, they are responsible for **immunologic surveillance** of surrounding tissues. The cells then return to the systemic circulation. **This population of cells is represented mainly by long-lived, mature lymphocytes (mainly T cells) that have developed the capacity to recognize and respond to foreign antigens and are in transit from one lymphatic tissue site to another.**

The remaining 30% of lymphocytes in the blood vessels do not circulate between the lymphatic tissues and the systemic circulation. This population comprises mainly short-lived, immature cells or activated cells destined for a specific tissue. These cells leave the capillaries and migrate directly to the tissues, especially into the connective tissue that underlies the lining epithelium of the respiratory, GI, and urogenital tracts as well as into the intercellular spaces of these epithelia. Functionally, three major types of lymphocytes are present in the body: **T lymphocytes**, **B lymphocytes**, and **NK cells**. The functional classification of lymphocytes is independent of their morphologic (size) characteristics.

T lymphocytes differentiate in the thymus and account for the majority of circulating lymphocytes.

T lymphocytes (T cells) are named for the thymus, where they differentiate. They have a long life span and are involved in **cell-mediated immunity**. They account for 60%–80% of circulating lymphocytes. T cells express CD2, CD3, CD5, and CD7 markers and TCRs; however, they are subclassified according to the presence or absence of two other important surface markers: CD4 and CD8. It is essential to mention here that both CD4 and CD8 proteins are not only passive cell markers but also active co-receptors that recognize peptide antigens bound to MHC molecules (see pages 492–493).

- **Helper CD4⁺ T lymphocytes** are T cells that express CD4 markers. These cells are further subdivided into three major subsets by their ability to secrete cytokines (see page 498); however, more subsets are actively being discovered. The first subset includes helper T cells that synthesize primary interferon- γ (IFN- γ) and

other cytokines (e.g., interleukin-2 [IL-2] and tumor necrosis factor [TNF]); these cells are called **Th1 cells**. Th1 cells activate macrophages that destroy intracellular pathogens, such as bacteria and other microorganisms. The second subset of helper T cells synthesizes IL-4, IL-5, IL-10, and IL-13 and is called **Th2 cells**. Th2 cells activate eosinophils, mast cells, and B cells (for IgE production). Th2 cells initiate antibody E (IgE)-, mast cell- and eosinophil-mediated immune responses that destroy extracellular parasites (helminths) and mediate allergic reactions. The third subset of helper T cells synthesizes IL-17 and IL-22 and is called **Th17 cells**. Their principal function is to destroy extracellular bacteria and fungi by recruiting neutrophils to the site of inflammation. In addition, IL-22 produced by Th17 cells increases the production of antimicrobial peptides (e.g., defensins) and supports epithelial barrier function. Defective Th17 function is associated with Job syndrome (hyper-IgE syndrome), which is characterized by frequent and recurrent fungal and bacterial infections of the skin.

- **Cytotoxic CD8⁺ T lymphocytes (CTLs)** are T cells that express CD8 markers. Following recognition of the antigen and subsequent activation, these cells kill target cells-expressing antigen by delivery of cytotoxic proteins that induce apoptosis. The major cytotoxic proteins found in cytoplasmic granules in cytotoxic T cells are the same as those in NK cells, including granzymes, perforin, and granulysin. Cytotoxic T cells kill target cells, such as virus-infected cells, cancer-transformed cells, cells infected with intracellular microorganisms, and parasites, and play a critical role in the acute rejection of transplanted cells and organs.
- **Regulatory (suppressor) T lymphocytes** represent a phenotypically diverse population of T lymphocytes that can functionally suppress an immune response to foreign and self-antigens by influencing the activity of other cells in the immune system. For example, T lymphocytes with CD4⁺CD25⁺FOXP3⁺ markers are regulatory cells that can diminish the ability of T lymphocytes to initiate immune responses. The FOXP3 marker indicates an expression of the forkhead family of transcription factors that are characteristic of many T cells. Another tumor-associated T lymphocyte with CD8⁺CD45RO⁺ markers is able to suppress T-cell activation. Other suppressor T cells may also function in suppressing B-cell differentiation and in regulating erythroid cell maturation in the bone marrow.

- **Gamma/delta (γ/δ) T lymphocytes** represent a small population of T cells (<5%) that possess a distinct TCR on their surface composed of one γ -chain and one δ -chain. Most other TCRs are composed of two glycoprotein chains: α -chain and β -TCR chain. These cells develop in the thymus and **migrate to various epithelial tissues** (e.g., the skin, oral mucosa, respiratory mucosa, intestines, and vagina). Once they colonize an epithelial tissue, they do not recirculate between blood and lymphatic organs. **Gamma/delta (γ/δ) T cells are strategically positioned at the interfaces of the external and internal environments and function as the first line of defense against invading organisms. They encounter antigen on the surface of the epithelial cells even before it enters the body.**
- **Mucosa-associated invariant T (MAIT) lymphocytes** represent a subset of T cells that express receptors composed of two invariant α - and β -TCR chains. These cells recognize **metabolites of riboflavin** (vitamin B₂) synthesis pathway that occurs in fungi and bacteria. These metabolites must be presented to MAIT lymphocytes by other cells expressing MHC I-like complexes called **MHC I-related proteins (MR1)**. After activation, MAIT cells secrete inflammatory cytokines, such as IFN- γ and TNF- α , and are capable of destroying infected cells. MAIT cells account for about 50% of all T lymphocytes found in the liver. **A functional impairment of MAIT cells was found in chronic hepatitis B virus (HBV) and human immunodeficiency virus (HIV) infections. They most likely represent a second defense mechanism against microorganisms that cross the mucosal epithelial barrier of the gastrointestinal tract and enter the portal circulation.**
- **Resident memory T lymphocytes (Trm)** represent a new T-lymphocyte lineage of nonrecirculating memory T cells. They are generated after exposure to antigen in peripheral tissues and provide immunologic memory at the site of initial exposure. Trm cells express specific markers of residency CD69, CD103, and CD49a but lack molecules enabling them to leave the peripheral tissues and migrate to lymph nodes. Trm cells are distributed throughout the epithelial barrier tissues, including the GI tract, lung, skin, and reproductive tract. They are more potent effector cells compared with other circulating T cells. Resident Trm cells maintain immune surveillance of the specific tissue, and they are crucial for initiating rapid robust immune responses at times of infection.

B lymphocytes differentiate in the bursa-equivalent organ and participate in humoral immunity.

B lymphocytes (B cells) are so named because they were first recognized as a separate population in the bursa of Fabricius in birds (page 315) or bursa-equivalent organ such as bone marrow in mammals (see Folder 14.1). They have variable life spans and are involved in the production and secretion of the various circulating antibodies, also called immunoglobulins (Ig), the immune proteins associated with humoral immunity (Fig. 14.3 and Table 14.2). B cells account for 20%–30% of the circulating lymphocytes. In addition to secreting circulating Igs, B cells express membrane-bound forms of Ig called B-cell receptors (BCRs) that serve as the antigen-specific binding site. During differentiation, the BCR isotype switches from a single immunoglobulin M (IgM) in immature B cells to a mixture of IgD and M (IgM) in mature B cells. The recognition of antigens by BCRs activates these lymphocytes and initiates the humoral response. B cells also express major histocompatibility complex II (MHC II) molecules on the cell surface for antigen presentation to T cells. Their CD markers are CD9, CD19, and CD20. Mature B cells equipped with membrane-bound forms of IgM and IgD enter the blood circulation and migrate to the periphery where they colonize the spleen and the other secondary lymphatic organs.

TABLE 14.2

Characteristics of Human Immunoglobulins

Isotype	Molecular Weight (kDa)	Serum Level (mg/mL)	Percentage of All Ig in Adult Blood	Cells to Which Bind via F _c Region	Major Functions
IgG	145	12.0	85	Macrophages, B cells, NK cells, neutrophils, eosinophils	Principal Ig in secondary immune response Longest half-life (23 days) of all five Igs Activates complement Stimulates chemotaxis Crosses placenta, providing newborn with passive immunity
IgM	190 (950) ^a	1.5	5–10	B cells	Principal Ig produced during primary immune response Most efficient Ig in fixing complement Activates macrophages Serves as Ag receptor of B lymphocytes
IgA	160 (385) ^b	2.0	5–15	B cells	Ig present in body secretions, including tears, colostrum, saliva, and vaginal fluid, and in secretions of nasal cavity, bronchi, intestine, and prostate Provides protection against proliferation of microorganisms in these fluids and aids in defense against microbes and foreign molecules penetrating body via cell linings of these cavities
IgD	185	0.03	<1	B cells	Acts as an antigen receptor (together with IgM) on surface of mature B lymphocytes (only traces in serum)
IgE	190	3 × 10 ⁻⁵	<1	Mast cells, basophils	Stimulates mast cells to release histamine, heparin, leukotrienes, and eosinophil chemotactic factor of anaphylaxis Responsible for anaphylactic hypersensitivity reactions Increased levels in parasitic infections

^aIgM found in serum as a pentameric molecule.

^bIgA found in serum as dimeric molecule.

Ag, antigen; Ig, immunoglobulin; NK, natural killer.

FOLDER 14.1

FUNCTIONAL CONSIDERATIONS: ORIGIN OF THE NAMES *T LYMPHOCYTE* AND *B LYMPHOCYTE*

In the early 1960s, investigators using chicken embryos demonstrated that the bursa of Fabricius, a mass of lymphatic tissue associated with the cloaca of birds, was one of the anatomic sites of lymphocyte differentiation. When this tissue was destroyed in the chicken embryos (by either surgical removal or administration of high doses of testosterone), the adult chickens were unable to produce antibodies, leading to impaired humoral immunity. The chickens also demonstrated a marked reduction in the number of lymphocytes found in specific bursa-dependent areas of the spleen and lymph nodes. These affected lymphocytes were, therefore, named **B lymphocytes** or **B cells**. The bursa-equivalent organ in mammals (including humans) is the **bone marrow**, where B lymphocytes differentiate into immunocompetent cells.

Thus, the “B” refers to the **bursa of Fabricius** in birds or the **bursa-equivalent organ** in mammals.

Investigators studying newborn mice found that removal of the thymus results in profound deficiencies in cell-mediated immune responses. The rejection of transplanted skin from a heterologous donor is an example of a cell-mediated immune response. Thymectomized mice demonstrate a marked reduction in the number of lymphocytes found in specific regions of the spleen and the lymph nodes (thymus-dependent areas). The areas of depletion differ from those identified after removal of the bursa of Fabricius in the chicken. These affected lymphocytes were, therefore, named **T lymphocytes** or **T cells**; thus, the “T” refers to **thymus**.

Natural killer lymphocytes (NK cells) are neither T nor B cells and are specialized to kill certain types of target cells.

Natural killer (NK) cells are part of nonspecific (innate) immunity but share similarities with cells of the adaptive immune system, including T and B cells. NK cells are named for their ability to kill certain target cells. They develop from the common lymphoid progenitor (CLP) cell in the bone marrow, similar to B and T cells. NK cells constitute about 5%–15% of circulating lymphocytes. Because NK cells are larger than T and B cells and possess cytoplasmic granules, they are sometimes called large granular lymphocytes (LGLs). They do not mature in the thymus and, therefore, do not express TCRs. However, during their development, they are genetically programmed to recognize transformed cells by expressing **natural cytotoxicity receptors (NCRs)** on their surface. These germline-encoded activating receptors can bind directly to stress-induced or pathogen-derived antigens on tumor- and virus-infected cells. NK cells kill these target cells in a similar manner to that of cytotoxic CD8⁺ T lymphocytes. After recognition of the target cell, NK cells directly eliminate these cells by releasing **perforins** (pore-forming proteins) and **granzymes** (necessary for triggering **apoptosis** of target cells). The specific markers expressed on NK cells are CD16a, CD56, and CD94.

In addition to directly triggering apoptosis in target cells, NK cells employ additional mechanisms to kill cells. NK cells kill target cells indirectly by secretion of pro-inflammatory cytokines that lead to inflammatory responses and cell lysis. They kill antibody-coated target cells using the **antibody-dependent cell-mediated cytotoxicity (ADCC)** immune response (see pages 495–496). **CD16a** (F_cγRIIIa) is an **F_c receptor for IgG** antibodies. Interaction between the CD16a receptor on NK cells and IgG antibodies coating a

microorganism triggers the ADCC mechanism. Through this mechanism, the antigen specificity of the adaptive immune system (represented by IgG antibodies secreted from plasma cells) is paired with the toxicity of NK cells to provide antigen-specific killing. Thus, the engagement of CD16a on NK cells acts as a strong proapoptotic signal and induces NK cell-mediated killing.

Natural killer (NK) cells are activated to kill target cells by recognizing an imbalance between activating and inhibitory signals derived from their surface receptors.

The function of NK cells is determined by the integration of numerous signals generated by activating and inhibitory receptors on their surfaces (Fig. 14.4). Under physiologic conditions, circulating NK cells are mostly inactive. They become activated through various signaling pathways that cause them to migrate and infiltrate certain tumor- or virus-infected tissues. In general, among other receptors, NK cells express two classes of regulatory receptors on their surface:

FIGURE 14.4. Activation of NK cells. Natural killer (NK) cells are activated to kill target cells by recognizing the imbalance between activating and inhibitory signals derived from their surface receptors. Note that under normal conditions (*left panel*), activating receptors (i.e., NKp46, NKp44, or NKp30) recognize ligands expressed on most “healthy” cells by sending activating signals to NK cells. These signals are neutralized by inhibitory signals derived from inhibitory receptors (i.e., KIR, NKG2A, KLRG1, or TIGIT), which interact with major histocompatibility complex class I (*MHC I*) molecules. NK cells are inactive when both inhibitory and signals are present and appropriately balanced. Under pathologic conditions, such as viral infection, *MHC I* molecules are downregulated or lost, lowering NK inhibitory signaling (*upper right panel*). In addition, tumor-transformed cells often overexpress activating ligands on their surface, which are recognized by activating receptors on NK cells (*lower right panel*). It is the imbalance between activating and inhibitory signals that causes NK cells to become activated and enter killing mode.

- **Activating receptors** known as **natural cytotoxicity receptors (NCRs)**, such as NKp46, NKp44, and NKp30, that recognize ligands expressed by tumor- and virus-infected cells and send activating signals, and
- **Inhibitory receptors**, such as killer cell immunoglobulin-like receptors (KIRs), NKG2A, KLRG1, and TIGIT, that react with MHC I molecules that inhibit the action of NK cells.

NK cell activation is controlled by a **dynamic imbalance** between **activating** and **inhibitory pathways** initiated by respective receptors during interaction with potential target cells. All normal healthy cells express sufficient MHC I molecules that act as ligands for inhibitory receptors on NK cells. The balance between inhibitory and activating pathways keeps NK cells inactive (in the no-killing mode), sparing healthy normal cells from NK cell attack (see Fig. 14.4). However, during viral infection, MHC I molecules are usually downregulated or sometimes lost, which decreases the signaling to the NK inhibitory pathways and creates an imbalance between inhibitory and activating signals. A similar imbalance is also created when tumor-transformed cells overexpress activating ligands on their surface, which is recognized by increased signaling from NK-activating receptors. NK cells are thus regulated by the integration of activating and inhibitory signals via surface receptors that recognize the appropriate ligand. Any imbalance between these signals activates natural killer cells into the killing mode (see Fig. 14.4).

Lymphocyte development and differentiation

Lymphocytes undergo antigen-independent differentiation in the primary lymphatic organs.

In humans and other mammals, the **bone marrow** (called the **bursa-equivalent organ**) and the **thymus** have been identified as **primary (central) lymphatic organs**. Lymphocytes differentiate into immunocompetent cells in these organs. Initially, lymphocytes are genetically programmed to recognize a single antigen out of virtually an infinite number of possible antigens, a process called **antigen-independent proliferation and differentiation**. These immunocompetent naïve cells then enter the blood or lymph and are transported throughout the body, where a large number of them are dispersed in the secondary lymphatic organs.

Lymphocytes undergo antigen-dependent activation in the secondary lymphatic organs.

Immunocompetent lymphocytes (together with plasma cells derived from B lymphocytes and with macrophages) organize around reticular cells and their reticular fibers to form the adult effector lymphatic tissues and organs (i.e., lymphatic nodules, lymph nodes, tonsils, and spleen). Within these **secondary (peripheral) lymphatic organs**, naïve T and B lymphocytes undergo **antigen-dependent activation into effector lymphocytes and memory cells**.

Immune responses to antigens

Inflammation is the initial response to an antigen.

The initial reaction of the body to invasion by an antigen, either a foreign molecule or a pathogenic organism, is the nonspecific defense known as the **inflammatory response**. The inflammatory response may either sequester the antigen, physically digest it with enzymes secreted by neutrophils, or phagocytose and degrade the antigen in the cytoplasm of macrophages. Degradation of antigens by macrophages may lead to subsequent presentation of a portion of the antigen displayed on MHC II molecules to immunocompetent helper CD4⁺ T lymphocytes to elicit a specific immune response.

Specific immune responses are either primary or secondary.

When immunocompetent cells encounter a foreign antigen (e.g., antigen associated with pathogenic microorganisms, tissue transplants, or toxins), a **specific immune response** to the antigen is generated.

A **primary immune response** refers to the body's first encounter with an antigen. This response is characterized by a lag period of several days before antibodies (mostly IgM) or specific lymphocytes directed against the invading antigen can be detected in the blood. The initial response to an antigen is initiated by only one or a few B lymphocytes that have been genetically programmed to respond to that specific antigen. After this initial immune response, a few antigen-specific B lymphocytes remain in circulation as **memory cells**.

The **secondary immune response** is usually more rapid and more intense (characterized by higher levels of secreted antibodies, usually of the IgG class) than the primary response because of the presence of specific memory B lymphocytes already programmed to

respond to that specific antigen. The secondary response is the basis of most immunizations for common bacterial and viral diseases. Some antigens, such as penicillin and insect venoms, may trigger intense secondary immune responses that produce hypersensitivity reactions such as type I, also known as anaphylactic hypersensitivity (see Folder 14.2). However, antibodies themselves do not kill or destroy invading antigens; they simply neutralize them and mark them for destruction by cells of the immune system.

FOLDER 14.2

CLINICAL CORRELATION: HYPERSENSITIVITY REACTIONS

When an individual has been immunologically sensitized by exposure to an **antigen**, subsequent exposure may lead not only to a secondary immune response but also to undesirable tissue-damaging reactions called **hypersensitivity reactions**. Such reactions are observed in sensitized humans after insect bites or injections of penicillin. There are several types of hypersensitivity reactions; however, the most common type is the **allergic reaction (type I, immediate, or anaphylactic hypersensitivity)**. The reaction usually develops ~15 - 30 minutes from the time of exposure to the **antigen (allergen)** and may cause a variety of symptoms involving the skin (urticaria and eczema), eyes (conjunctivitis), nasal cavities (rhinorrhea, rhinitis), lungs (airway constriction), and alimentary tract (gastritis). Allergic reactions are mediated by **IgE antibodies** that are responsible for the antibody-induced discharge of **mast cell** or **basophil** granules. These granules contain preformed mediators (i.e., histamine, serine proteases, eosinophil chemotactic factor) and newly synthesized mediators (i.e., leukotrienes, interleukins), which account for the distressing features of hypersensitivity reactions. **Eosinophils** are attracted by eosinophil chemotactic factor to the site of mast cell degranulation, where they neutralize the effects of mediators released by mast cells and basophils. Thus, eosinophils are frequently seen in connective tissue at allergic or other hypersensitivity reaction sites. The allergic reactions are amplified by platelet activation factor (PAF), which causes platelet aggregation and additional release of histamine, heparin, and vasoactive substances. Treatment of symptoms is achieved with **antihistamine medications** that block histamine receptors.

Helper T and cytotoxic T lymphocytes recognize and bind to antigens that are bound to MHC molecules.

Helper and cytotoxic T lymphocytes play central roles in initiating **specific immune responses** (humoral and cell-mediated responses) by acting as immune system “patrols.” Both kinds of lymphocytes have a **T-cell receptor (TCR)**, a transmembrane protein whose exposed

portion is on the T-cell membrane in close proximity to the CD3 marker (Fig. 14.5). The TCR recognizes antigen only when it is attached to “identification molecules,” the **MHC molecules**. In addition, helper T lymphocytes can only recognize an antigen when it is “presented” to them by cells called **antigen-presenting cells (APCs)**. Cytotoxic T lymphocytes can only react to “foreign” antigen exposed on cells, such as those transformed by cancer or infected with a virus.

FIGURE 14.5. Schematic diagram of the molecular structure of the CD3-TCR complex. The CD3 molecule consists of five different polypeptide chains with molecular weights ranging from 16 to 28 kDa. This molecule is

closely associated with the T-cell receptor (*TCR*), which has two polypeptide chains (α and β). The T cell may be activated after the interaction of the *TCR* with antigen (*Ag*) displayed on the surface of a major histocompatibility complex (*MHC*) molecule. This interaction transmits the signals to the interior of the cell through the CD3 molecule. This signal stimulates the T cell to secrete interleukins, which, in turn, stimulate T cells to divide and differentiate.

The two classes of MHC molecules display peptides on the surface of cells.

MHC molecules serve as peptide display molecules for recognition by T lymphocytes. They display short fragments of digested “foreign” and “self” proteins on the cell surface. These proteins bind to MHC molecules inside the cell and are then transported to the cell surface. MHC I and MHC II molecules are products of a “supergene” located on chromosome 6 in humans known as the **major histocompatibility gene complex**. The expression of this gene complex produces molecules that are specific not only to the individual cell that produces them but also to the tissue type and degree of cellular differentiation.

MHC I is expressed on the surface of all nucleated cells and platelets. The MHC I molecules present fragments of peptides derived from **cytosolic** proteins to **cytotoxic CD8⁺ T lymphocytes**. MHC I molecules perform this function by displaying on their surface short fragments of all peptides (8–10 amino acids in length) that are actively synthesized by the cell. MHC I molecules act as a target to allow the elimination of abnormal host cells (e.g., virus-infected or cancer-transformed cells). Therefore, all endogenous “self” peptides are displayed on the surface of every cell in the body, but viral or cancer-specific peptides are displayed only on the surface of infected or transformed cells (Fig. 14.6).

FIGURE 14.6. Schematic diagram of the molecular structure of MHC I and MHC II molecules. The major histocompatibility complex (*MHC*) I molecule is a glycoprotein that is expressed on the surface of all nucleated cells of the body and on platelets. *MHC I* molecules present endogenously synthesized peptides for recognition by cytotoxic $CD8^+$ T lymphocytes. Therefore, the *MHC I* molecule acts as the target for the elimination of abnormal host cells producing abnormal proteins (e.g., cells infected by an intracellular agent such as a virus or cells that have been transformed such as cancer cells). *MHC I* consists of an α heavy chain (45 kDa) and a smaller, noncovalently attached β_2 microglobulin polypeptide (12 kDa). The β_2 microglobulin promotes maturation of T cells and acts as a chemotactic factor. The *MHC II* molecule is also a glycoprotein but is expressed only on a restricted population of cells known as *antigen-presenting cells* (*APCs*). *MHC II* molecules present exogenous (foreign) peptides to helper $CD4^+$ T lymphocytes. They consist of two chains—an α -chain (33 kDa) and a β -chain (29 kDa)—each of which possesses oligosaccharide groups. Note that the antigen-binding region on the *MHC I* molecule is narrower than that on *MHC*

II; therefore, the size of the displayed peptides varies from 8 to 10 amino acids in *MHC I* and 18 to 20 amino acids in *MHC II*.

MHC II is limited in its distribution (see Fig. 14.6). It is expressed on the surface of all APCs (e.g., macrophages, dendritic cells, and lymphocytes B) and is critical in immune interactions. The MHC II molecules present partially digested, endocytosed foreign peptides (18–20 amino acids in length) acquired by APCs through phagocytosis to **helper CD4⁺ T lymphocytes**.

Tissue distribution of MHC molecules uniquely restricts T-cell responses.

It is important to recognize that the tissue distribution of MHC I and MHC II molecules uniquely restricts T-cell responses. Because all nucleated cells contain the cellular machinery for the replication and reproduction of viruses, they must be equipped with **MHC I** molecules that allow them to communicate with **cytotoxic CD8⁺ T lymphocytes** if they become infected or transformed. In this way, MHC I molecules present intracellular antigens to cytotoxic CD8⁺ T lymphocytes. In the absence of infection or transformation, MHC I molecules present endogenous antigen peptides to cytotoxic CD8⁺ T lymphocytes. Because self-reactive T cells are selected and eliminated in the thymus, the presentation of self-antigen allows for constant surveillance by the cytotoxic CD8⁺ T lymphocytes, which react only to cells expressing aberrant, nonself antigens. Through this mechanism, infected and transformed cells are eliminated.

In contrast, **MHC II** molecules are only expressed on the surface of professional APCs, which obtain antigen peptides by sampling the extracellular environment through phagocytosis. Presentation of antigen to helper CD4⁺ T lymphocytes leads to the **coordination of an immune response** and recruitment of innate immune cells and cytotoxic CD8⁺ T lymphocytes to the site of infection. The subset of helper CD4⁺ T lymphocytes produced after antigen presentation depends on the cytokines secreted by the APC. Different cytokines are secreted in response to the activation of different PRRs and their downstream transcription factors.

Activation of T and B Cells

Activation of helper CD4⁺ T cell requires the presence of three stimulatory signals.

Helper CD4⁺ T cells require three stimulatory signals to become fully activated and subsequently differentiate and proliferate.

- The **first signal**, called the **antigen signal**, is generated by the interaction of the **TCR** with the **antigen-MHC** complex. This binding triggers the initial activation of the naïve helper T cell. Subsequent binding of the **CD4 molecule** to the TCR-antigen-MHC complex helps to stabilize this interaction. This process usually takes place in the secondary lymphatic organs.
- The **second signal**, called the **costimulatory signal**, is delivered by the interaction of membrane molecules on T cells and molecules on the APC. The most well-characterized interactions are between the **CD28** molecule expressed on the T-cell membrane and **B7** molecules, either B7-1 (CD80) or B7-2 (CD86) expressed on the APC membrane. Another pair of costimulatory signals is generated by the interaction of **CD40** (on APCs) with **CD40L** (CD154) on T cells. T cells also possess high-affinity inhibitory receptors known as *cytotoxic T lymphocyte-associated protein 4* (**CTLA-4**), which competes for binding with B7 (CD80 and CD86) protein. Thus, CTLA-4 is a competitive inhibitor of B7-CD28 interaction and inhibits the immune response, which is important for maintaining tolerance (nonresponsiveness) to self-antigens. Interaction of the TCR with antigen-MHC complex in the absence of costimulatory signal shuts down the activation process of the T cells, so they do not respond inappropriately. Recently, a new therapeutic **CTLA-4-Ig fusion protein** has been developed to inhibit the immune response by blocking the B7-CD28 costimulatory signal. This protein, which consists of the extracellular domain of the CTLA-4 receptor fused with the F_c fragment of human IgG, binds to and blocks B7 molecules. CTLA-4-Ig (abatacept) is used to treat rheumatoid and juvenile idiopathic arthritis and is in clinical trials for the prevention of transplant rejection.
- The **third signal**, called the **cytokine signal**, is generated after the helper CD4⁺ T cell receives a specific antigen signal (first signal) and a costimulatory (second) signal. The third signal consists of instructions for future development in the form of **cytokines** secreted by an APC. These different cytokines activate specific transcription factors that determine the pathway for helper T-cell differentiation. Cytokines trigger further differentiation of helper CD4⁺ T cells into a specific subset (Th1, Th2, or Th17). Each of these cells performs a different role in furthering the immune response. For example, IFN-γ and IL-12 lead

to activation of the T-box transcription factor TBX21, also called *T-bet* (T-box expressed in T cells), which induces differentiation of the helper CD4⁺ Th1 cell phenotype. In contrast, IL-4 activates the transcription factor GATA-3, leading to a differentiation of Th2 cell phenotype, and IL-6 and IL-23 lead to activation of RORγT transcription factor, leading to helper CD4⁺ Th17 cell differentiation. The selection of which cytokines to be secreted by the APC when it presents antigen to the helper T cell depends on pattern recognition receptors (PRRs) activated by the pathogen-associated molecules expressed on invading microorganisms. For example, the specific PRR called toll-like receptor-9 (TLR9) detects viral and bacterial DNA within the endosomal compartment, leading to the secretion of interferon (IFN-γ). IFN-γ not only inhibits protein synthesis in neighboring cells to prevent viral or bacterial spread but also induces helper Th1 phenotype differentiation to promote intracellular killing of endosomal contents within macrophages.

Activation of cytotoxic CD8⁺ T cell is achieved through two different mechanisms.

Cytotoxic CD8⁺ T lymphocytes (CTLs) can be activated by interacting with antigen-presenting cells (i.e., macrophage, dendritic cells) through two different mechanisms.

- The first mechanism is similar to the activation of helper CD4⁺ cells described previously. The activation process of naïve cytotoxic T cells is initiated by the interaction of its TCR with the antigen-MHC complex. In contrast to helper T cells, cytotoxic T cells can only recognize the processed antigen displayed on MHC I molecules. This binding triggers the initial activation of the naïve cytotoxic T cell, and the TCR-MHC I complex is subsequently stabilized by the CD8 molecule. A required costimulatory signal is generated from interactions between the CD28 molecule expressed on the T-cell membrane and B7 molecules expressed on APC. If the initial binding stimulus is strong enough, the APC provides a strong enough costimulatory signal to induce IL-2 secretion by cytotoxic CD8⁺ cells. IL-2 then acts in an autocrine manner to induce and advance the differentiation of cytotoxic CD8⁺ cells into fully activated immunocompetent effector cells.
- The second mechanism of cytotoxic CD8⁺ T-cell activation requires help from CD4⁺ T helper cells, which recognize the same processed

antigen on the same APC as the naïve cytotoxic T cell. Recall that APCs express both MHC I and MHC II molecules so they can display the same antigen peptide to both cytotoxic CD8⁺ and helper CD4⁺ T cells simultaneously on different MHCs. TCRs of helper CD4⁺ and cytotoxic CD8⁺ cells bind to the respective MHCs. In this mechanism, the B7 molecule on the APC activates the expression of CD40L molecules and secretion of IL-2 cytokine by the effector helper CD4⁺ cell. Interaction between CD40L on helper CD4⁺ cells and CD40 on the APC increases expression of costimulatory molecules on the APCs, which, in turn, enhances the activation process of the naïve cytotoxic CD8⁺ cells. Given the highly toxic nature of cytotoxic CD8⁺ cells, this activation mechanism ensures that only those cytotoxic CD8⁺ cells targeting relevant antigens are activated.

When a fully activated **cytotoxic CD8⁺ T lymphocyte** recognizes an antigen-MHC I complex, the TCR attaches to it. Interaction of the cytotoxic CD8⁺ TCR with the MHC I molecule-presenting antigen peptide on the target cell results in secretion of perforin and granzyme B, which induces the intrinsic pathway of apoptosis in target cells by activating the enzymatic cascade of caspases.

Cytotoxic CD8⁺ T lymphocytes are MHC I restricted, and helper CD4⁺ T lymphocytes are MHC II restricted.

As mentioned earlier, MHC molecules are recognized by helper CD4⁺ T lymphocytes or cytotoxic CD8⁺ T lymphocytes, depending on the class of the MHC molecule engaged. *This restricted presentation of foreign antigens by MHC molecules to either cytotoxic or helper T lymphocytes is a key component of immune surveillance.*

The MHC I molecule with the peptide antigen displayed on its surface interacts only with the TCR and CD8 molecule expressed on cytotoxic **CD8⁺ T lymphocytes**; these cells are, therefore, described as **MHC I restricted**. This interaction allows cytotoxic T lymphocytes to recognize infected or transformed target cells (Fig. 14.7a).

FIGURE 14.7. Schematic diagram of the molecular interactions that occur during antigen presentation. To become activated, both cytotoxic and helper T lymphocytes need to identify presented antigens as “nonself” as well as recognize the appropriate class of major histocompatibility complex (MHC) molecules. Note that each interaction between an antigen–MHC complex with its specific T-cell receptor (*TCR*) requires a costimulatory signal from the interaction of CD28 with B7 molecules. Without a costimulatory signal, the T cell cannot be fully activated. **a.** In all nucleated cells of the body, viral antigen or cancer (tumor-specific) proteins are displayed in the context of *MHC I* molecules to interact with cytotoxic $CD8^+$ T lymphocytes. **b.** On antigen-presenting cells (e.g., macrophages), the foreign antigen is displayed in the context of *MHC II* molecules to interact with a helper $CD4^+$ T lymphocyte.

In contrast, the MHC II molecule with the peptide antigen displayed on its surface interacts only with the TCR and CD4 molecule expressed on helper $CD4^+$ T lymphocytes (Fig. 14.7b); these cells are, therefore, described as **MHC II restricted**. MHC II molecules are found on APCs, such as macrophages, whose main function is to present antigen to T lymphocytes.

For B cells to become activated and differentiate into plasma cells, they require interactions with helper T lymphocytes.

Each **B lymphocyte** reacts only with a single antigen or type of antigenic site that it has been genetically programmed to recognize. Activation of B cells requires **two signals**. The first signal is derived from interaction between **BCRs** and **antigen**. The bound antigen molecules are engulfed into B cells by receptor-mediated endocytosis, and fragments of the antigen are then displayed at the cell surface with the help of MHC II molecules. Helper T cells with complementary TCRs bind B cells and provide the second **costimulatory signal**. The binding usually involves a reaction between **CD40**

molecules on a B-cell surface with their ligands (**CD40L** or CD154) residing at the surface of a helper T cell. These interactions complete the activation process of a B lymphocyte and induce an involved T cell to secrete specific cytokines that stimulate divisions and differentiation of B cells. Details of B-cell activation are illustrated in Figure 14.8. Activated B lymphocytes differentiate into plasma cells and memory B cells.

FIGURE 14.8. Schematic diagram of B lymphocyte activation leading to plasma cell and B memory cell formation. B cells are activated by the binding of antigen (*Ag*) to B-cell receptors (*BCRs*; membrane-bound antibodies) expressed on their surface. As an antigen-presenting cell, a B cell internalizes the *BCR*-antigen complex, partially digests the antigen, and then displays parts of it on the surface of its own major histocompatibility complex (*MHC*) II molecules. The T-cell receptor (*TCR*) on a helper CD4⁺ T lymphocyte (Th2 cell) recognizes both the antigen and the *MHC* II molecule, activating the helper CD4⁺ T lymphocyte. The activated helper CD4⁺ T lymphocyte releases interleukins, including IL-2, IL-4, IL-5, IL-10, and IL-13, which promote division and differentiation of the B lymphocyte into plasma cells and memory B cells. Note the presence of a costimulatory molecule complex between the B and T cells.

- **Plasma cells** synthesize and secrete a specific antibody. During this process, activated B cells switch from synthesizing their BCRs as integral membrane proteins to forming a soluble version, which are called **antibodies**.
- **Memory B cells** respond more quickly to the next encounter with the same antigen. Memory B cells express high levels of Bcl-2 proteins, which, on lymphocytes, act as antiapoptotic agents

contributing to their long life span. In humans, a marker for memory B cells is CD27.

The specific antibody produced by the plasma cell binds to the stimulating antigen, forming an **antigen-antibody complex**. These complexes are eliminated in a variety of ways, including destruction by NK cells and phagocytosis by macrophages and eosinophils.

In **antibody-dependent cell-mediated cytotoxicity (ADCC)**, the specificity of IgG molecules directs NK cells to their targets.

The membranes of several cells, including NK cells, macrophages, neutrophils, and eosinophils, possess **immunoglobulin F_c receptors** and can kill certain target cells. The target cells are usually coated with IgG antibodies. NK cells express CD16a ($F_c\gamma$ RIIIa) receptor on their surface to recognize the F_c region of antibodies and preferentially attack and destroy these target cells (Fig. 14.9). The recognition and subsequent destruction of antibody-coated target cells by NK cells is called **antibody-dependent cell-mediated cytotoxicity (ADCC)**. The antibodies in ADCC that coat the target cells often include tumor-specific antibodies. As mentioned earlier (see page 489), through this mechanism, the antigen specificity of IgG antibodies, representing the adaptive immune system, is paired with the toxicity of NK cells to provide antigen-specific killing. This binding (through the F_c region) results in the apoptosis and lysis of the target cell.

FIGURE 14.9. Schematic diagram of activation of natural killer cells leading to destruction of a transformed tumor cell by antibody-dependent cell-mediated cytotoxicity (ADCC). The ADCC reaction involves (1) activation of natural killer (NK) cells by the binding of interferon- γ ($IFN-\gamma$), the powerful NK cell activator, to its cell surface receptor ($IFN-\gamma$ receptor) and (2) the binding of an antibody- or an

antibody- and complement-coated target cell to an *NK* cell-bearing F_c receptors. These reactions induce apoptosis, or lysis, of the target cell, usually through the action of tumor-specific antibodies or the action of perforins and granzymes (fragmentins) secreted by activated *NK* cells. *IgG*, immunoglobulin G.

If the antigen is a bacterium, the antigen-antibody complex may also activate a system of plasma proteins called the **complement system** and cause one of its components, usually C3, to bind to the bacterium and act as a ligand for its phagocytosis by macrophages. Complement-bound foreign cells are also the targets of ADCC.

In the cell-mediated immune response, cytotoxic $CD8^+$ T lymphocytes (CTLs) target and destroy transformed and virus-infected cells.

When the TCR of a cytotoxic T cell recognizes and binds to an antigen-MHC I complex on the surface of a transformed or virus-infected cell, the activation process is triggered. First, cytotoxic T cells undergo “**clonal expansion**” by entering the cell cycle and proceeding with cell divisions, followed by differentiation into effector (“killer”) cells. During differentiation, a large number of secretory vesicles are formed containing specific proteins that include perforins and granzymes (fragmentins). Cytotoxic T cells secrete these proteins as a result of their interaction with antigen. **Perforins** are pore-forming proteins that attach to the target cell and form ring-like transmembrane channels in the target cell membranes. These channels cause an increase in the permeability of the membrane that contributes to cell death. **Granzymes** are exogenous serine proteinases that are released from cytoplasmic granules and pass into the target cells through the pores created by perforins. Once inside the cell, granzymes activate caspases that induce the cell to undergo apoptosis (Fig. 14.10). After killing the target cell, the majority of activated cytotoxic T cells will die (apoptosis), but some of them that interacted with helper T cells will become memory cells.

FIGURE 14.10. Schematic diagram of T-cell activation leading to elimination of a virus-infected host cell. The T-cell receptor (*TCR*) - CD3 complex on a helper CD4⁺ T lymphocyte recognizes foreign antigen displayed on a major histocompatibility complex (*MHC*) II molecule on the surface of a macrophage. This recognition triggers a rapid response from B lymphocytes and the release of interleukin-2 (*IL-2*). The same macrophage also expresses *MHC I* molecules (like every other cell in the body) that interact with the appropriate *TCR* on the surface of a cytotoxic CD8⁺ T lymphocyte. The cytotoxic CD8⁺ T lymphocyte also possesses *IL-2* receptors. *IL-2* binding to these receptors stimulates the cell to divide and differentiate. The newly formed cytotoxic CD8⁺ T lymphocytes migrate to the site of viral infection. There, the *TCRs* recognize the viral antigens displayed on the surface of *MHC I* molecules of infected cells. After successfully recognizing these “nonself” proteins, the cytotoxic CD8⁺ T lymphocytes secrete perforins and granzymes, killing the infected cells. Note that interaction of cytotoxic CD8⁺ T lymphocytes with an infected cell does not require costimulatory signals.

CD4⁺ CD25⁺ FOXP3⁺ regulatory (suppressor) T lymphocytes represent a subset of helper CD4⁺ cells that suppress the immune responses of other lymphocytes.

Once the immune reactions are initiated by contact with antigen, the immune system is capable of controlling the magnitude of this response and terminating it over time. As discussed earlier, this process is regulated by **CTLA-4 receptors** expressed on activated T cells that inhibit B7-CD28 costimulatory signals (see page 494). In addition, certain T lymphocytes called **regulatory (suppressor) T**

cells diminish or suppress responses of other lymphocytes to antigen. They play an important role in regulating and maintaining immunologic **self-tolerance**, thus preventing autoimmune diseases. Characterization of these cells has proved to be difficult, but recent studies have convincingly shown that these cells belong to the population of CD4⁺ T lymphocytes that coexpress the CD25 and FOXP3⁺ marker proteins. **CD4⁺ CD25⁺ FOXP3⁺ T cells** originate in the thymus and account for about 5% of the total population of T cells. They secrete cytokines such as IL-10 and transforming growth factor β (TGF- β), the latter a potent suppressor of proliferation of specific classes of T and B effector cells.

Regulatory (suppressor) T cells diminish or suppress antibody formation by B cells as well as mitigate the ability of cytotoxic T cells to provide a cell-mediated immune response. They play important roles in delayed hypersensitivity reactions (type IV hypersensitivity reactions) by downregulating responses to antigen that enter the body through the skin or mucosa. The classic example of the delayed hypersensitivity reactions is the tuberculin screening (Mantoux) test, in which tuberculin (an extract of *Mycobacterium tuberculosis*) is injected between the layers of dermis causing skin induration (hardening) and erythema (redness) in individuals exposed to tuberculosis. The Mantoux reaction peaks 48 hours after the injection of tuberculin.

Regulatory (suppressor) T cells are involved in the pathogenesis of many autoimmune and infectious diseases and also play an important role in the prevention of graft rejection. Suppressor T lymphocytes may also function in the regulation of erythroid cell maturation in the bone marrow.

Activated T lymphocytes synthesize a variety of cytokines.

Cytokines are soluble polypeptide substances that modulate the immune responses. They are synthesized mainly by activated T lymphocytes, which affect the function of immune system effector cells (T, B, and NK cells), monocytes, macrophages, and other APCs. In general, cytokines and growth factors are similar in nature; the distinction between them is related to their effects on their target cell populations. **Cytokines** are defined as substances that are involved in immune defense mechanisms and **act on lymphocytes**, whereas growth factors act on other somatic cells. Included among these substances are chemotactic and mitogenic agents, migration inhibitory factors, interferon, and interleukins.

Cytokines serve as **chemical messengers** between cells of the immune system and act locally on the same cell that secreted them (autocrine control) or on neighboring cells (paracrine control). In a way similar to hormones, they may also communicate the state of the immune system to cells in other systems (e.g., central nervous system, endocrine system, and hemopoietic system). Cytokines function through specific receptors. Therefore, cells regulated by cytokines possess cytokine receptors.

Interleukins are synthesized by helper CD4⁺ T lymphocytes, monocytes, macrophages, and endothelial cells. Interleukins promote growth and differentiation of T, B, NK, and hematopoietic cells. Signaling transduction pathways downstream of cytokine receptors result in activation of specific transcription factors, which affect many different processes including differentiation, proliferation, and cell metabolism. Through interleukin secretion, helper CD4⁺ T cells can coordinate an immune response that involves many different cell types. Currently, more than 38 interleukins have been identified. IL-2 was the first cytokine to be discovered and characterized. It is also the most important cytokine that induces proliferation of T cells. **Several immunosuppressive agents** (e.g., cyclosporine A, tacrolimus, rapamycin) are widely used to prevent transplant rejection. They block T-cell proliferation by inhibiting expression of the **gene encoding IL-2**, an important growth factor for T lymphocytes. Rapamycin also inhibits T-cell proliferation by arresting them in the G₁ phase of the cell cycle and promoting apoptosis.

Mutations in the genes encoding several cytokine receptors have been identified in several immunodeficiency disorders, bacterial sepsis, certain lymphoid cancers, and autoimmune diseases. For instance, individuals with a mutation in the **IL-12 receptor gene** cannot mount an effective immune response against mycobacterial (fungal) infections. In addition, cytokines are being used to reverse cellular deficiencies after chemotherapy and radiation therapy and treat certain cancers. The major functions of selected interleukins are summarized in Table 14.3.

TABLE 14.3 Characteristics of Interleukins

Name	Symbol	Source	Major Functions
Interleukin-1	IL-1	Neutrophils, monocytes,	Stimulates various cells in inflammatory response;

		macrophages, endothelial cells	induces fever; facilitates proliferation and differentiation of CD4 ⁺ T (Th17) cells and B cells
Interleukin-2	IL-2	T cells	Induces proliferation and differentiation of CD4 ⁺ T cells and, to a lesser degree, CD8 ⁺ T cells, B cells, and NK cells; stimulus for Ig synthesis
Interleukin-3	IL-3	CD4 ⁺ T cells, epithelioreticular cells of thymus, stromal cells	Induces early proliferation of hematopoietic stem cells
Interleukin-4	IL-4	CD4 ⁺ T (Th2) cells, γ/δ T cells, mast cells, basophiles	Induces proliferation and differentiation of B cells and Th2 subset of CD4 ⁺ T cells; activates macrophages; promotes synthesis of IgE and IgG
Interleukin-5	IL-5	CD4 ⁺ T (Th2) cells, γ/δ T cells, NK cells, mast cells, eosinophils	Induces proliferation and differentiation of eosinophils; stimulates B cells to secrete IgA
Interleukin-6	IL-6	Endothelial cells, neutrophils, macrophages, T cells, osteoblasts, smooth muscle cells	Stimulates differentiation of hematopoietic cells; induces growth of activated B cells, differentiation of Th17 subset of CD4 ⁺ T cells
Interleukin-7	IL-7	Adventitial cells of bone marrow, endothelial cells	Stimulates growth and differentiation of progenitor B and T cells
Interleukin-8	IL-8	Macrophages, monocytes, endothelial cells	Acts as chemotactic factor on T lymphocytes, NK cells, and neutrophils
Interleukin-9	IL-9	CD4 ⁺ T (Th2, Th17) cells	Facilitates growth and activation of mast cells; stimulates growth of Th2 subset of CD4 ⁺ T cell and hematopoietic cells
Interleukin- 10	IL-10	Macrophages, dendritic cells, T cells, B cells	Immunosuppressive effect through APCs; acts on T cells as cytokine synthesis inhibitory

			factor; inhibits macrophage functions
Interleukin-11	IL-11	Bone marrow stromal cells (fibroblasts)	Facilitates growth of hematopoietic cells, mainly megakaryocytes
Interleukin-12	IL-12	Macrophages, monocytes, dendritic cells	Stimulates growth of NK cells, differentiation of Th1 subset of CD4 ⁺ T cells and CD8 ⁺ T cells
Interleukin-13	IL-13	T cells, mast cells, basophils	Modulates B-cell responses; promotes IgE synthesis; stimulates alternative activation of M2 macrophages; stimulates MHC II expression on B cells
Interleukin-14	IL-14	T cells, follicular dendritic cells, malignant B cells	Induces proliferation of both normal and malignant B cells
Interleukin-15	IL-15	CD4 ⁺ T cells, macrophages, monocytes, other cell types	Induces proliferation and differentiation of CD8 ⁺ T cells; stimulates activation of NK cells
Interleukin-16	IL-16	T cells, mast cells, eosinophils	Activates migration of CD8 ⁺ and CD4 ⁺ T cells, monocytes, and eosinophils
Interleukin-17	IL-17	Th17 subset of CD4 ⁺ T cells, CD8 ⁺ T cells, NK cells, γ/δ T cells, neutrophils	Stimulates epithelial, endothelial cells and fibroblasts to secrete cytokines, chemokines, and metalloproteases
Interleukin-18	IL-18	Activated macrophages dendritic cells, keratinocytes, and Kupffer cells	Induces differentiation of Th1 subset of CD4 ⁺ T cells; induces synthesis of IFN- γ by T cells and NK cells
Interleukin-19	IL-19	Monocytes	Activates monocytes
Interleukin-20	IL-20	Th1 subset of CD4 ⁺ T cells, monocytes, epithelial cells	Promotes differentiation of Th2 subset of CD4 ⁺ T cell; stimulates keratinocytes proliferation

APC, antigen-presenting cell; *IFN- γ* , interferon- γ ; *Ig*, immunoglobulin; *NK*, natural killer.

Antigen-Presenting Cells

APCs interact with helper CD4⁺ T lymphocytes to facilitate immune responses.

The interaction between most antigens and antibodies is insufficient to stimulate immune responses. The antigen must be broken into small peptides and presented in conjunction with MHC II molecules by specialized APCs to the appropriate helper CD4⁺ T lymphocytes. Antigen can also be processed as a part of the B-cell activation pathway (see Fig. 14.8). Most APCs belong to the mononuclear phagocyte system (MPS; described in Chapter 6, Connective Tissue, Folder 6.4, page 203). Examples of APCs include **macrophages**, **sinusoidal macrophages (Kupffer cells)** of the liver, **Langerhans cells** in the epidermis, **dermal macrophages** in the dermis, and **dendritic cells** of the spleen, thymus, lymph nodes, and skin. Two APCs that do not belong to the MPS are **B lymphocytes** and type II and type III **epithelioreticular cells** of the thymus.

To present an antigen to a helper T cell, the APC first processes the antigen intracellularly and then displays antigen peptides on its surface using MHC II molecules. Antigen processing begins when the APC endocytoses the antigen and breaks it down into 18–20 amino acid peptides. In the endosomal compartment of the APC, the peptides bind to MHC II molecules. The antigen–MHC II complex is then translocated to the plasma membrane of the APC and displayed on the cell surface (Fig. 14.11).

FIGURE 14.11. Schematic diagram of processing pathways for MHC I and MHC II synthesis and antigen presentation. During the processing and presentation of cytoplasmic antigen (*Ag*) for major histocompatibility complex (*MHC*) I molecules (*red pathway*), cytoplasmic protein antigens undergo proteasome-mediated degradation into 8–10 amino acid fragments that then enter the rough-surfaced endoplasmic reticulum (*rER*). In the *rER*, newly synthesized α -chains of *MHC I* molecules interact with both the processed antigen (*yellow*) and β_2 microglobulin (β_2M) and form a stable complex. This complex leaves the *rER* via the typical secretory pathway through the Golgi apparatus. The antigen–*MHC I* complex is displayed on the cell surface, where it is available for recognition by cytotoxic $CD8^+$ T lymphocytes. *MHC II* molecules are assembled in the *rER* and then bind to an invariant chain, which blocks the antigen-binding site. At this point, the *MHC II* molecule and the invariant chain are secreted to the cell surface (*blue pathway*). After a brief stay on the cell surface, the *MHC II* molecule and invariant chain are endocytosed, and in an early endosome, the invariant chain is degraded. The foreign (exogenous) antigen (*orange*) is endocytosed and partially digested by proteolytic degradation in endosomes (*grey pathway*). The *MHC II* molecule can now bind the processed foreign antigen and return with it to the cell surface. On the cell surface, the antigen–*MHC II* complex is recognized by helper $CD4^+$ T lymphocytes, which initiates the immune response. If the *MHC II* molecule fails to capture the antigen, it will be degraded in the lysosomal compartment (*green pathway*).

In addition to acting as APCs, macrophages perform other crucial functions in the immune response.

In addition to presenting antigens to both T and B lymphocytes, **macrophages** have other important, although nonspecific, functions in the immune response:

- They endocytose and partially degrade both protein and polysaccharide antigens before they present them in conjunction with MHC II molecules to helper CD4⁺ T lymphocytes.
- They digest pathogenic microorganisms through lysosomal action in combination with the helper CD4⁺ T lymphocytes.
- They secrete multiple cytokines, including lymphokines, complement components, and interleukins as well as acid hydrolases, proteases, and lipases.

Activated macrophages destroy phagocytosed bacteria and foreign antigens.

After contact with an antigen, activated helper CD4⁺ T lymphocytes trigger the macrophage activation process. Macrophages undergo one of two activation processes characterized by multiple functional and morphologic changes. When **Th1 lymphocytes** are stimulated by antigen, the cells express CD40L markers on their surface and secrete IFN- γ . Macrophages that are activated by IFN- γ and costimulated by interaction of CD40L and CD40 (at the surface of macrophage) are called **classically activated macrophages (M1 macrophages)**. They increase in size, as do the number of lysosomes and cytoplasmic vacuoles (Fig. 14.12). M1 macrophages become avidly phagocytotic with a greater ability to lyse ingested pathogenic microorganisms and foreign antigens. They promote inflammation, the destruction of extracellular matrix, and apoptosis. In contrast, macrophages that are activated by interleukins produced by **Th2 lymphocytes** are called **alternatively activated macrophages (M2 macrophages)**. They downregulate inflammation; promote rebuilding of extracellular matrix, fibroblast proliferation, and collagen synthesis; and stimulate angiogenesis. Cytokines produced by Th2 cells also suppress classically activated macrophages (M1 macrophages). A detailed description of both types of macrophages, their activation pathways, and their functions is provided in Chapter 6, Connective Tissue (page 200).

FIGURE 14.12. Classic activation process of the macrophage by a helper CD4⁺ T cell. Helper CD4⁺ T lymphocytes recognize the bacterial antigen expressed in the context of major histocompatibility complex (*MHC*) II molecules on the surface of a macrophage that has phagocytosed the bacteria. The recognition of *MHC II* molecules activates the T cell, which, in turn, secretes IL-2. IL-2 acts as an autocrine hormone to stimulate T-cell division and differentiation. Newly formed helper CD4⁺ T lymphocytes also interact with *MHC II* molecules and release interferon-γ (*IFN-γ*). This cytokine stimulates the macrophage to transform into classically activated (M1) macrophage to destroy the bacteria inside its phagosomes. CD4 molecules on the surface of the T cell also potentiate antibacterial reactions. *TCR*, T-cell receptor.

Macrophages also play a vital role in sequestering and removing foreign materials and organisms that either do not provoke an immune response or are ingested but not digested. These include both organic and inorganic particulate materials (e.g., carbon particles), pigment (e.g., from tattoos), cellulose, and asbestos as well as tuberculosis and leprosy bacilli and the organisms that cause malaria and other diseases. In these instances, macrophages often fuse to form multinucleate giant cells called Langhans giant cells that isolate these pathogens from the body.

■ LYMPHATIC TISSUES AND ORGANS

Lymphatic Vessels

Lymphatic vessels are the route by which cells and large molecules pass from the tissue spaces back to the blood.

Lymphatic vessels begin as networks of blind capillaries in loose connective tissue. They are most numerous beneath the epithelium of skin and mucous membranes. These vessels remove substances and fluid from the extracellular spaces of the connective tissues, thus producing lymph. Because the walls of the lymphatic capillaries are more permeable than the walls of blood capillaries, large molecules, including antigens and cells, gain entry more readily into the lymphatic capillaries than into blood capillaries.

As lymph circulates through the lymphatic vessels, it passes through lymph nodes. Within the lymph nodes, foreign substances (antigens) conveyed in the lymph are trapped by follicular dendritic cells. The antigen exposed on the surface of follicular dendritic cells can be processed by antigen-presenting cells which reside within the lymph node.

Lymphocytes circulate through both lymphatic and blood vessels.

The circulation of lymphocytes through the lymphatic vessels and the bloodstream enables them to move from one part of the lymphatic system to another at different stages in their development and to reach sites within the body where they are needed. Lymphocytes conveyed in the lymph enter lymph nodes via **afferent lymphatic vessels**, whereas lymphocytes conveyed in the blood enter the node through the walls of **postcapillary venules (high endothelial venules [HEVs]**; Fig. 14.13). B and T cells that enter lymph node migrate to and populate distinct regions within the lymph node. Activated lymphocytes pass through the substance of the node and leave via the **efferent lymphatic vessels**, which lead to the right lymphatic trunk or to the thoracic duct. In turn, both of these channels empty into the blood circulation at the junctions of the internal jugular and subclavian veins at the base of the neck. The lymphocytes are conveyed to and from the various lymphatic tissues via the blood vessels.

FIGURE 14.13. Diagram depicting circulation of lymphocytes in the body. Lymphocytes enter lymph nodes by two routes: afferent lymphatic vessels and through the wall of high endothelial venules (*HEVs*) in the deep cortex. *Inset* shows details of the *HEV*, which include cuboidal endothelium, continuous basement membrane, and occasional pericytes (*purple*). Some lymphocytes move to the T and B domains of the lymph node; others pass through the parenchyma of the node and leave via an efferent lymphatic vessel. Ultimately, the lymphocytes enter a major lymphatic vessel—in this case, the right lymphatic trunk—that opens into the junction of the right internal jugular and right subclavian vein. The lymphocytes continue to the arterial side of the circulation and, via the arteries, to the lymphatic tissues of the body or to tissues where they participate in immune reactions. From the lymphatic tissues, lymphocytes again return to the lymph nodes to gain entry via the *HEV*.

■ DIFFUSE LYMPHATIC TISSUE AND LYMPHATIC NODULES

Diffuse lymphatic tissue and lymphatic nodules guard the body against pathogenic substances and are the site of the initial immune response.

The alimentary canal, respiratory passages, and genitourinary tract are guarded by accumulations of lymphatic tissue that is not enclosed by a capsule. Lymphocytes and other free cells of this tissue are found in the **lamina propria** (subepithelial tissue) of these tracts. This form of lymphatic tissue is called **diffuse**

lymphatic tissue or mucosa-associated lymphatic tissue (MALT) because of its association with mucous membranes (Fig. 14.14). These cells are strategically located to intercept antigens and initiate an immune response. After contact with antigen, they travel to regional lymph nodes, where they undergo proliferation and differentiation. Progeny of these cells then returns to the lamina propria as effector B and T lymphocytes.

FIGURE 14.14. Photomicrograph of diffuse lymphatic tissue. This photomicrograph shows the diffuse lymphatic tissue in the lamina propria (*LP*) of the large intestine. The lower portion of two intestinal glands (*GI*)

is also evident. The highly cellular, diffuse lymphatic tissue includes fibroblasts, plasma cells, and eosinophils. However, the most abundant cell component, whose presence characterizes diffuse lymphatic tissue, is the lymphocyte, which can be identified by its small, round, dark-staining nucleus. $\times 320$.

The importance of **diffuse lymphatic tissue** in protecting the body from antigens is indicated by two factors:

- The regular presence of large numbers of plasma cells, especially in the lamina propria of the GI tract, a morphologic indication of local antibody secretion
- The presence of large numbers of eosinophils, also frequently observed in the lamina propria of the intestinal and respiratory tracts, an indication of chronic inflammation and hypersensitivity reactions

Lymphatic nodules are discrete concentrations of lymphocytes contained in a meshwork of reticular cells.

In addition to diffuse lymphatic tissue, localized concentrations of lymphocytes are commonly found in the walls of the alimentary canal, respiratory passages, and genitourinary tract. These concentrations, called **lymphatic nodules** or **lymphatic follicles**, are sharply defined, but not encapsulated (Fig. 14.15). A lymphatic nodule consisting chiefly of small lymphocytes is called a **primary nodule**. However, most nodules are **secondary lymphatic nodules** and have distinctive features that include the following:

FIGURE 14.15. Photomicrograph of a lymphatic nodule. This photomicrograph shows a section of the wall of the small intestine (duodenum). Short villi and intestinal glands are present in the *upper part* of the micrograph. A lymphatic nodule (LN) occupies most of the remainder of the micrograph. The lighter central region of the nodule is the germinal center. The lymphocytes in the germinal center are larger than those in the denser region of the nodule. They have more cytoplasm, so their nuclei are more dispersed, giving the appearance of a less compact cellular mass. $\times 120$.

- A **germinal center** is located in the central region of the nodule (Fig. 14.16) and appears lightly stained in histologic sections. The germinal center develops when a B lymphocyte that has recognized an antigen undergoes extensive division and proliferation. The lighter staining is attributable to the presence of the large lymphocytes (**lymphoblasts**) and migratory B cells committed to secreting antibodies called **plasmablasts**. These cells have large amounts of dispersed euchromatin in their nuclei rather than the dense heterochromatin of small lymphocytes. **Follicular dendritic cells (FDCs)**, **follicular helper CD4⁺ lymphocytes (T_{FH})**, and resident **macrophages** are also present in germinal centers interspersed between populations of B lymphocytes. The germinal center is a morphologic indication of lymphatic tissue response to antigen. The presence of a germinal center represents a cascade of events (often called the **germinal center reaction**) that includes helper T cell-dependent activation, proliferation, and genetic diversification of B lymphocytes; generation of memory B cells; differentiation of plasma cells; and antibody production. Mitotic figures are frequently observed in the germinal center, reflecting the proliferation of new lymphocytes at this site. The number of follicular dendritic cells and macrophages in the germinal center often increases dramatically after a period of intense response to an antigen.

FIGURE 14.16. Photomicrograph of a lymph node. This photomicrograph shows the superficial cortex (*SC*), deep cortex (*DC*), and medulla (*M*) of the lymph node in a routine hematoxylin and eosin (H&E) preparation. The capsule (*Cap*) is composed of dense connective tissue from which trabeculae (*T*) penetrate into the organ. Below the capsule is the subcapsular sinus

(SCS). It receives lymph from afferent lymphatic vessels that penetrate the capsule. The subcapsular sinus is continuous with the trabecular sinuses that course along the trabeculae. The superficial cortex contains the lymphatic nodules (LN). The deep cortex is nodule free. It consists of densely packed lymphocytes and contains the unique high endothelial venules (not visible at this magnification). The medulla consists of narrow strands of anastomosing lymphatic tissue called *medullary cords* (MC), which are separated by light-appearing spaces, the medullary sinuses (MS). The medullary sinuses receive lymph from the trabecular sinuses as well as lymph that has filtered through the cortical tissue. $\times 140$.

- A **mantle zone** or **corona** is present that represents an outer ring of small lymphocytes that encircles the germinal center. These lymphocytes represent **naïve B lymphocytes** that have not been previously stimulated by antigen.

FOLDER 14.3

CLINICAL CORRELATION: HUMAN IMMUNODEFICIENCY VIRUS (HIV) AND ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

Human immunodeficiency virus (HIV) is an RNA retrovirus; it contains an enzyme called *reverse* transcriptase. HIV is the virus that causes **acquired immunodeficiency syndrome (AIDS)**. It has an incubation period that may be as long as 11 years before symptoms of clinical AIDS occur. The great majority of HIV-infected individuals eventually develop AIDS. HIV gains entry to helper T cells by binding to CD4 molecules. The virus then injects its own genetic information into the cell cytoplasm (Fig. F14.3.1). This injected genetic information consists of single-stranded RNA. The viral RNA is incorporated into the infected host T-cell genome through reverse transcription of the RNA into DNA. The T cell then makes copies of the virus, which are extruded from the T cell through exocytosis. These HIV particles then infect other helper T cells. The immune system responds to this condition by generating cytotoxic CD8⁺ T cells and antibodies directed against the virus particles. Cytotoxic CD8⁺ T cells kill HIV-infected helper CD4⁺ T cells, reducing the number of helper T cells (the helper T-cell count is actually used as a clinical indicator of the progress of HIV infection). As the helper CD4⁺ T-cell population becomes depleted, infected individuals eventually become incapable of generating an immune response against bacterial or viral infections. They usually die of secondary infections caused by opportunistic microorganisms or cancer.

FIGURE F14.3.1. Schematic diagram of the interaction between HIV and the helper $CD4^+$ T cell. Human immunodeficiency virus (*HIV*) is an RNA virus that possesses the enzyme reverse transcriptase. The envelope of the HIV virus contains a high concentration of glycoproteins called *gp120*, which bind to the CD4 molecules on helper T cells. This results in the formation of the CD4-*gp120* complex, which pulls the *gp120* away from the viral envelope, allowing for another glycoprotein, *gp41*, to be exposed on the viral surface. The unveiled *gp41* interacts with the helper T cell by anchoring the virus into the lymphocyte's cell membrane. In addition, *gp120* interacts with C-C chemokine receptor type 5 (CCR5), which is a major coreceptor for this binding. Other chemokine receptors may also interact with *gp120* proteins. Next, the viral envelope fuses with the T-cell membrane, thus allowing the virus to inject its genetic information (viral RNA with reverse transcriptase) into the T-cell cytoplasm. The reverse transcriptase produces a double-stranded DNA copy of a single-stranded viral RNA. The newly synthesized viral DNA is then transported into the T-cell nucleus. With the help of another viral enzyme integrase, this viral DNA is incorporated into the cell genome, at which point it is referred to as a "provirus." Simultaneously, the viral RNA in the T-cell cytoplasm is translated using protein-making machinery, resulting in the synthesis of new viral proteins.

Anti-HIV treatment is the major strategy against HIV infection and AIDS. Azidothymidine (AZT), an inhibitor of reverse transcriptase, was the first promising drug used to treat HIV infection. Currently, the

most effective treatment is **multidrug antiretroviral therapy (ART)**, which uses a combination of several chemotherapeutic agents. Regimens generally include nucleoside reverse transcriptase inhibitors (NRTIs) plus either a non-nucleoside reverse transcriptase inhibitor, protease inhibitor (which blocks viral protease), or integrase strand transfer inhibitor (which prevents integration of the virus into the host cell). ART offers several advantages over monotherapy, such as synergistic dosage effects and reduced side effects as well as reduced drug resistance.

Lymphatic nodules are usually found in structures associated with the alimentary canal, such as the tonsils, ileum, and vermiform appendix.

Generally, nodules are dispersed singly in a random manner. In the alimentary canal, however, **aggregations of nodules** are found in specific locations, including:

- **Tonsils** form a ring of lymphatic tissue at the entrance of the oropharynx. The **pharyngeal tonsils** (**adenoids**, located in the roof of the pharynx), the **palatine tonsils** (or simply the tonsils, located on either side of the pharynx and between the palatopharyngeal and palatoglossal arches), and the **lingual tonsils** at the base of the tongue all contain aggregates of lymphatic nodules. The palatine tonsils consist of dense accumulations of lymphatic tissue located in the mucous membrane. The squamous epithelium that forms the surface of the tonsil dips into the underlying connective tissue in numerous places, forming **tonsillar crypts** (Fig. 14.17 and Plate 14.1, page 526). The walls of these crypts usually possess numerous lymphatic nodules. Like other aggregations of lymph nodules, tonsils do not possess afferent lymphatic vessels; however, lymph drains from the lymphatic tissue of the tonsil via efferent lymphatic vessels.

FIGURE 14.17. Photomicrograph of a palatine tonsil. **a.** This low-magnification photomicrograph shows a hematoxylin and eosin (H&E)-stained palatine tonsil. The stratified squamous epithelium that forms the surface of the tonsil dips into the underlying connective tissue in numerous places, forming tonsillar crypts. $\times 25$. **b.** This higher magnification photomicrograph of the *rectangular area* in **a** shows the stratified squamous epithelium (*SSE*) lining the tonsillar crypt. In the portion of the photomicrograph below the lumen of the crypt, *SSE* is well defined and separated by a connective tissue layer (*CT*) from the lymphatic nodule (*LN*). In the *upper portion* of the photomicrograph, the *SSE* is just barely recognized because of the heavy infiltration of lymphocytes; the epithelial cells are present, however, although they are difficult to identify. In effect, the lymphatic nodule has literally grown into the epithelium, distorting it and resulting in the disappearance of the more typical, well-defined epithelial-connective tissue boundary. $\times 450$.

- **Peyer patches** are located in the **ileum** (distal portion of the small intestine) and consist of numerous aggregations of lymphatic nodules containing T and B lymphocytes (Fig. 14.18). In addition, numerous isolated **single (solitary) lymph nodules** are located along both the large and small intestines.

FIGURE 14.18. Photomicrograph of aggregated nodules in the wall of the ileum. This low-magnification photomicrograph provides an example of aggregated nodules. The multiple lymphatic nodules (indicated by a *dashed line*) with visible germinal centers are typically found in the ileum. This accumulation of lymphatic tissue is known as a *Peyer patch*. The nodules

originate in the lamina propria and extend into the submucosa of the ileum. $\times 5$.

- The **vermiform appendix** arises from the cecum. The lamina propria is heavily infiltrated with lymphocytes and contains numerous lymphatic nodules. Although the appendix is often described as a *vestigial organ*, the abundant lymphatic tissue that it contains during early life suggests that it is functionally associated with immune reactions. With age, the amount of lymphatic tissue within the organ regresses and is difficult to recognize.

As noted, diffuse lymphatic tissue and lymphatic nodules are named according to the region or organ in which they appear. In the alimentary canal, they are collectively referred to as **gut-associated lymphatic tissue (GALT)**; in the bronchial tree, they are known as **bronchus-associated lymphatic tissue (BALT)**; and in the eyelids, they are referred as **conjunctiva-associated lymphatic tissue (CALT)**. The term **mucosa-associated lymphatic tissue (MALT)** includes GALT, CALT, and BALT. Diffuse lymphatic tissue and lymphatic nodules of MALT are present in many other regions of the body (e.g., female reproductive tract) where the mucosa is exposed to the external environment. All lymphatic nodules become enlarged as a consequence of encounters with antigen.

■ LYMPH NODES

Lymph nodes filter lymph along the pathway of lymphatic vessels and initiate adaptive immune responses to antigens.

Lymph nodes are small, bean-shaped, encapsulated lymphatic organs. They range in size from about 1 mm (barely visible with the unaided eye) to about 1–2 cm in their longest dimension. Lymph nodes are interposed along lymphatic vessels (Fig. 14.19) and serve as filters through which **lymph** percolates on its way to the blood vascular system. Because of their location, lymph nodes have access to the antigens that enter the organism through the epithelia or originate in tissues drained by lymphatic vessels. As **antigens** enter the lymph node, they **activate antigen-specific lymphocytes** that undergo proliferation and differentiation into effector cells. These cells then leave the lymph node and travel to the tissue where they will act. Although widely distributed throughout the body, lymph nodes

are concentrated in certain regions, such as the axilla, groin, neck, and mesenteries.

FIGURE 14.19. Structure of a lymph node. **a.** This diagram depicts the general features of a lymph node as seen in a section. The substance of the lymph node is divided into a cortex, including a deep cortex, and a medulla. The cortex, the outermost portion, contains spherical or oval aggregates of lymphocytes called *lymphatic nodules*. In an active lymph node, nodules contain a lighter center called the *germinal center*. The medulla, the innermost region of the lymph node, consists of lymphatic tissue that appears as irregular cords separated by lymphatic medullary sinuses. The dense population of lymphocytes between the superficial cortex and the medulla constitutes the deep cortex. It contains the high endothelial venules. Surrounding the lymph node is a capsule of dense connective tissue from which trabeculae extend into the substance of the node. Under the capsule and adjacent to the trabeculae are, respectively, the subcapsular sinus and the trabecular lymphatic sinuses. Afferent lymphatic vessels (*arrows*) penetrate the capsule and empty into the subcapsular sinus. The subcapsular sinus and trabecular sinuses communicate with the medullary sinuses. The *upper portion* of the lymph node shows an artery and a vein and the location of high endothelial venules of the lymph node. **b.** Photomicrograph of a lymph node in a routine hematoxylin and eosin (H&E) preparation. The *dense outer portion* of the lymph node is the cortex. It consists of aggregations of lymphocytes organized as nodules and a nodule-free deep cortex. The *innermost portion* of the lymph node, the medulla, extends to the surface at the hilum, where blood vessels enter or leave and where efferent lymphatic vessels leave the node. Surrounding the lymph node is the capsule, and immediately beneath it is the subcapsular sinus. $\times 18$.

Two types of lymphatic vessels serve the lymph node:

- **Afferent lymphatic vessels** convey lymph toward the node and enter it at various points on the convex surface of the capsule.

- **Efferent lymphatic vessels** convey lymph away from the node and leave at the hilum, a depression on the concave surface of the node that also serves as the entrance and exit for blood vessels and nerves.

The supporting elements of the **lymph node** are as follows:

- **Capsule**, composed of dense connective tissue that surrounds the node
- **Trabeculae**, also composed of dense connective tissue, which extend from the capsule into the substance of the node, forming a gross framework
- **Reticular tissue**, composed of reticular cells and reticular fibers that form a fine supporting meshwork throughout the remainder of the organ (Fig. 14.20). The reticular meshwork of lymphatic tissues and organs (except the thymus) consists of cells of mesenchymal origin and reticular fibers and ground substance produced by those cells.

FIGURE 14.20. Photomicrograph of a lymph node. This silver preparation shows the connective tissue capsule (*top*), subcapsular sinus, and the superficial cortex of the lymph node (*bottom*). The reticular fibers (*arrows*) form an irregular anastomosing network throughout the stroma of the lymph node. Note elongated oval nuclei of reticular cells (*arrowheads*), which are in intimate contact with reticular fibers in the sinus. $\times 640$.

Cells of the Reticular Meshwork

The reticular meshwork of the lymph node contains several types of cells that perform different functions in generating immune responses.

The **cells of the reticular meshwork** appear as stellate or elongated cells with an oval euchromatic nucleus and a small amount of acidophilic cytoplasm. These cells can take up dyes and colloidal materials. Using immunocytochemistry and transmission electron microscopy (TEM), several populations of cells have been identified:

- **Reticular cells** are indistinguishable from typical fibroblasts. These cells synthesize and secrete type III collagen (reticular fibers) and the associated ground substance that forms the stroma observed with the light microscope (Plate 14.3, page 530). Elongated cytoplasmic processes of these cells wrap around the bundles of reticular fibers, effectively isolating these structural components from the parenchyma of the lymphatic tissue and organs (Fig. 14.21). Besides their supporting role, they express surface molecules and produce substances (chemokines) that attract lymphocytes and dendritic cells.

FIGURE 14.21. Electron micrograph of a reticular cell. The body of a reticular cell and its processes (*arrows*) are evident. The arrangement of the reticular cells contains and isolates the collagen fibrils from exposure to the lymphocytes. Note the adjacent lymphocytes on the *right*.

In the light microscope and using a silver-staining method, these collagen fibrils are recognized as a reticular fiber. $\times 12,600$.

- **Dendritic cells (DCs)** are unique bone marrow-derived antigen-presenting cells. Dendritic cells monitor the local environment for foreign substances that they then process and present to antigen-specific T cells. They are much more efficient in antigen presentation than other antigen-presenting cells and can present virtually any form of protein antigen on both MHC I and MHC II molecules. They express an exceptionally high level of MHC II and costimulatory molecules necessary for **activation of T cells**. In the lymph node, dendritic cells are usually localized in T lymphocyte-rich areas.
- **Macrophages** are both phagocytic cells and antigen-presenting cells that express MHC I, MHC II, and costimulatory molecules. However, the expression levels of MHC II and costimulatory molecules are much lower than those of the dendritic cells, making them less efficient APCs. Instead, they have an immense capacity for endocytosis and digestion of internalized materials. The structure, microscopic characteristics, and functions of macrophages are described in Chapter 6, Connective Tissue (pages 199-200).
- **Follicular dendritic cells (FDCs)** have multiple, thin, hair-like branching cytoplasmic processes that interdigitate between **B lymphocytes** in the germinal centers (Fig. 14.22). Antigen-antibody complexes adhere to the dendritic cytoplasmic processes by means of the antibody's F_c receptors, and the cell can retain antigen on its surface for weeks, months, or years. Although this mechanism is similar to the adhesion of antigen-antibody complexes to macrophages, the antigen is not generally endocytosed, as it is by the macrophage. Follicular dendritic cells are thus not antigen-presenting cells because they lack MHC II molecules.

FIGURE 14.22. Diagram of a follicular dendritic cell. This cell, usually found in germinal centers, has multiple, thin, hair-like cytoplasmic processes that interdigitate between B lymphocytes. Antigen-antibody complexes adhere to the dendritic cytoplasmic processes by means of F_c receptors. Follicular dendritic cells are not antigen-presenting cells because they lack MHC II molecules.

General architecture of the lymph node

The **parenchyma** of the lymph node is divided into a cortex and medulla (Fig. 14.23). The **cortex** forms the outer portion of the node, except at the hilum. It consists of a dense mass of lymphatic tissue (reticular framework, dendritic cells, follicular dendritic cells, lymphocytes, macrophages, and plasma cells) and lymphatic sinuses, the lymph channels. The **medulla** is the inner part of the lymph node.

FIGURE 14.23. Schematic diagram of lymphocyte circulation within a lymph node. The *green arrows* indicate the circulation pathway of lymphocytes that enter the lymph node with the flow of lymph. Afferent lymphatic vessels carry lymph from the surrounding tissues and neighboring lymph nodes into the elaborate network of lymphatic sinuses. The wall of the sinuses allows lymph to percolate freely into the superficial and deep cortex, allowing lymphocytes to engage in immunosurveillance. The lymphocytes that enter the tissue next migrate back to the sinuses and leave the lymph node with the flow of the lymph. Lymphocytes that migrate to the lymph node from the blood (*blue arrows*) enter the deep cortex via high endothelial venules (*HEVs*) and also migrate to the superficial cortex. Here, lymphocytes perform the same functions as lymphocytes that enter via lymphatic vessels. They also leave the lymph node by the efferent lymph vessels.

Lymphocytes in the superficial cortex are organized into nodules.

Similar to other lymphatic tissues, the lymphatic nodules of the cortex of lymph node are designated primary nodules if they consist chiefly of small lymphocytes or secondary nodules if they possess a germinal center. Lymphatic nodules are found in the outer part of the cortex, called the **superficial (nodular) cortex** (Plate 14.2, page 528). The portion of the cortex between the medulla and the superficial cortex is free of nodules; it is called the **deep cortex (paracortex)**. This region contains most of the T cells in the lymph node (Fig. 14.24a). Because of its dependence on the thymus, perinatal thymectomy in animals results in a poorly developed deep cortex. On the basis of this observation, the deep cortex is also called the **thymus-dependent cortex**.

FIGURE 14.24. Distribution of T and B lymphocytes in the superficial cortex of the lymph node. **a.** Distribution of T lymphocytes in the lymph node of a marmoset monkey was visualized using an immunocytochemical method employing antibodies against CD3 protein, a specific marker for T lymphocytes. Tissue sections were initially treated with primary rabbit antihuman antibodies against a CD3 marker and later exposed to biotinylated secondary swine antirabbit antibodies. After incubation with avidin-biotin-peroxidase complex, the positive response was then visualized with diaminobenzidine (DAB) solution (*brown-colored reaction*). Cell nuclei were counterstained with hematoxylin. Note that the majority of T cells are distributed within the deep cortex (*DP*); a small number of T cells are present in the superficial cortex (*SC*), mainly around germinal centers (*GC*). **b.** Using the same immunoperoxidase DAB reaction described in **a**, B cells were localized using primary monoclonal antibodies against human CD20 protein (specific marker for B lymphocytes). Subsequently, secondary rabbit antimouse antibodies were used to visualize location of B cells, the accumulations of which are found within germinal centers (*GC*) of the superficial cortex (*SC*). *Cap*, capsule. $\times 200$. (Courtesy of Dr. Douglas F. Paulsen.)

The medulla of the lymph node consists of the medullary cords and medullary sinuses.

The **medulla**, the inner part of the lymph node, consists of cords of lymphatic tissue separated by lymphatic sinuses called **medullary sinuses**. As described earlier, a network of reticular cells and fibers traverses the medullary cords and medullary sinuses and serves as the framework of the parenchyma. In addition to reticular cells, the **medullary cords** contain lymphocytes (mostly B lymphocytes), macrophages, dendritic cells, and plasma cells (Fig. 14.24b). The medullary sinuses converge near the hilum, where they drain into efferent lymphatic vessels.

Filtration of lymph in the lymph node occurs within a network of interconnected lymphatic channels called *sinuses*.

There are three types of **lymphatic channels** called *sinuses* in the lymph node. Just beneath the capsule of the lymph node is a sinus interposed between the capsule and the cortical lymphocytes called the **subcapsular (cortical) sinus** (Plate 14.3, page 530). Afferent lymphatic vessels drain lymph into this sinus. **Trabecular sinuses** that originate from the subcapsular sinuses extend through the cortex along the trabeculae and drain into **medullary sinuses**. Lymphocytes and macrophages or their processes readily pass back and forth between the lymphatic sinuses and the parenchyma of the node. The sinuses have a lining of endothelium that is continuous where it is directly adjacent to the connective tissue of the capsule or trabeculae but discontinuous where it faces the lymphatic parenchyma. Although a macrophage may reside in the lymphatic parenchyma, it often sends pseudopods (long cytoplasmic processes) into the sinus through these endothelial discontinuities. These pseudopods monitor the lymph as it percolates through the sinus.

Lymphatic sinuses are not open spaces, as are blood sinuses. Particularly in the medulla, macrophage processes, along with the reticular fibers surrounded by reticular cell processes, span the lumen of the sinus and form a crisscrossing meshwork that retards the free flow of lymph and enhances its filtration. **Antigenic material and transformed cells of malignant tumors are trapped by this mechanical filter and then phagocytosed by macrophages.** In metastatic cancer, the system can be overwhelmed by an excessive number of cancer cells flowing through the lymphatic sinuses; as a result, the cells may establish a new metastatic site in the lymph node.

Specialized high endothelial venules (HEVs) are the site of entrance for circulating lymphocytes into the lymph node and fluid absorption.

In addition to lymph, **lymphocytes** also circulate through the lymph nodes. Although some lymphocytes enter nodes through afferent lymphatic vessels as components of lymph, most (about 90%) enter the node through the walls of postcapillary venules located in the deep cortex (see Fig. 14.23 and Plate 14.3, page 530). Because the postcapillary venules are lined by cuboidal or columnar endothelial cells, they are referred to as **high endothelial venules (HEVs)**. In histologic sections, the wall of the venule is often infiltrated by a number of lymphocytes in various stages of migration (Fig. 14.25). HEVs are also present in other parts of the lymphatic system, such as diffuse lymphatic tissue and lymph nodules in Peyer patches of the ileum.

FIGURE 14.25. The deep cortex of a lymph node containing high endothelial venules. a. This photomicrograph shows several longitudinally sectioned high endothelial venules (HEVs) as well as several that are seen in cross section (*arrows*). These vessels are lined by cuboidal endothelial cells. In some preparations, the walls of an HEV may be infiltrated with

migrating lymphocytes, making it difficult to recognize. $\times 400$. **Inset.** The cross section of an *HEV* shown here at higher magnification reveals several lymphocytes (*arrowheads*) in the process of migrating from the *HEV* into the parenchyma of the lymph node. $\times 640$. **b.** This relatively low-magnification electron micrograph shows a cross section of a high endothelial venule from the deep cortex of a lymph node lined by cuboidal endothelial cells (*EnC*). Cells are resting on a fenestrated basal lamina and are surrounded by occasional smooth muscle (*SM*) cells and pericytes (*Pct*). Note several lymphocytes (*arrowheads*) in various stages of migration between the lumen of the vessels and the parenchyma of the lymph node. $\times 5,000$. (Copyright © 2010. Regents of the University of Michigan. Reprinted with permission.)

Endothelial cells of HEVs play an important role in attracting T and B lymphocytes to migrate to underlying lymphatic tissues by expressing specific adhesion molecules and secretion of specific chemokines. Endothelial cells are also involved in circulating and concentrating lymph by transporting approximately 35% of the fluid and electrolytes entering via afferent lymph vessels directly into the bloodstream. The cells of HEVs express a high concentration of water channels (aquaporin-1 [AQP1] molecules). The rapid resorption of the interstitial fluid via water channels into the bloodstream causes lymph entering through the afferent lymph vessels to be drawn into the deep cortex by solvent drag.

Migration of naïve T and B lymphocytes through the high endothelial venules (HEVs) into the lymph node is mediated by specific adhesion molecules and chemokines.

Naïve circulating T and B cells are mature lymphocytes that have not been previously stimulated by antigen. These cells recirculate between the blood and lymphatic organs. The endothelial cells of specialized HEVs possess specific adhesion molecules that interact with **L-selectin** and **integrins** expressed on migrating lymphocytes. Both B and T cells leave the bloodstream crossing the endothelium by diapedesis—that is, by migrating between the endothelial cells in a manner similar to that described for neutrophils (see Fig. 10.9, page 308). The cytokines that determine and regulate migration of lymphocytes through the HEVs in lymph node are called **chemokines**, and they bind to chemokine receptors on the lymphocytes. Chemokines signal lymphocytes to leave the circulation and migrate into the lymph node. T cells express CCR7 receptors that interact with the chemokines CCL19 and CCL21 produced by the HEV's endothelial cells. In a similar manner, B cells express different CXCR5 receptors that bind to another chemokine called CXCL13. Interactions of these

chemokines with their receptors on respective T and B lymphocytes allow them to enter the lymph node.

Chemokines also determine the regional distribution of T and B cells within the lymph node. **T cells** remain in the thymus-dependent **deep cortex** attracted by CCL19 and CCL21 chemokines that are produced by reticular and other stromal cells in this region. In contrast, **B cells** migrate to the **superficial cortex** following secretion of CXCL13 chemokine that is produced by follicular dendritic cells residing in lymph nodules and germinal centers of the superficial cortex (see Fig. 14.24). After B cells have been exposed to antigen, a subset of T cells differentiates into **follicular helper CD4⁺ lymphocytes (TFH)**, which also express CXCR5 receptors (the same as those on B cells). These cells are essential in the formation and function of germinal centers, especially formation of memory B cells.

The lymph node is an important site for phagocytosis and initiation of immune responses.

Phagocytosis of particulate material by macrophages and APCs within the lymph nodes is an important step in initiating an immune response. Antigens conveyed to the lymph percolate through the sinuses and penetrate the lymph nodules to initiate an immune response. Some antigens become trapped on the surface of follicular dendritic cells, whereas others are processed by macrophages, dendritic cells, and B cells, leading to activation of both T and B lymphocytes. **Activated B cells** differentiate into plasma cells, memory B cells, and plasmablasts. These cells represent the population of migratory B cells committed to secreting antibody.

Plasma cells migrate to the medullary cords where they synthesize and release specific antibodies into the lymph flowing through the sinuses. Plasma cells account for 1%-3% of the cells in resting lymph nodules. Their number increases dramatically during an immune response, thereby increasing the amount of circulating Igs. **Plasmablasts** leave the lymph node and migrate into the bone marrow where they further differentiate into plasma cells that secrete antibodies for a long period of time. **Memory B cells** may leave the lymph nodes and circulate to various regions throughout the body, where they can proliferate in response to subsequent exposure to their specific antigen. The presence of memory cells in various sites throughout the body ensures a more rapid secondary response to an antigen.

Lymph nodes in which lymphocytes are responding to antigens often enlarge, reflecting the formation of germinal centers and proliferation of lymphocytes. This phenomenon is often seen in the lymph nodes of the neck in response to nasal or oropharyngeal infection and in axillary and inguinal regions because of infection in extremities. **Lymphadenitis**, a reactive (inflammatory) lymph node enlargement, is a common complication of microbial infections. These enlarged lymph nodes are commonly referred to as **swollen glands** (see Folder 14.4).

FOLDER 14.4

CLINICAL CORRELATION: REACTIVE (INFLAMMATORY) LYMPHADENITIS

Reactive (inflammatory) lymphadenitis refers to enlargement of the lymph nodes that is often secondary to bacterial and other microbial infections. Lymph nodes enlarge because of edema and hyperplasia of lymphatic nodules and their cellular components (Fig. F14.4.1). These include B lymphocytes, T lymphocytes, macrophages, and other antigen-presenting cells. In addition, infiltration of lymphatic sinuses by neutrophils is also prominent. In severe bacterial infections, lymphadenitis may be accompanied by lymphangitis, an inflammation of afferent lymphatic vessels that carry infected lymph into regional lymph nodes. Inflamed lymph vessels may be visible as red streaks under the skin in the affected area of lymphatic drainage.

FIGURE F14.4.1. Photomicrograph of a lymph node with reactive lymphadenitis. Section through a superficial cortex of the lymph node shows a hyperplastic germinal center (GC) projecting toward the connective tissue capsule. The majority of pale-staining cells within the germinal center are represented by B lymphocytes and macrophages; accumulation of T lymphocytes forms a distinct mantle zone that encircles the germinal center. $\times 120$. (Reproduced from Schwarting R, McKenzie S, Rubin R. Hematopathology. In: Rubin R, Strayer DS, eds. *Rubin's Pathology: Clinicopathologic Foundations of Medicine*. 5th ed. Lippincott Williams & Wilkins; 2008.)

Common symptoms of acute lymphadenitis are swollen lymph nodes that are tender to palpation, fever, chills, loss of appetite, tachycardia, and general weakness. Lymph nodes are usually palpable and tender, with red discoloration on the overlying skin. In severe cases of suppurative necrosis (necrosis with pus formation), a fistula (false opening) may develop that allows pus to drain from the enlarged lymph node to the surface.

The most common microbial organisms that cause lymphadenitis are streptococcal and staphylococcal bacteria. Other less common organisms are viruses (as in mononucleosis or rubella), protozoa, rickettsiae, fungi, and the tuberculosis bacillus. Tonsillitis, infections originating from teeth, and bacterial pharyngitis (sore throats) are the most common causes of lymphadenitis in the neck area. Generalized lymphadenopathy is typical for rheumatoid arthritis and is detected as an early sign of HIV infection. In chronic lymphadenitis, lymph nodes are enlarged, but they are usually not tender.

Exit of T and B lymphocytes from the lymph node is regulated by chemotactic lipid sphingosine-1-phosphate (S1P) and expression of its receptors on the lymphocyte cell surface.

Most lymphocytes leave the lymph node by entering lymphatic sinuses from which they flow to an efferent lymphatic vessel. Their exit from the lymph node is regulated by **S1P exit pathway**, which depends on expression of **sphingosine-1-phosphate receptor 1 (S1PR1) molecules** on the surface of lymphocytes and their interactions with **sphingosine-1-phosphate (S1P)**. S1P, which has signaling properties similar to those of chemokines, is a blood-borne lipid that is present at higher concentrations in lymph and blood than in other tissues. Naïve T cells entering the lymph node express small amounts of S1PR1. If they fail to recognize antigen for several hours, their expression of S1PR1 increases and the T cells are allowed to leave the lymph node via efferent lymphatic vessels. If a naïve T cell is activated by antigen, its expression of S1PR1 is suppressed for several days and the ability of the cell to leave the lymph node is delayed. This process allows activated T cells to remain in the

lymph node and undergo division and differentiation into effector and memory T cells that will eventually return to the blood circulation using the same S1P exit pathway.

Naïve B cells that are not activated by antigen leave the lymph node in a manner similar to that of naïve T cells. Activated B cells that differentiate into memory B cells and plasmablasts also leave the lymph node and enter the circulation via the S1P pathway.

The regulation of the exit of lymphocytes from lymph nodes and other secondary lymphatic organs is the basis of development of new immunomodulating drugs. For instance, a fungus-derived metabolite called fingolimod (FTY720) is used in the treatment of multiple sclerosis (MS). When introduced into the body, it becomes phosphorylated and mimics activity of S1P molecule. After binding to the S1PR1 receptor on lymphocytes, the S1PR1-receptor complex is internalized, which inhibits the body's immune response and prevents fully immunocompetent effector cells from exiting the lymph nodes. Lymphocytes then become sequestered in secondary lymphatic organs, causing peripheral lymphopenia (abnormally low level of lymphocytes in the blood).

Specific features of lymph nodes in comparison with other major lymphatic organs are summarized in Table 14.4.

TABLE 14.4

Comparisons of the Major Lymphatic Organs

Features	Lymphatic Nodules (CALT, BALT, GALT, MALT)	Lymph Nodes	Thymus	Spleen
				
Major function	Immune surveillance of mucosal membranes	Filter lymph Generate immune responses to antigens in the lymph	Develops immunocompetent T lymphocytes	Filters blood Eliminates senescent erythrocytes Generates immune responses to circulating antigens
Connective tissue capsule	No	Yes	Yes	Yes; contains myofibroblasts
Cortex	No	Yes	Yes	No
Medulla	No	Yes	Yes	No
Lymph nodules	Yes	Yes; in the superficial cortex only	No	Yes; in white pulp only
Afferent lymphatic vessels	No	Yes; passing through the capsule	No	No
Efferent lymphatic vessels	Yes	Yes; leaving the node at the hilum	Yes (few); originate in connective tissue septa and capsule	Yes; inconspicuous, originate in white pulp near trabeculae
High endothelial venules (HEVs)	Yes; in well-established lymph nodules (i.e., tonsils, appendix, Peyer patches)	Yes; associated with deep cortex	No	No
Characteristic features	Diffuse lymphatic tissue with randomly distributed lymphatic nodules underlying epithelial surface	Presence of lymphatic sinuses (subcapsular, trabecular, and medullary) Reticular meshwork	Thymic lobules Meshwork of epithelioreticular cells Hassall corpuscles in medulla only	White pulp with PALS splenic nodules containing central artery Red pulp containing splenic sinuses, penicillar arteries, sheathed capillaries, and splenic cords

BALT, bronchus-associated lymphatic tissue; *CALT*, conjunctiva-associated lymphatic tissue; *GALT*, gut-associated lymphatic tissue; *HEV*, high endothelial venule; *MALT*, mucosa-associated lymphatic tissue; *PALS*, periarterial lymphatic sheath.

■ THYMUS

The thymus is a lymphoepithelial organ located in the superior mediastinum.

The **thymus** is a bilobed lymphoepithelial organ located in the superior mediastinum, anterior to the heart and great vessels. It develops bilaterally from the third (and sometimes also the fourth) branchial (oropharyngeal) pouch. During development, the epithelium invaginates, and the thymic rudiment grows caudally as a tubular projection of the endodermal epithelium into the mediastinum of the chest. The advancing tip proliferates and ultimately becomes disconnected from the branchial epithelium. **Common lymphoid progenitor (CLP) cells** from the bone marrow that are destined to

develop into immunocompetent T cells invade the epithelial rudiment and occupy spaces between the epithelial cells.

The thymus is fully formed and functional at birth. It persists as a large organ until about the time of puberty, when T-cell differentiation and maturation are reduced and most of the lymphatic tissue is replaced by adipose tissue (involution). However, some maturation of T cells may continue throughout adult life in the involuted thymus. The organ function can be restimulated under specific conditions that require a high demand for new mature T cells, such as in adult recipients of bone marrow transplants.

General Architecture of the Thymus

Connective tissue surrounds the thymus and subdivides it into thymic lobules.

The thymus possesses a thin connective tissue **capsule** from which **trabeculae** extend into the parenchyma of the organ. The capsule and trabeculae contain blood vessels, efferent (but not afferent) lymphatic vessels, and nerves. In addition to collagen fibers and fibroblasts, the connective tissue of the thymus contains variable numbers of plasma cells, granulocytes, lymphocytes, mast cells, adipose cells, and macrophages.

The trabeculae establish domains in the thymus called **thymic lobules**. They are not true lobules but cortical caps over portions of the highly convoluted but continuous inner medullary tissue (Fig. 14.26 and Plate 14.6, page 536). In some planes of section, the “lobular” arrangement of the cortical cap and medullary tissue superficially resembles a lymphatic nodule with a germinal center, which often confuses students. Other morphologic characteristics (described later in this chapter) allow positive identification of the thymus in histologic sections.

FIGURE 14.26. Photomicrograph of an infant human thymus. This hematoxylin and eosin (H&E) preparation reveals multiple lobules separated by connective tissue trabeculae that extend into the organ from the surrounding capsule. Each lobule is composed of a dark-staining basophilic cortex and a lighter staining and relatively eosinophilic medulla. The medulla is actually a continuous branching mass surrounded by the cortex. The cortex contains numerous densely packed lymphocytes, whereas the medulla contains fewer lymphocytes. Note that in some instances, the medulla may bear a resemblance to germinal centers of lymphatic nodules (*upper right* and

center left). Such isolated medullary profiles are continuous with the overall medullary tissue, but this continuity may not be seen within the plane of section. $\times 25$.

The thymic parenchyma contains developing T cells in an extensive meshwork formed by epithelioreticular cells.

The outer portion of the parenchyma, the **thymic cortex**, is markedly basophilic in hematoxylin and eosin (H&E) preparations because of the closely packed developing T lymphocytes with their intensely staining nuclei. These developing T lymphocytes, also called **thymocytes**, occupy spaces within an extensive meshwork of **epithelioreticular cells** (Fig. 14.27). **Macrophages** and **dendritic cells** are also dispersed among the cortical cells. The developing T cells arise from CLPs, which originate in the bone marrow. As development proceeds in the thymus, the cells derived from CLPs pass through a series of developmental stages that are reflected by their expression of different CD molecules.

FIGURE 14.27. Photomicrograph of a human thymus. **a.** The cortex contains a dense population of small, maturing T cells that create the dark staining of this region of the thymus. The medulla, in contrast, appears lighter. The medulla also contains the thymic corpuscles that stain with eosin and give it a further distinction. $\times 120$. **b.** This higher magnification photomicrograph shows the medulla with a thymic corpuscle (*left*) and surrounding cells. Thymic corpuscles are isolated masses of closely packed, concentrically arranged type VI epithelioreticular cells; these cells exhibit flattened nuclei. The more central mass of the corpuscle contains

fully keratinized cells. In addition to numerous lymphocytes, the micrograph also shows type V epithelioreticular cells (*arrows*), with their eosinophilic cytoplasm and large, pale-staining nuclei. $\times 600$.

As their name implies, epithelioreticular cells have features of both epithelial and reticular cells. They provide a framework for the developing T cells; thus, they correspond to the reticular cells and their associated reticular fibers in other lymphatic tissues and organs. Reticular connective tissue cells and their fibers, however, are not present in the thymic parenchyma. Epithelioreticular cells exhibit certain features characteristic of epithelium, such as intercellular junctions and intermediate filaments.

Six types of epithelioreticular cells are recognized on the basis of function: three types in the cortex and three types in the medulla. Each type is designated by roman numerals. In the cortex, the following cell types are recognized:

- **Type I epithelioreticular cells** are located at the boundary of the cortex and the connective tissue capsule as well as between the cortical parenchyma and the trabeculae. They also surround the adventitia of the cortical blood vessels. In essence, type I epithelioreticular cells serve to separate the thymic parenchyma from the connective tissue of the organ. The occluding junctions between these cells reflect their function as a barrier that isolates developing T cells from the connective tissue of the organ—that is, capsule, trabeculae, and perivascular connective tissue.
- **Type II epithelioreticular cells** are located within the cortex. The TEM reveals maculae adherents (desmosomes) that join long cytoplasmic processes of adjacent cells. The cell body and cytoplasmic processes contain abundant intermediate filaments. Because of their processes, these cells are stellate. They have a large nucleus that stains lightly with H&E because of its abundant euchromatin. This nuclear feature allows the cell to be easily identified in the light microscope. Type II cells compartmentalize the cortex into isolated areas for developing T cells. Unlike type I cells, type II cells express MHC I and MHC II molecules, which are involved in thymic cell education.
- **Type III epithelioreticular** cells are located at the boundary of the cortex and medulla. The TEM reveals occluding junctions between sheet-like cytoplasmic processes of adjacent cells. Like type I cells, type III epithelioreticular cells create a

functional barrier—in this case, between the cortex and the medulla. Like type II cells, they possess MHC I and MHC II molecules.

- **Macrophages** and **dendritic cells** reside within the thymic cortex and are responsible for phagocytosis of T cells that do not fulfill thymic education requirements. These T cells are programmed to die before leaving the cortex. Approximately 98% of the T cells undergo this apoptosis and are then phagocytosed by the macrophages. The macrophages in the cortex are difficult to identify in H&E preparations. However, the periodic acid-Schiff (PAS) reaction readily defines them because of the staining of their numerous large lysosomes. Accordingly, these macrophages are called **PAS cells**. Dendritic cells within the thymus regulate the expression of FOXP3 markers on the regulatory (suppressor) CD4⁺ T lymphocytes (see pages 497 and 498).

Although the epithelioreticular cells of the thymic cortex play an important role in the development of immunocompetent mature T cells, experimental evidence shows that T cells at different stages of differentiation control the microarchitecture of the thymic epithelioreticular cells, a phenomenon called **cross-talk**. The developing lymphocytes and epithelioreticular cells thus influence each other during T-cell development.

Thymic or Hassall corpuscles (derived from type VI epithelioreticular cells) are a distinguishing feature of the thymic medulla.

The thymic medulla, the inner portion of the parenchyma, contains a large number of epithelioreticular cells and loosely packed T cells (see Fig. 14.27). The medulla stains less intensely than the cortex because it contains mostly large lymphocytes. These lymphocytes have pale-staining nuclei and quantitatively more cytoplasm than small lymphocytes. Like the cortex, the medulla also contains three types of epithelioreticular cells:

- **Type IV epithelioreticular cells** are located between the cortex and the medulla close to type III cells. They possess sheet-like processes with occluding junctions between adjacent cells as well as between them and type III cells. In cooperation with type III cells, they create the barrier at the corticomedullary junction.
- **Type V epithelioreticular cells** are located throughout the medulla. Like the type II cells located in the cortex, processes

of adjacent cells are joined by desmosomes to provide the cellular framework of the medulla and to compartmentalize groups of lymphocytes. These nuclei contrast markedly with the densely staining lymphocyte nuclei.

- **Type VI epithelioreticular cells** form the most characteristic feature of the thymic medulla, the **thymic (Hassall) corpuscles** (Fig. 14.28 and Plate 14.5, page 534). Thymic corpuscles are isolated masses of closely packed, concentrically arranged type VI epithelioreticular cells that exhibit flattened nuclei. TEM studies of these cells reveal **keratohyalin granules**, bundles of cytoplasmic intermediate filaments, and lipid droplets. The cells are joined by desmosomes. The center of a thymic corpuscle may display evidence of keratinization, not a surprising feature for cells developed from oropharyngeal epithelium. Thymic corpuscles are unique, antigenically distinct, and functionally active multicellular components of the medulla. Although the function of thymic corpuscles is not fully understood, it is thought that thymic corpuscles produce interleukins (IL-4 and IL-7) that function in thymic differentiation and education of T lymphocytes.

FIGURE 14.28. Electron micrograph of a thymic (Hassall) corpuscle. This relatively low-magnification electron micrograph shows some of the nuclei (*N*) and cytoplasm of the concentrically arranged epithelioreticular cells of a thymic (Hassall) corpuscle. Bundles of intermediate filaments, keratohyalin granules, and lipid droplets are also evident within the

cytoplasm of the epithelioreticular cells. Fully keratinized cells (*black layer*) are present in the center of the thymic corpuscle. $\times 5,000$. (Courtesy of Dr. Johannes A. G. Rhodin.)

Blood vessels pass from the trabeculae to enter the parenchyma of the thymus. Typically, the blood vessels enter the medulla from the deeper parts of the trabeculae and carry a sheath of connective tissue along with them. This perivascular connective tissue sheath varies in thickness. It is thicker around larger vessels and gradually becomes thinner around smaller vessels. Where it is thick, it contains reticular fibers, fibroblasts, macrophages, plasma cells, and other cells found in loose connective tissue; where it is thin, it may contain only reticular fibers and occasional fibroblasts. Specific features of the thymus in comparison to other major lymphatic organs are summarized in Table 14.4.

Blood - Thymus Barrier and Thymic Cell Education

The blood-thymus barrier protects developing lymphocytes in the thymus from exposure to antigens.

Lymphocytes reaching the thymic cortex are prevented from contact with antigen by a physical barrier called the **blood-thymus barrier** (Fig. 14.29). The following components constitute the blood-thymus barrier between the T cells and the lumen of cortical blood vessels, from the lumen outward:

FIGURE 14.29. Schematic diagram of the blood-thymus barrier. The blood-thymus barrier consists of three major elements: (1) capillary endothelium and its basal lamina, (2) perivascular connective tissue space occupied by macrophages, and (3) type I epithelioreticular cells with their basal lamina. The perivascular connective tissue is enclosed between the basal lamina of the epithelioreticular cells and the endothelial cell basal lamina. These layers provide the necessary protection to the developing immature T cells and separate them from mature immunocompetent lymphocytes circulating in the bloodstream.

- The **endothelium** lining the capillary wall is of the continuous type with occluding junctions. It is highly impermeable to macromolecules and is considered a major structural component of the barrier within the cortical parenchyma. The underlying **basal lamina** of endothelial cells and occasional **pericytes** are also part of the capillary wall.
- **Macrophages** residing in the surrounding perivascular connective tissue may phagocytose antigenic molecules that escape from the capillary lumen into the cortical parenchyma.
- **Type I epithelioreticular cells** with their occluding junctions provide further protection to the developing T cells. The epithelioreticular cells surround the capillary wall in the cortex; with their basal lamina, they represent another major structural component of the blood-thymus barrier.

The thymus is the site of intense T-cell education where thymocytes must pass two sequential life-and-death tests to survive.

During fetal life, the thymus is populated by multipotential lymphoid stem cells that originate from the bone marrow and are destined to develop into immunocompetent, mature T cells. Stem cell maturation is also called **thymic cell education** (Fig. 14.30) and is driven by a precise order in which TCR genes are rearranged. This process is characterized by expression or deletion of specific surface CD molecules. These surface changes reflect the state of functional maturation of T cells, and expressed CD proteins are used as markers for T-cell differentiation.

FIGURE 14.30. Schematic drawing of the major steps in thymic education. The process of common lymphoid progenitor (CLP) cell maturation and differentiation into immunocompetent T cells is accomplished by the expression and deletion of specific surface CD antigens. The CLP stem cells enter the medulla of the thymus via a postcapillary venule and then migrate

to the periphery of the thymic lobule. The presence of CD2 and CD7 molecules on the cell surface indicates an early stage of differentiation. This is followed by expression of the CD1 molecule, indicating the middle stage of T-cell differentiation. As maturation progresses, the cells express TCRs, CD3, CD4, and CD8 molecules. These cells are then presented with self-antigens and foreign antigens by types II and III epithelioreticular (*erc*) cells. If the lymphocyte recognizes self-MHC and self-antigen, it will survive the selection (positive selection); if not, death of the cell will occur. Cells that pass the positive selection test leave the cortex and enter the medulla. Here, they undergo another selection process in which cells that react too strongly to self-antigen displayed by self-MHC are eliminated (negative selection). Cells that survive negative selection then become mature cytotoxic CD8⁺ T lymphocytes or helper CD4⁺ T lymphocytes. These cells are now mature (but naïve) T lymphocytes; they leave the thymus from the medulla and enter the blood circulation. Hormonal substances secreted by type VI epithelioreticular cells within the thymic (Hassall) corpuscle promote the process of thymic cell education. Note the distribution of all six types of epithelioreticular cells. *MHC*, major histocompatibility complex; *TCR*, T-cell receptor.

The expression of CD2 and CD7 molecules on the T-cell surface indicates an **early stage of differentiation (double-negative stage)**. The term *double-negative* refers to the absence of both CD4 and CD8 molecules. This early stage is followed by the expression of the CD1 molecule, which indicates the **middle stage of T-cell differentiation**. As maturation progresses, the T cells express CD3 and both CD4 and CD8 molecules. This is the **double-positive stage** of T-cell differentiation. The double-positive T cells, which have developed without any antigenic stimulation from outside, begin to express TCRs.

At this stage, the cells then undergo **positive selection** to make sure they have functional TCRs. Double-positive T cells encounter types II and III epithelioreticular cells that display a variety of self-peptides bound to MHC I and MHC II molecules. If the lymphocyte recognizes self-MHC molecules and displayed self-peptides with enough affinity to generate survival signals, it will survive this positive selection test. If the lymphocyte's TCR does not recognize self-MHC molecules, this nonreacting cell is eliminated by a process called **death by neglect** (a default pathway of apoptosis). During the positive selection process, T cells with TCRs that recognize self-MHC I molecules become cytotoxic CD8⁺ T lymphocytes (by losing CD4 and retaining CD8), and cells with TCRs that recognize self-MHC II molecules become helper CD4⁺ T lymphocytes (by losing CD8 and retaining CD4). This stage is called the **single-positive stage** of T-cell differentiation.

Cells that pass the positive selection test leave the cortex and enter the medulla. Here, they undergo another test called **negative selection** that checks whether their TCRs respond too enthusiastically to self-antigens. This process is performed by the epithelioreticular cells (types IV-VI), which display many tissue-specific self-antigens on their MHCs. A specific transcription factor known as the **autoimmune regulator (AIRE) protein** expressed by epithelioreticular cells promotes the promiscuous expression of upregulated **tissue-specific self-antigens** from every tissue and organ that are not normally required for the direct function of epithelioreticular cells. These antigens are specifically generated for the negative selection test and are presented to developing T cells as the antigenic mirror of self. The negative selection process eliminates cells that recognize self-antigens with high avidity by apoptosis. Any excessive stimulation of these immature T cells by self-antigens at this stage is unwanted and is the basis for their elimination.

The negative selection of T cells in the thymus regulated by AIRE is necessary to maintain self-tolerance. Mutations in the gene encoding AIRE protein cause abnormal negative selection (due to incomplete expression of tissue-specific self-antigens) and a breakdown in self-tolerance that allows self-reactive T cells to escape their death by apoptosis in the thymus. These lymphocytes are released into the blood circulation and colonize peripheral tissue and organs, leading to multiorgan autoimmune diseases. An example is **autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome**. This syndrome is characterized by the presence of autoantibodies directed toward multiple endocrine (e.g., parathyroid, adrenal, and thyroid glands) and nonendocrine organs (e.g., skin, gastrointestinal tract, liver, lungs, ovaries) and susceptibility to chronic mucocutaneous fungal infection with *Candida*.

The cells that survive both selection tests leave the thymus by passing from the medulla into the blood circulation as mature (but naïve) T lymphocytes. The process of thymic cell education is promoted by substances secreted by the epithelioreticular cells, including interleukins (IL-4 and IL-7), colony-stimulating factors, and IFN- γ .

It is important to emphasize that about 98% of thymocytes that divide and proliferate in the thymus do not pass thymic cell education and die in the thymus by apoptosis. Their cell fragments are phagocytosed by macrophages, which are present throughout the

thymus. Negative selection as a part of intense education of T cells to learn and appropriately recognize self-peptides is important for the development of **self-tolerance**, which is defined as the ability of the immune system to recognize self-produced antigens as a nonthreat while appropriately responding to foreign substances.

■ SPLEEN

The spleen is about the size of a clenched fist and is the largest lymphatic organ. It is located in the upper left quadrant of the abdominal cavity and has a rich blood supply. It has no direct connection with lymph circulation; instead, it gathers antigens, pathogenic microorganisms, and other particles (e.g., immune complexes) directly from the bloodstream. It is estimated that the spleen filters approximately 5% of the cardiac output every minute.

The spleen filters blood and initiates adaptive immune responses to blood-borne antigens.

The **spleen** has both morphologic and immunologic filtering functions. In addition to large numbers of lymphocytes, it contains specialized vascular spaces or channels, a meshwork of reticular cells and reticular fibers, and a rich supply of macrophages and dendritic cells. These contents allow the spleen to monitor the blood immunologically, much as the macrophages and dendritic cells of the lymph nodes monitor the lymph.

The spleen is enclosed by a dense connective tissue **capsule** from which **trabeculae** extend into the parenchyma of the organ (Fig. 14.31). The connective tissue of the capsule and trabeculae contains **myofibroblasts**. These contractile cells also produce extracellular connective tissue fibers. In many mammals, the spleen holds large volumes of red blood cells in reserve. In these species, contraction in the capsule and trabeculae helps discharge stored red blood cells into the systemic circulation. The human spleen normally retains relatively little blood, but it has the capacity for contraction by means of the contractile cells in its capsule and trabeculae.

FIGURE 14.31. Schematic diagram and photomicrograph of splenic structure. **a.** The substance of the spleen is divided into white pulp and red pulp. White pulp consists of a cylindrical mass of lymphocytes arranged around a central artery that constitutes the periarterial lymphatic sheath (*PALS*). Splenic nodules occur along the length of the *PALS*. When observed in cross section through part of the sheath that contains a nodule, the central artery appears eccentrically located with respect to the lymphatic mass. The red pulp consists of splenic sinuses surrounded by splenic cords (cords of Billroth). A capsule surrounds the spleen; trabeculae project from it into the substance of the spleen. Both capsule and trabeculae give the appearance of dense connective tissue infiltrated by numerous myofibroblasts. Blood vessels traverse the capsule and trabeculae before and after passage within the substance of the spleen. Lymphatic vessels originate in the white pulp near the trabeculae. **b.** This low-magnification photomicrograph of the spleen reveals the same components shown in the previous drawing. Note the capsule with several trabeculae projecting into the substance of the spleen. In the *center*, there is a trabecula containing a trabecular vein through which blood leaves the organ. The red pulp constitutes the greater bulk of the splenic tissue. The white pulp contains lymphatic tissue that follows and ensheathes the central artery. Expansion of the white pulp creates the splenic nodules. $\times 45$.

The **hilum**, located on the medial surface of the spleen, is the site for the passage of the splenic artery and vein, nerves, and lymphatic vessels. The lymphatic vessels originate in the white pulp

near the trabeculae and constitute a route for lymphocytes, leaving the spleen.

Most of the spleen consists of splenic pulp. Splenic pulp, in turn, is divided into two functionally and morphologically different regions: **white pulp** and **red pulp**, based on the color of fresh sections. White pulp appears as circular or elongated whitish gray areas surrounded by red pulp.

White pulp consists of a thick accumulation of lymphocytes surrounding an artery.

The **white pulp** consists of lymphatic tissue, mostly densely packed **lymphocytes**, which give the impression of white nodules against the background of red blood cells occupying splenic sinuses and splenic cords. In H&E-stained sections, white pulp appears basophilic because of the dense heterochromatin in the nuclei of the numerous lymphocytes (Plate 14.4, page 532). Within the white pulp, the branch of the splenic artery is called the **central artery**. Lymphocytes that aggregate around the central artery constitute the **periarterial lymphatic sheath (PALS)**. The PALS has a roughly cylindrical configuration that conforms to the course of the central artery. In cross sections, the PALS appears circular and may resemble a **lymphatic nodule**. The presence of the central artery, however, distinguishes the PALS from typical lymphatic nodules found in other sites. Nodules appear as localized expansions of the PALS and displace the central artery so that it occupies an eccentric rather than a central position. The architecture of white pulp is analogous to organization of a lymph node in which T and B cells are separated into different zones. In addition to lymphocytes, white pulp contains populations of specialized dendritic cells and macrophages. They later play an important role in phagocytosis of apoptotic B cells that arise during the germinal center reaction.

Migration of T and B lymphocytes into the spleen differs from that observed in lymph node.

Naïve T and B cells released from the thymus and bone marrow, respectively, enter the spleen through the open circulation. In contrast to lymph nodes, there are no HEVs in the spleen; thus, entry of lymphocytes is unregulated, and there is no need for adhesion molecules (i.e., selectin, integrins) or chemokines to be involved in the entry process.

T and B cells are then attracted to the external surface of small arteries and arterioles, forming the white pulp. The lymphatic nodules in the white pulp are the territory of B lymphocytes; other lymphocytes of the PALS are chiefly T lymphocytes that surround the nodules. Thus, the PALS may be considered a thymus-dependent zone similar to the deep cortex of a lymph node. The distribution of B and T lymphocytes is dependent on the production of different chemokines by the stromal cells and expression of specific receptors on B cells (CXCR5) and T cells (CCR7) in a process similar to that found in the lymph node (see pages 509–510). The nodules usually contain germinal centers, which, as in other lymphatic tissues, develop as B cells proliferate after their activation by antigen. Exit of lymphocytes from the white pulp to the red pulp is regulated and uses an S1P pathway similar to that found in lymph nodes (see page 511).

The lymphocytes pass through the spleen at very high rate; almost 50% of all circulating lymphocytes circulate through the spleen every 24 hours. In humans, germinal centers develop within 24 hours after antigen exposure and may become extremely large and visible with the naked eye. These enlarged nodules are called **splenic nodules** or Malpighian corpuscles (not to be confused with the renal corpuscles that have the same name).

Red pulp contains large numbers of red blood cells that it filters and degrades.

Red pulp has a red appearance in the fresh state as well as in histologic sections because it contains large numbers of red blood cells (Plate 14.5, page 534). Essentially, red pulp consists of **splenic sinuses** separated by **splenic cords** (cords of Billroth). Splenic cords consist of the now-familiar loose meshwork of reticular cells and reticular fibers that contain type III and type V collagen molecules. Large numbers of erythrocytes, platelets, macrophages, monocytes, lymphocytes, dendritic cells, plasma cells, and granulocytes reside within the reticular meshwork of splenic cords. **Red pulp macrophages** differ from macrophages associated with white pulp; they primarily phagocytose damaged red blood cells and other materials that need to be removed from the blood. The iron from destroyed red blood cells is either released from the macrophage or stored by the cell as ferritin or its aggregate hemosiderin, which is an insoluble complex of partially degraded ferritin. Inclusions of ferritin can easily be observed in red pulp

macrophages. Red pulp macrophages are essential to initiating the process of hemoglobin breakdown and iron reclamation, which is critical in the formation of new red blood cells.

The red pulp is also a large reservoir of monocytes that are clustered in splenic red cords. This pool of monocytes is larger than the pool of circulating monocytes in the blood and can be rapidly mobilized to be released from the spleen (e.g., as a response to infection). Megakaryocytes are also present in certain species, such as rodents and the cat, but not in humans, except during fetal life. Specific features of the spleen in comparison to other major lymphatic organs are summarized in Table 14.4.

The splenic or venous sinuses are special sinusoidal vessels lined by rod-shaped endothelial cells.

The **endothelial cells** that line the **splenic sinuses** are extremely long. Their longitudinal axis runs parallel to the direction of the vessel (Fig. 14.32). There are few contact points between adjacent cells, thus producing prominent intercellular spaces. These spaces allow blood cells to pass readily into and out of the sinuses. TEM images clearly demonstrate that human erythrocytes reenter the circulation from the splenic cords by squeezing through intracellular spaces between the sinus endothelial cells (Fig. 14.33). Endothelial cells contain actin filaments (stress fibers) arranged longitudinally just underneath the plasma membrane. Stress fibers are most prominent at the neighboring edges of adjacent cells. The presence of actin, myosin-like filaments, and α -actinin in stress fibers indicates their contractile properties and possible role in regulating the size of intercellular spaces, which could, in turn, control the passage of blood cells from the splenic cords into the sinuses.

FIGURE 14.32. Splenic sinus and splenic cord structure. a. Schematic diagram of the reconstructed structure of splenic sinus. Note the direction of blood flow in open and closed circulations. b. This scanning electron micrograph shows a cross section of a splenic sinus (SS), revealing the lattice structure of its wall. Through multiple openings in the wall, processes of macrophages (arrows) are inserted into the sinus lumen. The remainder of the micrograph shows characteristically smooth-surfaced processes of reticular cells (RC). The spaces of the reticular cell framework contain neutrophils (N), macrophages (M), and blood platelets (P). $\times 4,400$. c. Scanning electron micrograph of the splenic sinus showing the architecture of the sinus wall as seen from its luminal side. Rod-like endothelial cells run in parallel and are intermittently connected to each other by side processes. A nuclear swelling is shown at *lower right*. The

tapered ends of a few of the rod cells are seen. The macrophage, neutrophil, and lymphocyte are outside the sinus. $\times 5,300$. (Reprinted with permission from Fujita T, Tanaka K, Tokunga J. *SEM Atlas of Cells and Tissues*. Igaku-Shoin; 1981.)

FIGURE 14.33. Electron micrograph of the red pulp of the spleen. This low-magnification electron micrograph shows a section of the red pulp of the spleen. The junction of two splenic sinuses is visible in the *center*; the sinuses are surrounded by the stromal cells of the red pulp. Elongated nuclei belong to the rod-like endothelial (*EnC*) cells lining the sinuses. Note many profiles of red blood cells in the red pulp and in the splenic sinuses (*RBC*); several of them are in the process of passing through intercellular spaces between endothelial cells. Reticular cells (*RC*) are adjacent to the wall of the sinus. Many red pulp macrophages (*M*) are visible outside the wall of the sinus. *Mc*, monocyte; *N*, neutrophil; *P*, plasma. $\times 2,800$. (Copyright © 2010. Regents of the University of Michigan. Reprinted with permission.)

The sinuses do not possess a continuous basal lamina. **Strands of basal lamina** containing collagen IV and laminin loop around the outside of the sinus much like the hoops that loop around the staves of a barrel. These strands are at right angles to the long axes of the endothelial cells. This material stains with silver-containing

reagents or with the PAS reaction (Plate 14.5, page 534). Neither smooth muscle nor pericytes are present in the wall of splenic sinuses. Reticular cell processes extend to the basal side of the endothelial cells and are associated with the **reticular fibers** that appear to merge with the perisinusoidal loops of basal lamina. Blood fills both the sinuses and cords of the red pulp, often obscuring the underlying structures and making it difficult to distinguish between the cords and the sinuses in histologic sections.

Blood Circulation in Spleen

Circulation within red pulp allows macrophages to screen antigens in the blood.

Blood entering the spleen through the **splenic artery** is distributed through the branches of **trabecular arteries** that enter the white pulp. They branch throughout the spleen to reach a terminating vessel called the **central artery**, which is surrounded by lymphatic cells. The central artery in some animals (not humans) sends branches to the white pulp itself and to the sinuses at the perimeter of the white pulp called *marginal sinuses* (see Fig. 14.31). In contrast to other animals (i.e., mice and rats), humans do not exhibit marginal sinuses. The central artery continues into the red pulp, where it branches into several relatively straight arterioles called **penicillar arterioles**. The penicillar arterioles then continue as **arterial capillaries**. Some arterial capillaries are surrounded by aggregations of macrophages and are thus called **sheathed capillaries**. Sheathed capillaries have an open trumpet- or funnel-shaped ends, allowing blood to empty directly into the reticular meshwork of the splenic cords rather than connecting to the endothelium-lined splenic sinuses. Blood entering the red pulp in this manner percolates through the cords and is exposed to the macrophages of the cords before returning to the circulation by squeezing through the narrow (1–3- μ m wide) interendothelial slits in the wall of splenic sinuses. These slits are the smallest openings for erythrocyte passage in the body, which makes the spleen the largest filter of erythrocytes. In addition, the processes of macrophages extend between the endothelial cells and into the lumen of the sinuses to monitor the passing blood for foreign antigens (Figs. 14.33 and 14.34).

FIGURE 14.34. Schematic diagram of open and closed splenic circulations. In the open circulation, which occurs in humans, penicillar arterioles empty directly into the reticular meshwork of the cords rather than connect to the endothelium-lined splenic sinuses. Blood entering the red pulp then percolates through the cords and is exposed to the macrophages residing there. In the closed circulation, which occurs in other species, the penicillar arterioles empty directly into the splenic sinuses of the red pulp. *PALS*, periarterial lymphatic sheath.

This type of circulation is referred to as **open circulation**, and it is the only route by which blood returns to the venous circulation in humans. It is important to underline that all research data and three-dimensional (3D) imaging support the notion that splenic circulation forms an **entirely open system in humans**. In other species such as the rat and dog, some of the blood from the sheathed capillaries passes directly to the splenic sinuses of the red pulp. This type of circulation is referred to as **closed circulation**.

Open circulation exposes the blood more efficiently to the macrophages of the red pulp. Both TEM and scanning electron micrograph often show blood cells in transit across the endothelium of the sinus, presumably reentering the vascular system from the red pulp cords (see Fig. 14.33). The blood collected in the sinuses drains to tributaries of the trabecular veins that converge into larger veins and eventually leaves the spleen by the splenic vein. The splenic vein, in turn, joins the drainage from the intestine in the hepatic portal vein.

The spleen initiates adaptive immune responses and performs hemopoietic functions.

Because the spleen filters blood as the lymph nodes filter lymph, it functions in both the immune and the hemopoietic systems. The spleen is the largest secondary lymphatic organ in an adult human.

Immune system functions of the spleen include the following:

- Antigen presentation by antigen-presenting cells (mostly dendritic cells and macrophages) and initiation of immune response to blood-borne antigens
- Antigen activation and proliferation of B and T lymphocytes
- Production of antibodies against antigen present in circulating blood
- Removal of macromolecular antigens and opsonized microorganisms from the blood

Activation and proliferation of T cells and differentiation of B cells and plasma cells, as well as secretion of antibodies, occur in the white pulp of the spleen; in this regard, the white pulp is the equivalent of other lymphatic organs.

Hemopoietic functions of the spleen include the following:

- Removal and destruction of senescent, damaged, and abnormal erythrocytes and platelets
- Retrieval of iron from erythrocyte hemoglobin
- Formation of erythrocytes during early fetal life (10th–25th week of gestation)
- Storage of blood, especially red blood cells and platelets, in some species

The role of the red pulp is primarily **blood filtration** (i.e., removal of particulate material; macromolecular antigens; and aged, abnormal, or damaged blood cells and platelets from the circulating blood). These functions are accomplished by the macrophages embedded in the reticular meshwork of the red pulp, especially those that are situated directly beneath the endothelium of splenic sinuses. The open circulation in the spleen ensures that all materials circulating in the blood have direct access to red pulp macrophages. Senescent, damaged, or abnormal red cells are broken down by the lysosomes of the red pulp macrophages, and iron from the hemoglobin is retrieved and stored as ferritin or hemosiderin for future recycling. The heme portion of the molecule is broken down to

bilirubin, which is transported to the liver via the portal system and there conjugated to glucuronic acid. Conjugated bilirubin is secreted into the bile, giving it a characteristic color.

Red pulp macrophages recognize senescent or abnormal blood cells by several different mechanisms:

- **Nonspecific mechanisms** involve morphologic and biochemical changes that occur in aged erythrocytes; they become more rigid and are thus more easily trapped in the mesh of the red pulp.
- **Specific mechanisms** include opsonization of the cell membrane with antibody 3 IgG antibodies, which trigger F_c receptor-dependent phagocytosis of erythrocytes. In addition, specific changes in glycosylation of glycoproteins (see page 302) in aging erythrocytes act as a recognition signal that triggers the elimination of senescent erythrocytes by macrophages.

Despite these important functions, the spleen is not essential for human life. It can be removed surgically (splenectomy), which may be performed after trauma that causes intractable bleeding from the spleen. The removal and destruction of aging red blood cells then occur in the bone marrow and liver. The crucial role of the spleen in protection against blood-borne pathogens is demonstrated by studies of splenectomized patients, who cannot generate immune responses to several types of encapsulated bacteria such as meningococci, pneumococci, and *Haemophilus influenzae* type b. Polysaccharide capsules surrounding these microorganisms enable them to evade adaptive and specific immune defense mechanisms. Several studies have shown that antibody responses to polysaccharides occur more readily in the spleen than in other lymphatic tissues. In addition, specialized splenic macrophages are crucial for removing antibody-coated encapsulated organisms from the blood. People who have undergone splenectomy have an increased risk of infections caused by encapsulated bacteria (i.e., pneumococcal pneumonia).

IMMUNE SYSTEM AND LYMPHATIC TISSUES AND ORGANS

OVERVIEW OF THE IMMUNE SYSTEM

- The **immune system** is the body's defense system that generates immune responses against their own transformed cells and foreign invaders. The **lymphatic system** is practically indistinguishable from the immune system; it consists of groups of cells, tissues, and organs involved in immune responses.
- **Lymphocytes** are the definitive cells of the immune system and the effector cells in immune responses.
- Tissues and organs of the lymphatic system include diffuse lymphatic tissues, lymphatic nodules, lymph nodes, spleen, tonsils, bone marrow, and thymus.
- Immune responses can be divided into **nonspecific (innate) immunity** (represents the first line of defense against microbial aggression) and **specific (adaptive) immunity** (gradually acquired and based on contact with antigen and its presentation to various types of lymphocytes).
- Two types of responses are characteristic of specific immunity: the **humoral response** (production of antibodies against invaded foreign antigen) and the **cellular immune response** (targets transformed and virus-infected cells for destruction by specific "killer" cells).

CELLS OF THE IMMUNE SYSTEM

- Three major types of **lymphocytes** are present in the body: T lymphocytes, B lymphocytes, and NK cells.
- **T lymphocytes (T cells)** differentiate and mature in the thymus and are characterized by the presence of TCRs. They account for 60%–80% of the circulating lymphocytes and are subclassified based on the presence of different surface marker proteins named by the **cluster of differentiation (CD)** numbering system.
- **B lymphocytes (B cells)** differentiate and mature in the bone marrow and are characterized by the presence of BCRs (IgM and IgD bound to cell membranes). They participate in humoral immunity and differentiate into antibody-producing plasma cells.

- Natural killer lymphocytes (NK cells) are specialized in killing target cells by releasing perforins and granzymes.
- Lymphocytes undergo antigen-independent differentiation in the primary lymphatic organs (thymus and bone marrow). They undergo antigen-dependent activation in the secondary lymphatic organs and tissues.

TYPES OF IMMUNE RESPONSES

- Primary immune response refers to the body's first encounter with an antigen; it is delayed by several days and generates mainly IgM antibodies.
- Secondary immune response is more rapid and intense than the primary response; it generates IgG antibodies.
- Humoral (antibody-mediated) immunity is mediated by antibodies produced by B cells and plasma cells.
- Cell-mediated immunity is mediated by specific T cells.
- In antibody-dependent cell-mediated cytotoxicity (ADCC), IgG antibodies direct NK cells to their target.

ACTIVATION OF T AND B CELLS

- To initiate an immune response, helper and cytotoxic T cells must recognize and bind to an antigen (polypeptide) that is displayed on the major histocompatibility complex (MHC) molecules.
- Two classes of MHC molecules are found on cells: MHC I is expressed on the surface of all nucleated cells and platelets; MHC II has limited distribution and is expressed only on the surface of the antigen-presenting cells (APCs).
- Cytotoxic $CD8^+$ T cells are MHC I restricted, and helper $CD4^+$ T cells are MHC II restricted.
- Activation of T cells requires three signals.
 1. First (antigen) signal: The TCR and the CD4 or CD8 molecules interact with the antigen displayed on the MHC molecule.
 2. Second (costimulatory) signal: Interaction between the different CD molecules expressed on T cells and the antigen-presenting cells.

3. Third (cytokine) signal derives from the secretion of cytokines for differentiation of a specific subset of T cells.

- Activated helper T cells release cytokines (interleukins) that stimulate other T, B, and NK cells to differentiate and proliferate. Activated cytotoxic T cells also release cytokines that stimulate cells to proliferate and destroy the abnormal host cells.
- Activation of B cells requires interaction with helper T cells to produce specific cytokines and to differentiate into plasma cells and memory B cells.
- Regulatory (suppressor) T cells suppress the immune responses of other activated lymphocytes, thereby preventing autoimmune diseases.

LYMPHATIC TISSUES AND ORGANS

- Diffuse lymphatic tissues in the GI tract (GALT), respiratory system (BALT), eyelids (CALT), and genitourinary tract (MALT) guard the body against pathogenic substances.
- Diffuse lymphatic tissue is a site for the initial immune response that is characterized by clonal proliferation of B cells and subsequent development of lymphatic nodules (or follicles).
- A germinal center is located in the center of the lymph nodule; it contains activated B lymphocytes, plasmablasts, antigen-presenting follicular dendritic cells (FDCs), and a subset of follicular helper T (TFH) cells.
- Lymphatic nodules are found in the GALT (tonsils, Peyer patches, solitary lymph nodules, and vermiform appendix), BALT (bronchial tree), CALT (eyelids), and MALT (mucosa of urogenital system).
- Lymphatic vessels begin as networks of blind capillaries in loose connective tissue that collect lymph composed of extracellular fluid, large molecules (antigens), and cells (mainly lymphocytes). Many lymphatic vessels originate in the diffuse lymphatic tissues.

LYMPH NODES

- As lymph circulates through the lymphatic vessels, it passes through lymph nodes, which are small, encapsulated organs in which antigens are trapped by follicular dendritic cells and exposed to lymphocytes for their activation.
- Afferent lymphatic vessels pass the capsule and enter the cortex of a lymph node. Lymph is then filtrated within a network of interconnected lymphatic sinuses (subcapsular, trabecular, and medullary) and leaves the lymph node by an efferent lymphatic vessel.
- The reticular meshwork of the lymph node contains reticular cells, dendritic cells, follicular dendritic cells, and macrophages. They all interact with T and B cells that are dispersed throughout the superficial cortex, deep cortex, and the medulla of the lymph node.
- Lymphocytes from blood vessels enter the lymph node via specialized high endothelial venules (HEVs) located in the deep cortex, which contains most of the T cells.
- Most of the B cells are located in the lymph nodules within the superficial cortex.

THYMUS

- The thymus is a lymphoepithelial organ located in the superior mediastinum that contains developing T cells within an extensive meshwork of interconnected epithelioreticular cells. The thymus is fully formed at birth and persists until puberty.
- Epithelioreticular cells form compartments (cortex and medulla), secrete cytokines, surround blood vessels in the blood-thymus barrier, and, as APCs, are involved in cross-talk with developing T cells.
- The most characteristic microscopic feature of the thymic medulla is the presence of thymic (Hassall) corpuscles formed by type VI epithelioreticular cells.
- During thymic cell education (characterized by synthesis of TCRs and expression and deletion of specific surface CD molecules), T cells undergo differentiation and a two-stage selection process (positive and negative selection) that

leads to the development of immune tolerance by eliminating all T cells directed against the body's own tissues.

SPLEEN

- The **spleen** is the largest lymphatic organ and is located in the abdominal cavity. The spleen filters blood and reacts immunologically to blood-borne antigens. It removes senescent and defective erythrocytes and recycles iron from degraded hemoglobin.
- The spleen has two functionally and morphologically different regions: **white pulp** and **red pulp**.
- **White pulp** consists of lymphatic tissue associated with branches of the central artery. T cells that surround the central artery constitute the **periarterial lymphatic sheath (PALS)**.
- **Red pulp** consists of **splenic sinuses** separated by **splenic cords**, which contain large numbers of erythrocytes, macrophages, and other immune cells.
- The **splenic sinuses** are lined by rod-shaped endothelial cells with strands of incomplete basal lamina looping around the outside.
- Blood entering the spleen flows via **open circulation**, where capillaries open directly into the splenic cords (outside the circulatory system), or **closed circulation**, where blood circulates without leaving the vascular network. In humans, open circulation is the only route by which blood returns to the venous circulation.

PLATE 14.1 ■ PALATINE TONSIL

The **palatine tonsils** are paired structures consisting of masses of lymphatic tissue located on either side of the pharynx. They, along with the pharyngeal tonsils (adenoids) and lingual tonsils, form a ring at the entrance to the oropharynx (Waldeyer ring). Structurally, the tonsils contain numerous lymphatic nodules located in the mucosa. The stratified squamous epithelium that covers the surface of the palatine tonsil (and pharyngeal) dips into the underlying connective tissue forming many crypts, the **tonsillar crypts**. The walls of these

crypts contain lymphatic nodules. The epithelial lining of the crypts is typically infiltrated with lymphocytes and often to such a degree that the epithelium may be difficult to discern. While the nodules principally occupy the connective tissue, the infiltration of lymphocytes into the epithelium tends to mask the epithelial connective tissue boundary. The tonsils guard the opening of the pharynx, the common entry to the respiratory and digestive tracts. The palatine and pharyngeal tonsils can become enflamed due to repeated infection in the oropharynx and nasopharynx and can harbor bacteria that cause repeated infections if they are overwhelmed. When this occurs, the enflamed tonsils are removed surgically (tonsillectomy and adenoidectomy). Tonsils, like other aggregations of lymphatic nodules, do not possess afferent lymphatic vessels. Lymph, however, does drain from the tonsillar lymphatic tissue through efferent lymphatic vessels.

ORIENTATION MICROGRAPH: This low-magnification micrograph is a section through a palatine tonsil. The hematoxylin-staining areas represent the lymphatic tissue (*L*). The tonsil is surfaced by stratified squamous epithelium (*SSE*), which dips into the underlying connective tissue forming the tonsillar crypts (*TC*). At the base of one of the crypts are a number of mucus-secreting glands (*MG*).

Tonsil, human, hematoxylin and eosin (H&E) $\times 47$.

This micrograph is from the area in the *rectangle* of the orientation micrograph. At this higher magnification, part of the surface epithelium (*SE*) of the tonsil can be readily identified. In other sites, the lymphocytes (*Ly*) have infiltrated the epithelium to such an extent that the epithelium is difficult to identify. The body of the nodules

(*N*) lies within the mucosa, and because of their close proximity, they tend to merge. Several of the nodules have been cut in a plane that includes their germinal center (*GC*). Note the eosinophilic staining in these areas. Beneath the nodules is the submucosa (*S*) consisting of dense connective tissue, which is continuous with the dense connective tissue beyond the tonsillar tissue.

Tonsil, human, H&E $\times 365$.

At the higher magnification of this micrograph, the characteristic invasiveness of the lymphocytes into the overlying epithelium is readily evident. Note on the *lower left side* of the micrograph a clear boundary between the epithelium and the underlying lamina propria. The basal cells (*BC*) of the stratified squamous epithelium can be recognized.

The underlying lamina propria is occupied by numerous lymphocytes; only a few have entered the epithelial compartment. Also note the thin band of collagen fibers (*CF*) that can be seen at the boundary between the epithelium and the lamina propria. In contrast, the *lower right side* of the micrograph displays numerous lymphocytes that have invaded the epithelium. More striking is the presence of what appear as isolated islands of epithelial cells (*Ep*) within the periphery. The thin band of collagen (*C*) lying at the interface of the epithelium is so disrupted in this area that it appears as small fragments. In effect, the small portion of the nodule seen on the *right side* of the micrograph has literally grown into the epithelium with the consequent disappearance of the well-defined epithelial-connective tissue boundary.

BC, basal cells
C, collagen
CF, collagen fibers
Ep, islands of epithelial cells
GC, germinal center
L, lymphatic tissue
Ly, lymphocytes
MG, mucus-secreting glands
N, nodule
S, submucosa
SE, surface epithelium
SSE, stratified squamous epithelium
TC, tonsillar crypts

PLATE 14.2 ■ LYMPH NODE I

Lymph nodes are small, encapsulated lymphatic organs that are located in the path of the lymph vessels. They serve as filters of the lymph and as the principal site in which T and B lymphocytes undergo *antigen-dependent* proliferation and differentiation into *effector lymphocytes* (plasma cells and T cells) and *memory B cells* and *T cells*. A low-magnification ($\times 14$) micrograph of a section through a human lymph node is shown on this page for orientation. The **capsule** appears as a thin connective tissue covering.

The parenchyma of the node is composed of a mass of lymphatic tissue, arranged as a **cortex** (*C*) that surrounds a less dense area, the **medulla** (*M*). The cortex is interrupted at the **hilum** of the organ (*H*), where there is a recognizable concavity. It is at this site that blood vessels enter and leave the lymph node; the efferent lymphatic vessels also leave the node at the hilum.

Afferent lymphatic vessels penetrate the capsule at multiple sites to empty into an endothelium-lined space, the *cortical* or *subcapsular sinus*. This sinus drains into the trabecular sinuses that extend through the cortex alongside the trabeculae and then supply the *medullary sinuses*. These, in turn, drain to the *efferent lymphatic vessels* that leave the node at the hilum.

Cortex of lymph node, human, hematoxylin and eosin (H&E)
×120.

An area from the **cortex** is shown here at higher magnification. The **capsule** (*Cap*) is composed of dense connective tissue from which

trabeculae (*T*) penetrate into the organ. Immediately below the capsule is the cortical or **subcapsular sinus** (*CS*), which receives lymph from the afferent lymphatic vessels after they penetrate the capsule. The cortical sinus is continuous with the trabecular sinuses (*TS*) that course along the trabeculae.

The cortex contains the lymphatic nodules (*LN*) and a deeper component that lacks nodules, known as the *deep cortex*. Whereas lymph nodules and their lighter staining germinal centers characterize the outer cortex, a more dense mass of lymphocytes, which imparts a distinct basophilia, characterizes the deep cortex. In contrast to these areas, the medulla is characterized by narrow strands of anastomosing lymphatic tissue containing numerous lymphocytes, the medullary cords (*MC*), separated by light-appearing areas known as the *medullary sinuses* (*MS*). The medullary sinuses receive lymph from the trabecular sinuses and lymph filtered through the cortical tissue.

**Lymphatic nodule, lymph node, human, H&E $\times 400$;
inset $\times 640$.**

This higher magnification micrograph of a **lymphatic nodule** from the previous figure illustrates the **germinal center** (*GC*) containing medium and large lymphocytes (majority of activated B cells). Germinal centers also contain plasma cells. Dividing lymphocytes are shown at slightly higher magnification in the *inset* (*arrows*), which corresponds to the area in the *circle* in this figure. The *inset* also reveals nuclei of the **reticular cells** (*RC*) that form the connective tissue stroma throughout the organ. The ovoid reticular cell has a large pale-staining nucleus, and its cytoplasm forms long processes that surround the reticular fibers. In H&E preparations, the reticular fibers and the surrounding cytoplasm are difficult to identify. Reticular cells are best seen in the sinuses, where they extend across the lymphatic space and are relatively unobscured by other cells.

A unique vessel, the **high endothelial venule** (*HEV*), is found in relation to the lymphatic nodules, particularly in the deep cortex. These vessels have an endothelium composed of tall cells between which lymphocytes migrate from the vessel lumen into the parenchyma.

C, cortex
Cap, capsule
CS, cortical or subcapsular sinus
GC, germinal center
H, hilum
HEV, high endothelial venule

T, trabecular
TS, trabecular sinus
arrows, dividing lymphocytes

PLATE 14.3 ■ LYMPH NODE II

Immunocompetent B cells that have been exposed to an antigen that they can recognize and bind migrate to a lymph node, where they undergo activation and begin a series of mitotic divisions that produce large numbers of immature lymphocytes. They proliferate further in **superficial cortex** into a clone of lymphocytes that differentiate into antibody-secreting plasma cells and memory cells. B-cell proliferation and differentiation take place in **germinal centers** in the superficial cortex of the lymph node. T-cell activation and differentiation take place in the **deep cortex**. Newly differentiated plasma cells migrate to the medulla, where they release antibodies into the lymph leaving the node. They may also leave the node, enter the blood vascular system at the thoracic duct, and travel to localized sites in the connective tissue where they may continue to produce antibodies.

Deep cortex, lymph node, human, hematoxylin and eosin (H&E) $\times 365$.

This micrograph shows the lymph node **deep cortex**. As noted in the previous plate, it lies below the region containing the lymph nodules and consists of closely packed lymphocytes. A number of blood vessels can be seen in this region. Whereas typical small blood vessels such as capillaries (*Cap*) and venules are present, the more unusual postcapillary venule called **high endothelial venule (HEV)** is also found in this region. A small vessel that can be identified as a venule (*Ven*), based on lumen size and wall thickness, is seen at a point of transition to become a high endothelial venule (*arrowheads*). The endothelial cell nuclei at this point of juncture have become cuboidal. The high endothelial venule is identified by its endothelium, which is composed of cells that are cuboidal. A cross-sectioned profile of a postcapillary venule is shown in the *inset* at higher magnification ($\times 700$). The endothelial cell's nuclei are round and lightly stained, in contrast to the nuclei of the surrounding lymphocytes, which are of similar size and shape but are densely stained. This vessel also shows three lymphocytes (*arrows*) that are in the process of migrating through the wall of the vessel. The *lower right* corner of this figure reveals a region where there is a considerably lesser concentration of lymphocytes. This area, part of the medulla, contains spaces that represent medullary sinuses (*MS*).

Hilar region, lymph node, human, H&E $\times 250$.

The areas shown here, near the hilar region of the node, are part of a **lymph nodule** (*LN*), the **cortical sinus** (*CS*) just below the capsule (*Caps*), and some of the medullary sinus (*MS*). Both the cortical sinus and the medullary sinus are spanned by **reticular cells** (*RC*). These cells wrap around the collagen bundles that form the supporting trabecular framework of the node. The *inset* reveals the *boxed area* at higher magnification ($\times 530$). The nuclei of the reticular cells (*RC*) are larger and less densely staining than the lymphocyte nuclei, which are round and densely stained. In H&E preparations, these characteristics allow for the distinction between the reticular cell and the lymphocyte.

Hilar region, lymph node, monkey, H&E $\times 530$.

This micrograph shows an area in the region of the hilum of the node. Two of the vessels here are **efferent lymphatics**; both contain a valve (*Val*). The upper lymphatic vessel exhibits what appears to be an incomplete wall. The openings in the vessel wall (*arrows*) are sites in which the medullary sinuses are emptying their contents into the lymphatic vessel. Also present are a small artery (*A*) and a vein (*V*).

A, artery
 Cap, capillary
 Caps, capsule
 CS, cortical sinus
 HEV, high endothelial venule
 LN, lymph nodule
 MS, medullary sinus
 RC, reticular cells
 V, vein
 Val, valve
 Ven, venule
 arrowheads, endothelial cells of postcapillary venule
 arrows, top image endothelial cells of HEV; bottom image opening of medullary sinus to lymph vessel

PLATE 14.4 ■ SPLEEN I

The spleen is the largest lymphatic organ; it is surrounded by a capsule and located in the path of the bloodstream (splenic artery and vein). The spleen filters the blood and reacts immunologically to blood-borne antigens. It has both morphologic and immunologic filtering functions. The substance of the spleen, the splenic pulp,

consists of **red pulp** and **white pulp**, so named because of their appearance in fresh tissue. The white pulp is rich in lymphocytes that form a **periarterial lymphatic sheath (PALS)** around branches of the splenic artery that penetrate the white pulp. The red pulp contains large numbers of red blood cells that it filters and degrades. Aged, damaged, or abnormal red blood cells are trapped by macrophages associated with unusual vascular sinuses in the red pulp. These macrophages break down the red cells, begin the metabolic breakdown of hemoglobin, and retrieve and store the iron from the heme for reutilization in the formation of new red blood cells in the bone marrow.

Spleen, human, hematoxylin and eosin (H&E) $\times 65$.

This low-magnification micrograph of the spleen reveals its two major components, the **red pulp (RP)** and **white pulp (WP)**. In the *center* of the figure, there is a trabecula containing a blood vessel, a trabecular vein (*TV*) through which blood leaves the organ. The red pulp constitutes the greater bulk of the splenic tissue. In life, the red pulp has pulp-like texture; it is red as a result of the natural coloration of the numerous red blood cells present, hence its name.

The white pulp, on the other hand, is so named because its content of lymphocytes appears in life as whitish areas. In tissue sections, however, the nuclei of the closely packed lymphocytes impart an overall blue-staining response. The lymphatic tissue that constitutes the white pulp differs from nodules seen elsewhere in that it follows and ensheathes a blood vessel, the central artery. The lymphatic tissue surrounding the artery exhibits periodic expansion, thus forming the nodules. When this occurs, the **central artery (CA)** is displaced peripherally within the nodule.

In those regions where the lymphatic tissue is not in nodular form, it is present as a thin cuff around the central artery and is referred to as the *periarterial lymphatic sheath*. If the plane of section does not include the artery, the sheath may appear only as a localized and irregular aggregation of lymphocytes.

Red pulp, spleen, human, H&E $\times 160$.

This figure reveals, at a higher magnification, the **red pulp** and a portion of the trabecular vein from the area enclosed in the *uppermost rectangle* in the *top* figure. The red pulp is composed of two elements: **venous sinuses (VS)** and the **splenic cords** (of Billroth), the tissue that lies between the sinuses. In this specimen, the venous sinuses can be seen to have advantages because the red blood cells in the sinuses have lysed and appear as unstained "ghosts"; only the nuclei of the white cells are

readily seen. (This is better seen in Plate 14.5, page 534.) The paler, unstained areas thus represent the sinus lumina.

Near the *top* of the micrograph, two venous sinuses (*arrows*) empty into the trabecular vein (*TV*), thus showing the continuity between venous sinuses and the trabecular veins. The wall of the vein is thin, but the trabecula (*T*) containing the vessel gives the appearance of being part of the vessel wall. In humans as well as in other mammals, the capsule and the trabeculae that extend from the capsule contain myofibroblasts. Under conditions of increasing physical stress, contraction of these cells will occur and cause rapid expulsion of blood from the venous sinuses into the trabecular veins and thus into the general circulation. Note the small area of white pulp in the *upper right* portion of this image with labeled marginal zone (*MZ*) that separates white pulp and red pulp. This zone is not well defined in humans.

White pulp, spleen, human, H&E $\times 240$.

This figure reveals, at higher magnification, the **splenic nodule** in the *rectangle* in the *right* portion of the previous figure. Present are a **germinal center** (*GC*) and a cross section through the thick-walled **central artery** (*CA*). As noted earlier, the central artery is eccentrically placed in the nodule. The marginal zone (*MZ*) is not well defined in humans, but it is assumed to be in the area that separates white pulp and red pulp (*RP*). Small arterial vessels and capillaries, branches of the central artery, supply the white pulp, and some pass into the reticular network terminating in a funnel-shaped orifice. The details of the vascular supply are, at best, difficult to resolve in typical H&E preparations. The penicillar arterioles, the terminal branches of the central artery, supply the red pulp but are likewise difficult to resolve.

CA, central artery

GC, germinal center

MZ, marginal zone

RP, red pulp

T, trabecular

TV, trabecular vein

VS, venous sinus

WP, white pulp

arrows, venous sinuses emptying into the trabecular vein

PLATE 14.5 ■ SPLEEN II

Red pulp, spleen, human, hematoxylin and eosin (H&E) ×360.

As previously noted, the **red pulp** consists of the **venous sinuses** (*VS*) and the area between the venous sinuses, the **splenic cords** (of Billroth) (*SC*). In this specimen, the red blood cells have been lysed, leaving only a clear outline of the individual cells. Thus, the relatively clear spaces with scattered nuclei represent the lumen of the venous sinus; the nuclei are those of white blood cells. When the wall of a venous sinus is tangentially sectioned (*VW*), as in this figure, the endothelial cells, which are rod like in shape, appear as a series of thin, linear bodies.

Red pulp, spleen, human, H&E ×1,200.

This micrograph is a high magnification of the area in the *rectangle* of the previous micrograph. The **venous sinus** in the *center* of the micrograph has been cut in cross section. Other than the lysed red blood cells, which appear as empty circular profiles, a number of lymphocytes (*Ly*) are present in the lumen. The wall of the sinus as seen here consists of rod-like endothelial cells (*EC*) that have been cut in cross section. A narrow but clearly visible intercellular space is present between adjacent cells. These spaces allow blood cells to pass readily into and out of the sinuses. Also, processes of macrophages located outside the sinuses in the splenic cords extend between the endothelial cells and into the lumen of the sinuses to monitor the passing blood for foreign antigens. The endothelial cell nuclei (*ECN*) project into the lumen of the vessel and appear to be sitting on top of the cell. A macrophage (*M*), identified by residual bodies in its cytoplasm, is seen just outside the sinus.

Spleen, human, H&E ×160.

This figure shows a **trabecular vein** (*TV*) and surrounding red pulp. At the *top* of the micrograph, two venous sinuses (*arrows*) can be seen emptying into the trabecular vein. These small trabecular veins converge into larger veins, which eventually unite giving rise to the splenic vein.

Spleen, human, silver preparation $\times 128$.

This micrograph shows a **splenic nodule** (*SM*) occupying the *upper portion* of the micrograph and below red pulp (*RP*). The components that can be identified are a germinal center (*GC*), a central artery (*CA*), and venous sinuses (*VS*) in the red pulp. The structural elements that are stained by the silver in the nodule consist of reticular fibers. Note their paucity within the germinal center. The fine, thread-like stained material that encircles the venous sinuses is a usual modification of basement membrane.

Venous sinuses, spleen, human, silver preparation $\times 515$.

This micrograph reveals several **venous sinuses** (*VS*). Where the vessel wall has been tangentially sectioned, the **basement membrane** appears as a ladder-like structure (*BM*). Where the vessel has been cut deeper along its long axis, the basement membrane appears as dot-like structures (*arrowheads*). A three-dimensional reconstruction of the basement membrane would reveal it as a series of ring-like structures.

BM, basement membrane
CA, central artery
EC, rod-like endothelial cells
ECN, endothelial cell nuclei
GC, germinal center
Ly, lymphocytes
M, macrophage
RP, red pulp
SC, splenic cords
SN, splenic nodule
TV, trabecular vein
VS, venous sinuses
VW, venous sinus wall

PLATE 14.6 ■ THYMUS

The thymus is a lymphatic organ that exhibits certain unique structural features. The supporting reticular stroma arises from endodermal epithelium and produces a cellular reticulum. There are no

reticular fibers associated with these cells; instead, the cells, designated **epithelioreticular cells**, serve as the stroma. Lymphocytes come to lie in the interstices of the cellular reticulum, and these two cellular elements, the lymphocytes and the epithelioreticular cells, comprise the bulk of the organ. The stem lymphocytes that migrate into the endodermal rudiment in the embryo derive from the yolk sac and later from the red bone marrow. These lymphocytes proliferate and become immunologically competent in the thymus, differentiating into the **thymus-dependent lymphocytes** (i.e., T lymphocytes). Some of these lymphocytes migrate to other tissues to populate the thymus-dependent portions of lymph nodes and spleen as well as to reside in the loose connective tissue. Many lymphocytes die or are destroyed in the thymus because in the random process by which they acquire the ability to recognize and react to antigens, they become programmed against “self” antigens. Numerous macrophages are present to phagocytize these destroyed lymphocytes. A **blood-thymus barrier** is formed by the sheathing of the perivascular connective tissue of the thymus by the epithelioreticular cells. In addition, there are no afferent lymphatic vessels to the thymus. Thus, it cannot react to circulating antigens. The thymus involutes during adolescence and is often difficult to recognize in the adult.

A connective tissue **capsule** (*Cap*) surrounds each lobe of the two lobes of the thymus and sends trabeculae (*T*) into the parenchyma to form lobules. The lobules are not completely separate units; rather, they interconnect because of the discontinuous nature of the trabeculae.

Thymus, human, hematoxylin and eosin (H&E) $\times 40$.

Examination of the thymus at low magnification reveals the lobules (*L*) composed of a dark-staining basophilic **cortex** (*C*) and a lighter staining and relatively eosinophilic **medulla** (*M*). The cortex contains numerous densely packed lymphocytes, whereas the medulla contains fewer lymphocytes and is consequently less densely packed. A connective tissue capsule

of the thymus sends trabeculae (*T*) into the parenchyma of the gland to form lobules. However, trabeculae do not completely separate lobules owing to their discontinuous nature.

Thymus, human, H&E $\times 140$.

It is the relative difference in the lymphocyte population (per unit area) and, in particular, the staining of their nuclei with hematoxylin that creates the difference in appearance between **cortex** (*C*) and **medulla** (*M*). Note that some of the medullary areas bear a resemblance to germinal centers of other lymphatic organs because of the medulla

appearing as isolated circular areas (*upper left of top figure*). The

medullary component, however, is actually a continuous branching mass surrounded by cortical tissue. Thus, the “isolated” medullary profiles are actually united with one another, although not within the plane of section. A suggestion of such continuity can be seen on the *right in the top figure* where the medulla appears to extend across several lobules.

The main cellular constituents of the thymus are lymphocytes (thymocytes), with characteristic small, round, dark-staining nuclei, and epithelioreticular supporting cells, with large pale-staining nuclei. Both of the cell types can be distinguished in the figure on the *right*, which provides a high-magnification view of the medulla. Because there are fewer lymphocytes in the medulla, it is the area of choice to examine the epithelioreticular cells. The thymus also contains macrophages; however, they are difficult to distinguish from the epithelioreticular cells.

Medulla, thymus, human, H&E $\times 600$.

The medulla usually possesses varying numbers of circular bodies called **Hassall corpuscles**, or **thymic corpuscles** (*HC*). In addition to type IV and type V of **epithelioreticular cells** (*Ep*) that serve as a reticular stroma of the medulla, the Hassall corpuscles contain large concentric layers of flattened type VI **epithelioreticular cells** (*arrowheads*). They stain readily with eosin and can be distinguished easily with low magnification, as in the *top figure* and *lower left (arrows)*. The center of a corpuscle, particularly a large one, may show evidence of keratinization and appear somewhat amorphous. Note a blood vessel (*BV*) in the medulla that is surrounded by lymphocytes.

The thymus gland remains as a large structure until the time of puberty. At that time, regressive changes occur that result in a significant reduction in the amount of thymic tissue. The young thymus is highly cellular and contains a minimum of adipose tissue. On the other hand, in the older thymus, much adipose tissue is present between the lobules. With continued involution, adipose cells are found even within the thymic tissue itself. Occasional plasma cells may be present in the periphery of the thymic cortex of the involuting thymus gland.

■ OVERVIEW OF THE INTEGUMENTARY SYSTEM

The **skin (cutis, integument)** and its derivatives constitute the **integumentary system**. The skin forms the external covering of the body with an extensive surface area of approximately 1.8 m². It is also the largest organ of the body, constituting 15% – 20% of its total body mass. The skin consists of two main layers:

- The **epidermis** is composed of a keratinized stratified squamous epithelium that grows continuously but maintains its normal thickness through desquamation. Epidermis is derived from ectoderm.
- The **dermis** is composed of a dense irregular connective tissue that imparts mechanical support, strength, and thickness to the skin. Dermis is derived from mesoderm.

The **hypodermis** contains variable amounts of adipose tissue arranged into lobules separated by connective tissue septa. It lies deep to the dermis and is equivalent to the **subcutaneous fascia** described in gross anatomy. The adipose tissue can be quite thick in well-nourished individuals and those living in cold climates.

The **epidermal derivatives of the skin** (epithelial skin appendages) include the following structures and integumentary products:

- **Hair follicles** and **hair**
- **Nails**
- **Sweat (sudoriferous) glands**

- Sebaceous glands
- Mammary glands

The integumentary system performs essential functions related to its external surface location.

Skin and its derivatives constitute a complex organ composed of many different cell types. The diversity of these cells and their ability to work together provide many functions that allow the individual to cope with the external environment. Major functions of the skin include the following:

- It acts as a **barrier** that protects against physical, chemical, and biologic agents in the external environment (i.e., mechanical barrier, permeability barrier, ultraviolet [UV] barrier).
- It provides **immunologic information** obtained during antigen processing to the appropriate effector cells in the lymphatic tissue.
- It participates in **homeostasis** by regulating body temperature and water loss.
- It conveys **sensory information** about the external environment to the nervous system.
- It performs **endocrine functions** by secreting hormones, cytokines, and growth factors and converting precursor molecules into hormonally active molecules (vitamin D₃).
- It functions in **excretion** through the exocrine secretion of sweat, sebaceous, and apocrine glands.

In addition, certain lipid-soluble substances may be absorbed through the skin. Although not a function of skin, this property is frequently used to deliver therapeutic agents. For example, nicotine, steroid hormones, and seasickness medications are frequently delivered through the skin in the form of patches, sprays, creams, or gels. To reduce nicotine withdrawal symptoms during smoking cessation, nicotine patches are often used to provide a small, constant dose of nicotine without the dangerous effects of tobacco smoke.

■ SKIN

Skin is categorized as thick or thin, reflecting its thickness and location.

The thickness of the skin varies over the surface of the body, from less than 1 mm to more than 5 mm. However, the skin is grossly and histologically different at two locations: the palms of the hands and the soles of the feet. These areas are subject to the most abrasion, are hairless, and have a much thicker epidermal layer than skin in any other location. This hairless skin is referred to as **thick skin**. Elsewhere, the skin possesses a much thinner epidermis and is called **thin skin**. It contains hair follicles in all but a few locations.

The histologic terms thick skin and thin skin are misnomers and refer only to the thickness of the epidermal layer. Anatomically, the thickest skin is found on the upper back, where the dermis is exceedingly thick. However, the epidermis of the upper back is comparable to that of thin skin found elsewhere on the body. In contrast, in certain other sites, such as the eyelid, the skin is extremely thin.

■ EPIDERMIS

Layers of the Epidermis

The **epidermis** is composed of stratified squamous epithelium in which four distinct layers can be identified. In the case of thick skin, a fifth layer is observed (Figs. 15.1 and 15.2). Beginning with the deepest layer, these layers are as follows:

FIGURE 15.1. Photomicrograph showing the layers of thin skin. This hematoxylin and eosin (H&E)-stained specimen from human skin shows the two chief layers of the skin—the epidermis (*Epi*) and dermis (*Derm*). The epidermis forms the surface; it consists of stratified squamous epithelium that is keratinized. The dermis consists of two layers: the papillary layer, which is the most superficial layer and is adjacent to the epidermis, and the more deeply positioned reticular

layer. The boundary between these two layers is not conspicuous; the papillary layer is, however, more cellular than the reticular layer. In addition, the collagen fibers of the reticular layer are thick (clearly visible in the *lower part* of the figure); those of the papillary layer are thin. ×45.

FIGURE 15.2. Photomicrograph showing the layers of thick skin. This specimen obtained from the skin of the sole of the foot (human) shows epidermis (*Epi*) containing the extremely thick stratum corneum (*SC*). Remaining layers of the epidermis (except for the stratum lucidum, which is not present on this slide)—the stratum basale (*SB*),

the stratum spinosum (*SS*), and the stratum granulosum (*SGr*)—are clearly visible in this routine hematoxylin and eosin (H&E) preparation. The duct of a sweat gland (*D*) can be seen on the *left* as it traverses the dermis (*Derm*) and further spirals through the epidermis. At the sites where the ducts of the sweat gland enter the epidermis, note the epidermal downgrowths known as *interpapillary pegs*. The dermis contains papillae, protrusions of connective tissue that lie between the interpapillary pegs. Note also the greater cellularity of the papillary layer (*PL*) and that the collagen fibers of the reticular layer (*RL*) are thicker than those of the papillary layer. ×65.

- **Stratum basale**, also called the **stratum germinativum** because of the presence of mitotically active cells, the stem cells of the epidermis
- **Stratum spinosum**, also called the **spinous layer** or **prickle cell layer** because of the characteristic light microscopic appearance of short processes extending from cell to cell
- **Stratum granulosum**, which contains numerous intensely staining granules
- **Stratum lucidum**, which is limited to thick skin and considered a subdivision of the stratum corneum
- **Stratum corneum**, which is composed of keratinized cells

Differentiation of epithelial cells constitutes a specialized form of apoptosis.

Terminal differentiation of the epidermal cells, which begins with the cell divisions in the stratum basale, is considered a specialized form of apoptosis. Cells in the stratum granulosum exhibit typical apoptotic nuclear morphology, including fragmentation of their DNA. However, the cellular fragmentation associated with normal apoptosis does not occur; instead, the cells become filled with filaments of the intracellular protein **keratin** and are later sloughed from the skin surface.

The stratum basale provides for epidermal cell renewal.

The **stratum basale** is represented by a single layer of cells that rests on the basal lamina (Plate 15.1, page 576). It contains the **stem cells** from which new cells, called **keratinocytes**, arise by mitotic division. For this reason, the

stratum basale is also called the **stratum germinativum**. The cells are small and cuboidal to low columnar. They have less cytoplasm than the cells in the layer above; consequently, their nuclei are more closely spaced. The closely spaced nuclei, in combination with the basophilic cytoplasm of these cells, impart a noticeable basophilia to the stratum basale. Basal cells also contain various amounts of **melanin** (described later) in their cytoplasm that is transferred from neighboring melanocytes interspersed in this layer. Basal cells exhibit extensive cell junctions; they are connected to each other and to keratinocytes by desmosomes and to the underlying basal lamina by hemidesmosomes. As new keratinocytes arise in this layer by mitotic division, they move into the next layer, thus beginning their process of upward migration. This process terminates when the cell becomes a mature keratinized cell, which is eventually sloughed off at the skin surface.

The cells of the stratum spinosum characteristically exhibit spinous processes.

The **stratum spinosum** is at least several cells thick. **Keratinocytes** in this layer are larger than those of the stratum basale. They exhibit numerous **cytoplasmic processes** or spines, which gives this layer its name (Fig. 15.3 and Plate 15.1, page 576). The processes are attached to similar processes of adjacent cells by **desmosomes**. In the light microscope, the site of the desmosome appears as a slight thickening called the node of Bizzozero. The processes are usually conspicuous, in part because the cells shrink during preparation and a resultant expanded intercellular space develops between the spines. Because of their appearance, the cells that constitute this layer are often referred to as **prickle cells**. As the cells mature and move to the surface, they increase in size and become flattened in a plane parallel to the surface. This arrangement is particularly notable in the most superficial spinous cells, where the nuclei also become elongate instead of ovoid, matching the acquired squamous shape of the cells.

FIGURE 15.3. Photomicrograph of the stratum spinosum and stratum basale. The epidermis of thin skin is shown here at higher magnification. The one-cell-deep layer at the base of the epidermis just above the connective tissue (*CT*) of the dermis is the stratum basale (*SB*). The cells of this layer rest on the basement membrane. The *stratum spinosum* (*SS*) is located just above the stratum basale. It consists of cells with spinous processes on their surfaces. These processes are attached to spinous processes of neighboring cells by desmosomes and together appear as intercellular bridges. $\times 640$.

The cells of the stratum granulosum contain conspicuous keratohyalin granules.

The **stratum granulosum** is the most superficial layer of the nonkeratinized portion of the epidermis. This layer varies from one to three cells thick. **Keratinocytes** in this layer contain numerous **keratohyalin granules**, hence the name of the layer. These granules contain cystine-rich and histidine-rich proteins, which are the precursors of the protein **filaggrin** (keratin filament aggregating protein), which aggregates the **keratin filaments** present within the cornified cells of the stratum corneum. Keratohyalin granules are irregular in shape and variable in size. Because of their intense basophilic staining, they are readily seen in routine histologic sections.

The stratum corneum consists of anucleate squamous cells largely filled with keratin filaments.

Usually, an abrupt transition occurs between the nucleated cells of the stratum granulosum and the flattened, desiccated, anucleate cells of the **stratum corneum**. The cells in the stratum corneum are the most differentiated cells in the skin. They lose their nucleus and cytoplasmic organelles and become filled almost entirely with keratin filaments. The thick plasma membrane of these cornified, keratinized cells is coated from the outside, in the deeper portion of this layer, with an extracellular layer of lipids that form the major constituent of the **water barrier** in the epidermis.

The stratum corneum is the layer that varies most in thickness, being thickest in thick skin. The thickness of this layer constitutes the principal difference between the

epidermis of thick and thin skin. This cornified layer will become even thicker at sites subjected to unusual amounts of friction, as in the formation of calluses on the palms of the hands and the fingertips.

The **stratum lucidum**, considered a subdivision of the stratum corneum by some histologists, is normally only well seen in thick skin. In the light microscope, it often has a refractile appearance and may stain poorly. This highly refractile layer contains eosinophilic cells in which the process of keratinization is well advanced. The nucleus and cytoplasmic organelles become disrupted and disappear as the cell gradually fills with keratin.

■ CELLS OF THE EPIDERMIS

There are four different types of cells in the epidermis:

- **Keratinocytes** are highly specialized epithelial cells designed to perform a specific function: separating the organism from its external environment. They account for 85% of the cells in the epidermis.
- **Melanocytes** are the pigment-producing cells of the epidermis. They account for approximately 5% of the cells in the epidermis.
- **Langerhans cells** are antigen-presenting cells involved in signaling in the immune system. They account for approximately 2% - 5% of the cells in the epidermis.
- **Merkel cells** are the sensitive mechanoreceptor cells associated with sensory nerve endings. They account for approximately 6% - 10% of the cells in the epidermis.

Keratinocytes

The **keratinocyte** is the predominant cell type of the epidermis. These cells originate in the stratum basale of the epidermis. On leaving this layer, keratinocytes perform two essential activities:

- They produce **keratins (cytokeratins)**, major heteropolymeric structural proteins of the epidermis (see Table 2.3, page 74). Keratins form intermediate filaments; they constitute almost 85% of fully differentiated keratinocytes.
- They participate in the formation of the **epidermal water barrier**.

The keratinocytes in the basal layer contain numerous free ribosomes, scattered 7- to 9-nm intermediate (keratin) filaments, a small Golgi apparatus, mitochondria, and rough endoplasmic reticulum (rER). The cytoplasm of immature keratinocytes appears basophilic in histologic sections because of the large number of free ribosomes, most of which are engaged in synthesizing keratins, which will later be assembled into **keratin filaments**. These filaments are classified as intermediate filaments, although they are more commonly called **tonofilaments**.

As the cells enter and are moved through the stratum spinosum, the synthesis of keratin filaments continues, and the filaments become grouped into bundles sufficiently thick to be visualized in the light microscope. These bundles are called **tonofibrils**. The cytoplasm becomes eosinophilic because of the staining reaction of the tonofibrils that fill more and more of the cytoplasm.

Keratohyalin granules contain intermediate filament-associated proteins that aid in the aggregation of keratin filaments.

In the upper part of the stratum spinosum (Fig. 15.4), the free ribosomes within the keratinocytes begin synthesizing **keratohyalin granules** that become the distinctive feature of the cells in the stratum granulosum (Plate 15.1, page 576). Keratohyalin granules contain the two major intermediate filament-associated proteins: **filaggrin** and **trichohyalin**. The appearance of the granules and expression of filaggrin in keratinocytes are often used as a clinical marker for the initiation of the final stage of apoptosis. As the number of granules increases, their contents are released into the

keratinocyte cytoplasm. Filaggrin and trichohyalin function as promoters in the aggregation of keratin filaments into tonofibrils, thus initiating the conversion of granular cells into cornified cells. This process is called **keratinization** and occurs in 2-6 hours, the time it takes for the cells to leave the stratum granulosum and enter the stratum corneum. The keratin fibril formed in this process is called **soft keratin** in contrast to the **hard keratin** of hair and nails (see later).

FIGURE 15.4. Schematic diagram of keratinocytes in the epidermis. The keratinocytes in this figure reflect different stages in the life cycle of the cell as it passes from the basal layer to the skin surface, where it becomes desquamated. The basal cell begins to synthesize intermediate (keratin) filaments; these are grouped into bundles and are seen in the light microscope as tonofibrils. The cell enters the spinous layer, where the synthesis of intermediate filaments continues. In the upper part of the spinous layer, the cells begin to produce keratohyalin granules containing intermediate filament-associated proteins and glycolipid-containing lamellar

bodies. Within the granular layer, the cell discharges lamellar bodies that contribute to formation of the water barrier of the epidermis; the remainder of the cell cytoplasm contains numerous keratohyalin granules that, in close association with tonofilaments, form the cell envelope. The surface cells are keratinized; they contain a thick cell envelope and bundles of tonofilaments in a specialized matrix. Desquamation of keratinized cells is regulated by the activity of KLK and its interaction with LEKTI in desmosomes, which in turn is dependent on pH. Keratinocytes positioned near the granular layer exhibit neutral pH, which maintains desmosomal interactions and allows a strong interaction in the extracellular matrix between LEKTI and its KLK targets. As the pH acidifies toward the skin surface, LEKTI and KLK dissociate, releasing KLKs into the extracellular space. In the most superficial layers of keratinocytes, the pH is low enough for active KLK molecules to digest desmosomal proteins. In concert with other proteinase activities, this action leads to a complete degradation of desmosomal junctions, resulting in the detachment of the most superficial layer of keratinocytes. *rER*, rough-surfaced endoplasmic reticulum; *LEKTI*, lymphoepithelial Kazal-type inhibitor; *KLK*, kallikrein-related serine peptidase.

The transformation of a granular cell into a keratinized cell also involves breakdown of the nucleus and other organelles and thickening of the plasma membrane. This is accompanied by a change in pH, which decreases from approximately neutral (pH 7.17) in the stratum granulosum to acidic at the surface of the stratum corneum, ranging between pH 4.5 and 6.0.

Desquamation of surface keratinocytes from the stratum corneum is regulated by proteolytic degradation of the cells' desmosomes.

Cells are regularly exfoliated or desquamated from the surface of the stratum corneum. The **continuous exfoliation** of surface keratinocytes is a regulated proteolytic process that involves the degradation of the cells' desmosomes. The human **kallikrein-related serine peptidases**, such as **KLK5**, **KLK7**, and **KLK14**, cause cleavage of desmosomes in a pH-dependent manner. A physiologic serine protease inhibitor, **lymphoepithelial Kazal-type inhibitor (LEKTI)**, through its interactions with KLKs in neutral pH, prevents desmosomal cleavage. However, as pH decreases in more superficial portions of the stratum corneum

as described, LEKTI progressively releases KLKs at the lower pH, thus allowing KLKs to degrade the desmosomes and cause keratinocyte release (see Fig. 15.4). Under normal conditions, the process allows a controlled renewal of the epidermis by means of its pH gradient. There are known pathogenic mutations in the gene called serine protease inhibitor Kazal-type 5 (SPINK5), which encodes LEKTI. Netherton syndrome, a rare genetic disorder, is associated with a mutation in the SPINK5 gene. This syndrome is characterized by decreased skin barrier function, generalized redness of the skin (erythroderma), and scaling.

Lamellar bodies contribute to the formation of the intercellular epidermal water barrier.

An epidermal water barrier is essential for mammalian “dry” epithelia and is responsible for maintaining body homeostasis. The barrier is established primarily by two factors in terminally differentiating keratinocytes: (1) deposition of insoluble proteins on the inner surface of the plasma membrane and (2) a lipid layer that is attached to the outer surface of the plasma membrane.

As the keratinocytes in the stratum spinosum begin to produce keratohyalin granules, they also produce membrane-bounded lamellar bodies (membrane-coating granules). They are tubular or ovoid-shaped membrane-bound organelles that are unique to the mammalian epidermis (Fig. 15.5). Spinous and granular cells synthesize a heterogeneous mixture of probarrier lipids and their respective lipid-processing enzymes, such as glycosphingolipids, phospholipids, ceramides, acid sphingomyelinase, and secretory phospholipase A2; this mixture is assembled into lamellar bodies in the Golgi apparatus (Fig. 15.6). In addition, lamellar bodies contain proteases (i.e., stratum corneum chymotryptic enzyme, cathepsin D, acid phosphatase, glycosidases, and protease inhibitors). The contents of the granules are then secreted by exocytosis into the intercellular spaces between the stratum granulosum and stratum corneum. The organization of these intercellular lipid lamellae is responsible for the formation of the

epidermal water barrier (see Fig. 15.6). In addition to their major role in the formation of barrier homeostasis, lamellar bodies are also involved in the formation of the cornified envelope, desquamation of cornified cells, and antimicrobial defenses in the skin.

FIGURE 15.5. Electron micrographs of keratinocytes. **a.** Much of the keratinocyte cytoplasm is filled with tonofilaments. One keratinocyte exhibits a keratohyalin granule (*KG*). Near the plasma membrane closest to the surface (*upper left*), two keratinocytes display lamellar bodies (*arrowheads*). $\times 8,500$. **b.** A lamellar body at higher magnification. $\times 135,000$. **c.** Part of a keratinized cell and the underlying keratinocyte. Located between the cells are the contents of the lamellar bodies, which have been discharged into the intercellular space (*arrow*) to form the lipid envelope. $\times 90,000$. (Courtesy of Dr. Albert I. Farbman.)

FIGURE 15.6. Schematic diagram of the epidermal water barrier. The heterogeneous mixture of glycosphingolipids, phospholipids, and ceramides makes up the lamellae of the lamellar bodies. The lamellar bodies, produced within the Golgi apparatus, are secreted by exocytosis into the intercellular spaces between the stratum granulosum and stratum corneum, where they form the lipid envelope. The lamellar arrangement of lipid molecules is depicted in the intercellular space just below the thickened plasma membrane and forms the cell envelope of the keratinized keratinocyte. The innermost part of the cell envelope consists primarily of loricrin molecules (*pink spheres*) that are cross-linked by small proline-rich (*SPR*) proteins and elafin. The layer adjacent to the cytoplasmic surface of the plasma membrane consists of the two tightly packed proteins involucrin and cystatin α . Keratin filaments (tonofilaments) bound by filaggrin are anchored into the cell envelope.

The **epidermal water barrier** thus consists of two structural elements:

- The **cell envelope (CE)** is a 15-nm-thick layer of insoluble proteins deposited on the inner surface of the plasma membrane that contributes to the strong mechanical properties of the barrier. The thickness of the CE increases in epithelia that are subject to considerable mechanical stress (e.g., lip, palm of the hand, sole of the foot). The CE is formed by cross-linking **small proline-rich (SPR) proteins** and larger structural proteins. The structural proteins include **cystatin, desmosomal proteins (desmoplakin), elafin, envoplakin, filaggrin, involucrin**, five different **keratin** chains, and **loricrin**. Loricrin is the major structural protein and accounts for almost 80% of the total CE protein mass. This 26-kDa insoluble protein has the highest glycine content of any known protein in the body.
- The **lipid envelope** is a 5-nm-thick layer of lipids attached to the cell surface by ester bonds. The major lipid components of the lipid envelope are **ceramides**, which belong to the class of sphingolipids, **cholesterol**, and **free fatty acids**. However, the most important component is the monomolecular layer of **acylglucosylceramide**, which provides a “Teflon-like” coating on the cell surface. Ceramides also play an important role in cell signaling and are partially responsible for inducing cell differentiation, triggering

apoptosis, and reducing cell proliferation. As the cells continue to move toward the free surface, the barrier is constantly maintained by keratinocytes entering the process of terminal differentiation. Lamellae may remain as recognizable discs in the intercellular space or may fuse into broad sheets or layers.

Experiments have shown that the epidermis of animals with induced essential fatty acid deficiency (EFAD) is more permeable than normal to water. The membrane-coating granules also have fewer lamellae than normal. Destruction of the epidermal water barrier over large areas, as in severe burns, can lead to life-threatening loss of fluid from the body.

The epidermis is in a state of dynamic equilibrium in which exfoliated keratinized cells are constantly replaced by a steady flow of terminally differentiated cells.

Epidermal cell replacement is maintained by the following processes:

- Division of basal cells in the stratum basale
- Differentiation and programmed cell death as the cells move upward to the stratum corneum
- Cell loss by exfoliation from the skin surface

To maintain this equilibrium, each cell in the epidermis has a predetermined amount of time to perform specific functions. Several scientific experiments and empirical calculations have concluded that the turnover time for the keratinocyte compartment (stratum spinosum and granulosum) is about 31 days, with an additional 14 days for the stratum corneum (average thickness in humans, 16–20 cell layers). Adding 1–2 days for mitotic divisions in the stratum basale, total **epidermal turnover** takes approximately **47 days** (Fig. 15.7). One cell layer in the stratum corneum has been found to produce and exfoliate every 22.4 hours. In hyperproliferative diseases, such as psoriasis, the epidermal turnover time is accelerated and takes approximately 8–10 days. In this disorder, epidermal thickness increases, and the rate of cell death is reduced.

Clinically, psoriasis appears as elevated, reddish patches of itchy skin, often covered by silvery-white scales. Patches vary in size and typically appear on knees, elbows, lower back, and scalp.

FIGURE 15.7. Schematic diagram of epidermal cell differentiation and replacement. Epidermal cell replacement is initiated by the division of stem cells in the stratum basale. Newly formed cells undergo additional divisions in the stratum basale and move upward as they differentiate into keratinized cells, which eventually are lost by exfoliation on the skin surface. To maintain this equilibrium between cell division and cell loss at the skin surface, each cell has a predetermined time to travel through specific compartments of the epidermis and to perform specific functions. Mitotic divisions in the stratum basale take about 1-2 days; after that, it takes an average of 31 days for keratinocytes to move through the stratum spinosum (spinous cells) and differentiate into granular cells in the stratum granulosum. It takes an additional 14 days for the keratinized cell to cross the stratum corneum (assuming an average thickness of 16-20 cells in humans). Therefore, the total epidermal turnover time is approximately 47 days. At each stage of differentiation, cells express different molecular markers (see *yellow*

boxes), which can be useful in identifying specific cells using immunocytochemical methods. *Inset* on the *left* shows full-thickness section of the epidermis from a human fingertip stained with Mallory trichrome. $\times 260$.

Melanocytes

Neural crest-derived melanocytes are scattered among the basal cells of the stratum basale.

During embryonic life, **melanocyte precursor cells** migrate from the neural crest and enter the developing epidermis. A specific functional association is then established—the **epidermal-melanin unit**—in which one melanocyte maintains an association with a given number of keratinocytes. In humans, each epidermal-melanin unit is estimated to contain one melanocyte associated with approximately 36 keratinocytes. The ratio of melanocytes to keratinocytes or their precursors in the stratum basale may vary from 1:4 to 1:40 or even higher, depending on the area of the body. This ratio is constant in all individuals but is influenced by age and environmental factors, such as exposure to sunlight.

In adults, a pool of undifferentiated melanocyte stem cells resides in the area of the hair follicle called the **follicular bulge**. Differentiation of the melanocyte stem cell is regulated by the expression of the **Pax3 gene** that belongs to the paired box (PAX) family of transcription factors. Pax3 activates the expression of the **microphthalmia-associated transcription factor (MITF)**, which is critical for the development and differentiation of melanocytes (melanogenesis). Melanocytes maintain the capacity to replicate throughout their life, although at a much slower rate than keratinocytes, thus maintaining cell ratio in the epidermal-melanin unit.

The epidermal **melanocyte** is a dendritic cell scattered among the basal cells of the stratum basale (Fig. 15.8). They are called dendritic cells because the rounded cell body resides in the basal layer and extends long processes between the keratinocytes of the stratum spinosum. Neither the processes nor the cell body forms desmosomal attachments with neighboring keratinocytes. However, melanocytes that reside

close to the basal lamina have structures that resemble hemidesmosomes. In routine hematoxylin and eosin (H&E) preparations, melanocytes are seen in the stratum basale with elongated nuclei surrounded by a clear cytoplasm. With the transmission electron microscope (TEM), however, they are readily identified by the presence of developing and mature melanin granules in the cytoplasm (see Fig. 15.8).

FIGURE 15.8. Diagram of the epidermis and electron micrograph of a melanocyte. **a.** This diagram shows a melanocyte interacting with several cells of the stratum basale and the stratum spinosum. The melanocyte has long dendritic processes that contain accumulated melanosomes and extend between the cells of the epidermis, which are also visible on the electron micrograph. The Langerhans cell is a dendritic cell often confused with a melanocyte but is actually part of the mononuclear *phagocyte* system and functions as an antigen-presenting cell of the immune system in the initiation of cutaneous hypersensitivity reactions (contact allergic dermatitis). **b.** The melanocyte reveals several processes extending between neighboring keratinocytes. The *small dark bodies* are melanosomes. $\times 8,500$. (Courtesy of Dr. Bryce L. Munger.)

Melanocytes produce two forms of melanin pigment, a brownish-black eumelanin and a reddish-yellow pheomelanin.

Epidermal melanocytes produce and secrete two forms of melanin pigment, a brownish-black pigment called eumelanin and a reddish-yellow pigment called pheomelanin. The relative amounts of these two pigments are responsible for hair and skin color. The most important function of melanin is to protect the organism against the damaging effects of nonionizing UV irradiation. Individuals who produce more eumelanin than pheomelanin have brown or black hair and darker skin that is protected from damage caused by UV radiation in sunlight. In contrast, individuals who produce more pheomelanin than eumelanin have red or blond hair and lighter skin that is poorly protected from UV radiation. These individuals are at increased risk of skin damage caused by UV radiation.

Melanocytes produce melanin in membrane-bounded organelles called melanosomes.

Melanin production occurs in membrane-bounded, lysosome-related organelles called melanosomes, which are derived from the Golgi apparatus (Fig. 15.9). Melanin is produced by hydroxylation of the amino acid L-tyrosine to L-3,4-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosinase. The subsequent oxidation of L-DOPA produces the melanin precursor known as L-DOPAquinone. This compound undergoes further modification via two different pathways depending on the availability of the amino acid cysteine. With cysteine present in sufficient amounts, the L-DOPAquinone is gradually transformed into pheomelanin pigment. When cysteine is insufficient, L-DOPAquinone is spontaneously converted to eumelanin pigment. This conversion pathway requires the presence of tyrosinase-related protein 1 (TRP1) and tyrosinase-related protein 2 (TRP2), which are enzyme regulators in this process.

FIGURE 15.9. Formation of melanin and mechanism of pigment donation. Melanocytes produce lysosome-related membrane-bound structures that originate from the Golgi apparatus as premelanosomes (1) that are involved in melanin synthesis. Melanin is produced from tyrosine by a series of enzymatic reactions and its accumulation is visible in the melanosomes (2). As maturation progresses, melanosomes travel toward the ends of the melanocyte processes. Mature melanosomes (3) have a high concentration of melanin and accumulate at the ends of melanocyte processes that invaginate into the keratinocyte's cell membrane (4). Keratinocytes phagocytose the tips of the melanocyte processes containing the melanosomes (5). In the process described as pigment donation, melanin is transferred to neighboring keratinocytes in vesicles containing melanosomes with a small amount of melanocyte cytoplasm (6). Once inside the keratinocytes, melanosomes are released into the cytoplasm (7). Melanosomes are distributed within the keratinocytes but are most numerous in areas over and around the nuclei, creating "dark umbrellas"—so-called melanosome microparasol (8)—that protect the nuclear DNA from the sun's harmful ultraviolet (UV) radiation.

Melanosomes are formed through a series of well-defined stages.

There are four stages (I – IV) of melanosome development, starting with the premelanosome and ending with the mature melanosome. With each stage, their location within the cell shifts as more melanin accumulates. Premelanosomes (stage I) and early melanosomes (stage II) are concentrated near the Golgi apparatus and interact with the rER, smooth ER (sER), and mitochondria. Nearly mature melanosomes (stage III) are relocated using microtubule-dependent transport to the bases of the melanocyte processes. Mature melanosomes (stage IV) travel further toward the ends of the melanocyte processes (see Fig. 15.9).

- In eumelanin-producing melanocytes, the lumen of premelanosomes (stage I) lacks pigment. With the TEM, premelanosomes exhibit a finely ordered internal structure composed of proteinaceous fibrils. These fibrils are composed primarily of premelanosome protein (PMEL17) and become the core for melanin deposition within the melanosome. The assembly of this internal structure is usually completed in the early melanosome (stage II), which confers an ellipsoid shape to the premelanosomes.
- In pheomelanin-producing melanocytes, PMEL17 expression is downregulated, which might explain why melanosomes in these cells lack internal fibrils and have spherical-shaped nucleosomes.

Production of the electron-opaque melanin granules begins when they acquire an elliptical shape at the end of stage II, and the process continues throughout stages III and IV. During the last two stages, the internal structure of melanosomes becomes obscured. The mature organelles (stage IV) filled with melanin granules are transported to the tips of the melanocyte processes for transfer into keratinocytes.

During development, melanosomes share several features with lysosomes, such as a lower pH necessary for melanin synthesis and the presence of lysosomal membrane proteins and lysosomal

hydrolases. Melanosomal pH is an important factor in the regulation of skin pigmentation. Melanosomes derived from melanocytes in light skin are more acidic and have lower tyrosinase activity than melanosomes in dark skin, which have a more neutral pH and higher tyrosinase activity. Therefore, tyrosinase activity is increased in dark skin without upregulation of tyrosinase gene expression.

Melanocytes distribute melanin to keratinocytes in the process of pigment donation.

The melanin transfer mechanism called pigment donation between pigment-producing melanocytes and pigment-recipient keratinocytes is critical in determining skin color. Its molecular mechanism remains unclear; however, the classical description of pigment donation based on phagocytosis of the tips of the melanocyte processes by keratinocytes is the most accepted. This model has been confirmed by TEM observation of cells cultured in vitro. In this model, a keratinocyte engulfs the tip of a melanocyte process, pinching it off to form a melanosome-filled cytoplasmic vesicle. A small amount of cytoplasm surrounding the melanosome is also phagocytosed, which characterizes this process as a type of cytotrine secretion. Other recent models of pigment donation include: direct membrane fusion between melanocytes and keratinocytes with melanosome transfer; phagocytosis of membrane-bound vesicles by keratinocytes containing melanosomes originating from the melanocyte cytoplasmic blebs; and exocytosis of melanin pigment by melanocytes and subsequent endocytosis by keratinocytes.

After pigment transfer, most melanosomes in light skin reside in keratinocytes near the basal layer of the epidermis (60% - 80% of total melanosomes); however, in dark skin, distribution of melanosomes is equal throughout all layers of the epidermis. Melanosomes in keratinocytes are generally positioned around and above the nucleus, forming an umbrella-like structure called the “dark umbrella” or melanosome microparasol, which protects nuclear DNA against harmful UV radiation (Fig. 15.10).

FIGURE 15.10. Electron micrograph of a keratinocyte. This high-magnification electron micrograph shows the nucleus of the keratinocyte surrounded by melanosomes containing melanin pigment. This arrangement is often described as the “dark umbrella,” or melanosome microparasol, which protects nuclear DNA against harmful sun ultraviolet radiation. During pigment donation, the tips of the melanocyte process containing melanosomes are pinched off by a keratinocyte, and the resulting cytoplasmic vesicle fuses with a lysosome to produce phagolysosome. Note that a few melanin pigments are not surrounded by the cytoplasmic membrane, which was most likely dissolved in the phagolysosomes of the keratinocyte. $\times 19,200$. (Reprinted with permission from Kanik A. Skin. In: Mills SM, ed. *Histology for Pathologists*. Wolters Kluwer; 2020:3–30.)

Melanin production is genetically determined and highly regulated by many factors.

More than 125 genes regulate melanocyte differentiation, survival, synthesis, and function. In humans, approximately 15 genes have been associated with variations in skin

pigmentation. Variations in the **melanocortin 1 receptor (MC1R) gene**, the key gene in human pigmentation, appear to be associated with normal differences in skin and hair color.

The critical enzymes in melanin synthesis are **tyrosinase**, **TRP1**, and **TRP2**, which dramatically affect the quality and quantity of melanin produced. Melanin synthesis is also regulated by **melanocyte-stimulating hormone (MSH)** produced by the anterior lobe of the pituitary gland. MSH binds to the **melanocortin 1 receptor (MC1R)** on melanocytes and affects tyrosinase activity through the G-protein signaling cascade. Stimulation of MC1R receptors by MSH and **adrenocorticotrophic hormone (ACTH)** leads to increased tyrosinase activity, resulting in eumelanin synthesis. The opposite effect is achieved by the **Agouti signaling protein (ASIP)**, which decreases tyrosinase activity and results in pheomelanin production. In this way, the MC1R signaling regulates the balance between eumelanin and pheomelanin synthesis within melanocytes, leading to diversity in skin pigmentation.

Steroid hormones do not act on MC1R receptors. However, recent studies show that sex steroids such as **estrogen (17 β -estradiol)** and **progesterone** may indirectly regulate melanin synthesis. This finding may explain **pregnancy-associated hyperpigmentation** of specific areas of the skin (i.e., face, external genitalia, linea alba of the abdomen, and areolae surrounding the nipples). Researchers suggest that the newly discovered, nonclassical membrane-bound G-protein-coupled sex hormone receptors **GPER** and **PAQR7** are involved in melanocyte signaling (see pages 817–818 for membrane-initiated steroid signaling). Activation of these receptors is sufficient to change skin pigmentation. Estrogen increases melanin synthesis, whereas progesterone counterbalances the effect of estrogen by decreasing melanin production. **Some individuals who use hormonal contraceptives containing estrogen and progesterone might develop darkening or discoloration of the skin called melasma.** Therapeutic use of inhibitors or stimulators of GPER or PAQR7 receptors could potentially modulate melanin pigment production and alter skin color.

In addition to regulating melanin synthesis in melanocytes, recent research shows that **paracrine regulators** of melanocyte microenvironment (i.e., growth factors and cytokines) can result in skin pigmentation changes. Skin also responds to sun exposure (see Folder 15.3, page 580). Epidermal keratinocytes have been shown to release exosomes that may also be responsible for stimulation of pigmentation after UV exposure.

The number of melanocytes in normal skin is constant in all individuals.

Despite variations in skin color among different individuals, the number of melanocytes remains constant, with a similar ratio of melanocytes to keratinocytes. This ratio oscillates in the range of one melanocyte for every 4–40 basal keratinocytes. **Changes in the melanocyte-to-keratinocyte ratio are diagnostically useful in identifying certain pigmented skin lesions. For instance, vitiligo (acquired loss of skin pigmentation) is characterized by selective loss of melanocytes. In contrast, skin from individuals with albinism (a disorder resulting in the partial or complete absence of skin color) has a normal melanocyte-to-keratinocyte ratio; however, the melanin synthesis pathway is defective (see page 547). The number of melanocytes also decreases with age, diminishing the number of melanosomes in keratinocytes. The skin becomes lighter in color, and the incidence of skin cancer increases. The increased number of melanocytes is observed in lentigo (pigmented skin lesions) and melanocytic neoplasms.**

Skin color is mainly determined by the number and size of melanosomes, not by the number of melanocytes.

Dark skin has the largest number of more prominent melanosomes with larger pigment cores, and these melanosomes are distributed throughout the cytoplasm of keratinocytes. **Light skin** has fewer, less prominent melanosomes with smaller pigment cores; these melanosomes are aggregated in clusters. In addition, in light skin, keratinocytes do not have detectable melanin content in the upper layers of the epidermis; in contrast, in dark skin, keratinocytes maintain the melanin

pigment throughout the entire thickness of the epidermis (Fig. 15.11).

FIGURE 15.11. Melanosome number and size differences in light and dark skin. The first column shows photographs of the dorsum of the hand from a dark- and light-skinned individual. These correspond to the diagrams in the middle column showing the distribution of melanosomes in dark and light skin. Note that the melanosomes and melanin pigments accumulate around and above the nuclei, forming the melanosome micoparasol that protects nuclear DNA against harmful sun ultraviolet radiation. Dark skin has numerous prominent melanosomes with larger pigment cores that are equally distributed throughout the keratinocyte cytoplasm. Keratinocytes in dark skin maintain melanin pigment throughout the entire thickness of the epidermis. In contrast, light skin has fewer, less prominent melanosomes with smaller pigment cores aggregated in clusters in the keratinocyte cytoplasm. In addition, most of the melanosomes reside in keratinocytes near the basal layer of the epidermis. The corresponding photomicrograph in the last column shows that the number of melanocytes (*arrowheads*) is similar. Note the differences in the distribution of melanosomes. Note also that the keratinocytes in light skin do not have detectable melanin content in the upper layers of the epidermis.

Melanosomes and their contents are degraded in the process of **macroautophagy** at various rates in different individuals. In individuals with dark skin, melanin is degraded slowly, and melanosomes remain discrete; in those with light skin, melanin is degraded more rapidly (see Fig. 15.11). Degradation efficacy is attributed to the higher expression of hydrolytic enzymes, particularly **cathepsin L2** in light skin, and the higher autophagic activity of keratinocytes in light skin compared with dark skin.

Because of the complexity of melanin biogenesis, protein trafficking, organelle movement, and cell-to-cell interactions within the epidermal-melanin unit, even minor changes in the cellular environment can affect melanosome structure and the pigment donation process. Numerous intrinsic and extrinsic factors are also responsible for **skin pigmentation**, including age, ethnicity, and sex differences; variable hormone levels and affinities of their receptors; genetic defects; UV radiation; climate and season changes; and chemical exposure to toxins and pollutants.

Langerhans Cells

Langerhans cells represent the population of antigen-presenting resident macrophages in the epidermis.

Langerhans cells are dendritic-appearing, antigen-presenting resident macrophages in the epidermis. They are derived from **erythro-myeloid progenitor cells** originating from the **yolk sac**. Yolk sac-derived resident macrophages (i.e., Langerhans cells in the epidermis and dermal macrophages in the dermis) are self-sustaining and represent a resident self-renewing phagocyte population in the tissues (see page 203). Langerhans cells in the epidermis are long-lived and cannot be replenished by bone marrow-derived monocytes. In early development, their precursors migrate through the bloodstream and ultimately enter the epidermis, where they differentiate into immunocompetent cells. Langerhans cells provide immunosurveillance of the epidermis by processing antigens on the skin.

Langerhans cells are specialized at “sensing” the microenvironment of the epidermis by extending their processes through intercellular tight junctions to sample the outermost layers of the skin (stratum corneum). Once the antigen is phagocytized, processed, and displayed on the surface of the Langerhans cell, the cell presents antigen to T cells within the epidermis to initiate a local immune response. They also can migrate from the epidermis to a regional lymph node. Within the lymph node, the interaction of Langerhans cells with T lymphocytes initiates instruction of the adaptive immune system toward either immune tolerance or immune activation and response to the antigen. Exposure to UV radiation depletes Langerhans cells and decreases their ability to present antigen to T cells. Several experimental studies have determined that the ratio of Langerhans cells to other cells in the epidermis of normal human skin is constant at 1:53.

Langerhans cells cannot be distinguished with certainty in routine H&E-stained paraffin sections. Like melanocytes, Langerhans cells do not form desmosomes with neighboring keratinocytes. The nucleus stains heavily with hematoxylin, and the cytoplasm is clear. With special techniques, such as gold chloride impregnation or immunostaining with antibody against **CD1a molecules**, Langerhans cells can be readily seen in the stratum spinosum (Fig. 15.12). CD1a is a clinically useful marker expressed on the human Langerhans cell (see later) and is structurally related to the MHC I molecule. Langerhans cells possess dendritic processes resembling those of melanocytes. However, the TEM reveals several distinctive features of the Langerhans cell (see Fig. 15.12). Its nucleus is characteristically indented in many places, so the nuclear profile is uneven. Also, it possesses characteristic tennis racket-shaped **Birbeck granules**. These small vesicles appear as rods with a bulbous expansion at their end. For many years, Birbeck granules remained enigmatic until the **langerin (CD207) molecule**, a C-type lectin receptor, was finally identified as the main molecular component of these granules.

FIGURE 15.12. Electron micrograph of a Langerhans cell. The nucleus (N) of a Langerhans cell is characteristically indented in many places, and the cytoplasm contains distinctive rod-shaped bodies (arrows). Note the presence of tonofilaments (T) in adjacent keratinocytes (K) but the absence of these filaments in the Langerhans cell. $\times 19,000$. Inset. Photomicrograph of the epidermis shows the distribution and dendritic nature of the Langerhans cells that were stained via immunostaining techniques with antibodies against CD1a surface antigen. $\times 300$. (Reprinted with permission from Urmacher CD. Normal skin. In: Sternberg SS, ed. *Histology for Pathologists*. Lippincott-Raven; 1997:25 - 45.)

Birbeck granules play a role in the immune response against certain pathogens, including *Human immunodeficiency virus (HIV-1)*, *Mycobacterium leprae*, and *Candida albicans*. These pathogens express carbohydrates in the form of complex N-glycan residues that protect them from antibodies. Langerin expressed on the surface of Langerhans cells recognizes and binds to N-glycan residues. After the pathogen binds to langerin, the entire

complex is internalized and degraded in the Birbeck granule. Skin biopsy specimens from individuals with **acquired immunodeficiency syndrome (AIDS)** or AIDS-related diseases reveal that Langerhans cells contain *HIV* in their cytoplasm. Langerhans cells appear to be more resistant than T cells to the deadly effects of *HIVs* and may thus serve as a reservoir for the virus while waiting for degradation.

Like macrophages, Langerhans cells express both **MHC I** and **MHC II** molecules, which are essential for presenting antigen to cytotoxic CD8⁺ and helper CD4⁺ lymphocytes, respectively. They also express **F_c receptors (Fc γ Rs)** for immunoglobulin G (IgG), **complement C3b receptors**, and fluctuating quantities of **CD1a** molecules, which are used as a specific clinical marker for Langerhans cells. As an antigen-presenting cell, the Langerhans cell is involved in **delayed-type hypersensitivity reactions** (e.g., contact allergic dermatitis and other cell-mediated immune responses in the skin) through their recognition of antigens in the skin and their transport to the lymph nodes.

In addition, a malignant transformation of Langerhans cells is responsible for **histiocytosis X** (Langerhans cell histiocytosis), a group of immune diseases that are characterized by an abnormal increase and accumulation of Langerhans cells, which may form tumors affecting various parts of the body, including the bones, lungs, skull, and other areas and organs.

Merkel Cells

Merkel cells are epidermal cells that function in cutaneous sensation.

Merkel cells are dendritic cells located in the stratum basale. The origin of Merkel cells is unknown; they possess antigenic markers of both epidermal and neural types. They are most abundant in skin where sensory perception is acute, such as the fingertips and lips. Merkel cells are bound to adjoining keratinocytes by desmosomes and contain intermediate (keratin) filaments in their cytoplasm. The nucleus is lobed, and the

cytoplasm is somewhat denser than that of melanocytes and Langerhans cells. They may contain some melanosomes in their cytoplasm, but they are best characterized by the presence of **80-nm dense-core neurosecretory granules** that resemble those found in the adrenal medulla and carotid body (Fig. 15.13). Merkel cells are closely associated with the expanded terminal bulb of afferent myelinated nerve fibers. The neuron terminal loses its Schwann cell covering and immediately penetrates the basal lamina, where it expands into a plate-like ending called a *disc receptor* that lies in close apposition to the base of the Merkel cell. The combination of the neuron and epidermal cell, called a **Merkel corpuscle**, is a sensitive **mechanoreceptor**.

FIGURE 15.13. Electron micrograph of a Merkel cell. The cell has small neurosecretory granules in the cytoplasm and makes contact with a peripheral nerve terminal (*NT*) of a sensory neuron. The dermis (*D*) is in the *lower part* of the micrograph. $\times 14,450$. (Courtesy of Dr. Bryce L. Munger.)

Merkel cell carcinoma (MCC) is a rare but highly aggressive type of skin cancer that develops when Merkel cells undergo uncontrolled proliferation. It most often starts in areas of skin exposed to the sun, such as the head, neck, and upper and lower limbs. MCC tends to grow quickly and metastasizes via lymph vessels at an early stage.

■ DERMIS

The attachment of the epidermis to the dermis is enhanced by an increased interface between the two tissues.

The junction between the epidermis and dermis (**epidermal - dermal junction**) is seen in the light microscope as an uneven boundary except in the thinnest skin. Sections of skin cut perpendicular to the surface reveal numerous finger-like connective tissue protrusions, **dermal papillae**, that project into the undersurface of the epidermis (see Fig. 15.2). The papillae are complemented by what appear to be similar epidermal protrusions, called **epidermal ridges** or **rete ridges**, that project into the dermis. If the plane of section is parallel to the surface of the epidermis and passes at a level that includes the dermal papillae, however, the epidermal tissue appears as a continuous sheet of epithelium, containing circular islands of connective tissue within it. The islands are cross sections of true finger-like dermal papillae that project into the epidermis. At sites where increased mechanical stress is placed on the skin, the epidermal ridges are much deeper (the epithelium is thicker), and the dermal papillae are much longer and more closely spaced, creating a more extensive interface between the dermis and epidermis. This phenomenon is particularly well demonstrated in histologic

sections that show both palmar and dorsal surfaces of the hand, as in a section of a finger.

Friction ridge skin contains a genetically unique pattern of dermal ridges located on the palmar surface of the hand and plantar surface of the foot.

The thick skin on the palmar surface of the hands and the plantar surface of the feet is specialized. It is called **friction ridge skin** because it has a corrugated surface with elevated **dermal ridges** broken up by lower **furrows (grooves)** (Fig. 15.14). Friction ridge skin assists in gripping objects and surfaces. Eccrine sweat gland openings occur at regular intervals along the tops of the dermal ridges. The furrows are involved in a moisture-regulating mechanism (i.e., channel excess fluid), which provides optimal hydration to the keratinized cells in the epidermis that maximizes friction and reduces the possibility of slip. With the development of touchscreen devices and artificial hands for robotic and prosthetic applications, there is a renewed interest in the study of the structure and function of friction ridge skin.

FIGURE 15.14. Friction ridge skin in a histologic section, surface photograph, and fingerprint image. a. This low-magnification hematoxylin and eosin (H&E)-stained photomicrograph shows a section of friction ridge skin from the human fingertip. The epidermis is at the top of this image. Note that the upper layer of the epidermis is keratinized, forming dome-shaped surface projections. These represent cross sections through the dermal ridges *separated by the furrows*. The interface between the epidermis and dermis (on the bottom) is well demarcated by the corrugated pattern of epidermal ridges and dermal papillae. The secretory segments of eccrine sweat

glands are deeper in the dermis and are not visible on this image; however, their ducts pierce the epidermis to open at the top of the dermal ridges. Note eccrine sweat ducts (*arrowheads*) traversing through both the dermis and epidermis. The surface features of friction ridge skin produce the characteristic fingerprints of an individual. $\times 45$. b. This enlarged photograph of friction ridge skin from the fingertip shows the unique pattern of dermal ridges and furrows. At this magnification, the openings of the eccrine sweat ducts on the top of the dermal ridges are barely visible. $\times 10$. c. An impression of the unique arrangement of dermal ridges on the friction ridge skin is called a fingerprint. This image was obtained using an inkless fingerprinting technique in which a towelette moistened with a colorless, nontoxic solution is used to wipe the friction ridge skin of the finger, which is then imprinted on chemically treated paper. $\times 10$.

The interface between the epidermis and dermis is also uneven. The pattern of dermal ridges and furrows on the skin surface correlates with a complementary pattern of **epidermal ridges** and **dermal papillae** (see Fig 15.14). The epidermal ridges and dermal papillae are most prominent in the friction ridge skin. Here, the basal surface of the epidermis greatly exceeds its free surface. The germinal layer is thus spread over a large area; assuming a near-constant rate of mitosis in the stratum germinativum, more cells per unit of time enter the stratum corneum in thick skin than in thin skin. These additional cells are thought to account for the greater thickness of the cornified layer in thick skin.

FOLDER 15.1

CLINICAL CORRELATION: CANCERS OF EPIDERMAL ORIGIN

Three major types of **skin cancer** originate from cells in the epidermis. In general, skin cancer is caused by unprotected, long-term exposure to the sun's ultraviolet radiation. The most common type is **basal cell carcinoma**, which microscopically, as its name implies, resembles cells from the stratum basale of the epidermis. Basal cell carcinoma is a slow-growing tumor that usually does not metastasize. Typically, the cancer cells arise from the follicular bulge of the external root sheath of the hair follicle. In almost all cases of basal cell carcinoma, the recommended treatment is Mohs micrographic surgical removal of the tumor. Histologic monitoring of the excised tumor during the surgical procedure for the presence of malignant cells ensures

that margins of excised tissue are cancer free (for details about Mohs micrographic surgery, see Folder 15.2).

The second most common skin cancer is **squamous cell carcinoma**, with more than 200,000 cases each year. Individuals with this form of cancer usually develop a small painless nodule or patch surrounded by an area of inflammation. Squamous cell carcinoma is characterized by highly atypical cells at all levels of the epidermis (carcinoma in situ). Disruption of the basement membrane results in spread (metastasis) of tumor cells to the lymph nodes. Squamous cell carcinoma is known for variable differentiation patterns ranging from polygonal squamous cells arranged in orderly lobules and zones of keratinization to rounded cells with foci of necrosis and occasional single keratinized cells. Treatment for squamous cell carcinoma depends on histologic type, size, and location. It may include surgical excision, curettage and electrodesiccation, cryotherapy (freezing with liquid nitrogen), or chemotherapy or radiotherapy.

Malignant melanoma is the most serious form of skin cancer if not recognized at an early stage and surgically removed. Individual melanoma cells, which originate from melanocytes, contain large nuclei with irregular contours and prominent eosinophilic nucleoli. These cells either aggregate in nests or are scattered through the entire thickness of the epidermis (Fig. F15.1.1). They may reside only in the epidermis (melanoma in situ) or extend into the underlying papillary layer of the dermis. With time, the melanoma undergoes a **radial growth phase**. The melanocytes grow in all directions, upward in the epidermis, downward into the dermis, and peripherally in the epidermis. At this early stage, the melanoma tends not to metastasize. On the skin surface, it presents as an irregularly pigmented multicolor lesion, appearing black with parts brown to light brown, and a mixture of pink to red or shades of blue (Fig. F15.1.2). In time (approximately 1 or 2 years), melanocytes exhibit mitotic activity and form round nodules growing perpendicularly to the surface of the skin. In this **vertical growth phase**, the melanocytes display little or no pigment and usually metastasize into regional lymph nodes.

FIGURE F15.1.1. Photomicrograph of a malignant melanoma lesion early in the radial growth phase. This section of the skin shows a layer of the epidermis containing atypical (hyperplastic) cells loaded with dark brown pigment granules containing melanin. These cells represent atypical melanocytes that normally should reside in the stratum basale of the epidermis. At this stage of disease, these abnormal melanocytes migrate to the upper layers of the epidermis (melanocytic

hyperplasia). There are scattered small nests of atypical cells in the dermis. Note the accumulation of lymphocytes in the superficial dermis. $\times 320$. *Inset* shows an enlarged nest containing melanocytes with clearly visible processes containing melanin granules. $\times 640$.

FIGURE F15.1.2. Photograph of the skin with malignant melanoma during the radial growth phase. In this individual, malignant melanoma is represented by the relatively flat, irregularly pigmented multicolor lesion. The largest nodule appears *ebony black*. It is adjacent to a slightly elevated region that is colored in shades from *dark brown* to *light brown* with two *reddish* smaller nodules. At this early stage, melanocytes grow in all directions, upward in the epidermis, downward into the dermis, and peripherally in the epidermis. (Reproduced from Storm CA, Elder DE. The skin. In: Rubin R, Strayer DS, eds. *Rubin's Pathology: Clinicopathologic Foundations of Medicine*, 5th ed. Lippincott Williams & Wilkins; 2008.)

The **ABCD rule** is helpful for remembering the signs and symptoms of melanoma (see Fig. F15.1.2):

- Asymmetrical shape of skin lesion
- Border of the lesion is irregular.
- Color variations; melanomas usually have multiple colors.
- Diameter of skin lesion; moles greater than 6 mm are more likely to be suspicious.

Surgery is the treatment of choice for localized malignant melanoma of the skin. A multidisciplinary approach is used for advanced malignant melanoma, including surgery combined with chemotherapy or immunotherapy with adjuvant treatment.

Dermal ridges tend to have a parallel arrangement, with the dermal papillae located between them (see Fig. 15.14a). These ridges form a distinctive pattern that is genetically unique to each individual and is reflected in the appearance of furrows (grooves) and dermal ridges on the skin surface. An impression of the friction ridges of all or any part of the finger is called a fingerprint. The patterns of friction ridges are the basis of the science of fingerprint and footprint identification, which is called **dermatoglyphics** or **dactyloscopy**.

Hemidesmosomes strengthen the attachment of the epidermis to the underlying connective tissue.

When studied with the TEM, the basal surface of the basal epidermal cells exhibits a pattern of irregular cytoplasmic protrusions that increase the attachment surface between the epithelial cell and its subjacent basal lamina. A series of **hemidesmosomes** links the intermediate filaments of the cytoskeleton into the basal lamina. In addition, **focal adhesions** that anchor actin filaments into the basal lamina are also present. These specialized anchoring junctions are discussed on pages 145–150.

Layers of the Dermis

The dermis is composed of two layers: the papillary layer and the reticular layer.

Examination of the full thickness of the dermis in the light microscope level reveals two structurally distinct layers:

- The **papillary layer**, the more superficial layer, consists of loose connective tissue immediately beneath the epidermis (Plate 15.2, page 578). The collagen fibers located in this part of the dermis are not as thick as those in the deeper portion. This delicate collagen network contains predominately type I and type III collagen molecules. The number and diameter of collagen fibers decreases with age and the ratio of type III to type I collagen increases. Similarly, the elastic fibers are thread-like and form an irregular network. The papillary layer is relatively thin and includes the substance of the dermal papillae and dermal ridges. It contains blood vessels that serve but do not enter the epidermis. It also contains nerve processes that either terminate in the dermis or penetrate the basal lamina to enter the epithelial compartment. Because the blood vessels and sensory nerve endings are concentrated in this layer, they are particularly apparent in the dermal papillae.
- The **reticular layer** lies deep to the papillary layer. Although its thickness varies in different parts of the body, it is always considerably thicker and less cellular than the papillary layer. It is characterized by thick, irregular bundles of mostly type I collagen and coarser elastic fibers. Collagen fibers provide the skin with tensile strength and tissue integrity, whereas elastic fibers provide elasticity and resiliency. The collagen and elastic fibers are not randomly oriented but form regular lines of tension in the skin called Langer lines, also known as cleavage lines. Skin incisions made parallel to Langer lines heal with the least scarring.

■ CELLS OF THE DERMIS

Dermal fibroblasts and a diverse population of cells belonging to the mononuclear phagocyte system are found in the dermis.

The papillary and reticular layers of the dermis have a typical resident cell population embedded in the extracellular matrix of the dense irregular connective tissue. The dermis is rich in blood vessels, lymphatic vessels, and nerves. The network of lymphatic vessels in the dermis facilitates the migration of dermis-resident immune cells toward the lymph nodes. A few cells, such as **dermal fibroblasts**, deserve a closer look because of their unique function within the skin. Immune cell populations in the dermis are predominantly comprised of **dermal dendritic cells** and **resident dermal macrophages**. These cells belong to the mononuclear phagocyte system (see page 203). In addition, a transient population of other connective tissue cells, including **mast cells** and **several types of lymphocytes**, such as CD4⁺ and CD8⁺ lymphocytes, gamma/delta (γ/δ) T lymphocytes, regulatory CD4⁺ CD25⁺ FOXP3⁺ T lymphocytes, NK cells, and skin resident memory T lymphocytes (T_{rm}), are present in the dermis. Under normal skin conditions, neutrophils are usually absent. However, if the skin is injured or after exposure to sunlight, neutrophils infiltrate the dermis and contribute to the inflammatory reaction (i.e., sunburn).

Dermal Fibroblasts

Dermal fibroblasts are the structural cells of the dermis. Their primary function is to secrete extracellular matrix molecules (i.e., procollagen I, III, V, VII, proteoglycans, glycosaminoglycans, and multiadhesive glycoproteins). They control the self-assembly and arrangement of collagen and elastic fibers in the dermis. In addition to maintaining connective tissue integrity, dermal fibroblasts are involved in immune defense mechanisms. They express a full range of **toll-like receptors (TLRs)** that play an important role in pathogen pattern recognition. When triggered, these receptors lead to the production of inflammatory cytokines that initiate an immune response.

Dermal Dendritic Cells

Like the Langerhans cells in the epidermis, **dermal dendritic cells** also originate from yolk sac-derived erythro-myeloid progenitor cells. They are abundant in the papillary layer of the dermis. Dendritic cells sample the microenvironment and either present antigen to the T cells in the dermis or migrate through the lymphatics to the lymph node to initiate an immune response. They all express MHC II molecules and do not possess markers defining T cells, B cells, or NK cells. There are several subsets of dendritic cells characterized by the expression of different cell markers such as **CD1c**, **CD14**, and **CD141**. Dermal dendritic cells have increased expression of costimulatory receptors and are strong stimulators of T-cell proliferation.

Resident Dermal Macrophages

Resident dermal macrophages also originate from yolk sac-derived erythro-myeloid progenitor cells. They are long-lived, self-renewing cells with a slow turnover. They can be replenished by macrophages derived from circulating monocytes. Resident dermal macrophages are antigen-presenting cells that reside deep in the dermis; they respond to foreign substances (i.e., tattoo ink), tissue damage, and pathogens and initiate an appropriate immune response. Resident dermal macrophages maintain tissue homeostasis through anti-inflammatory mechanisms and contribute to wound healing. **CD163** has been proposed as a specific marker for resident dermal macrophages, as its expression distinguishes them from other monocyte-derived macrophages that migrated more recently into the skin.

Dermal macrophages are responsible for phagocytosis of the ink pigment injected into the skin during the tattoo procedure.

A **tattoo** involves inserting a needle through the epidermis and delivering ink into the underlying dermis (Fig. 15.15). The injection of the ink pigment, an insoluble foreign body resistant to enzymatic degradation, damages the skin and triggers the immune system to respond to the injury. Newly

tattooed skin becomes inflamed and infiltrated by immune cells. Although **resident dermal macrophages** phagocytize the ink, their lysosomal enzymes cannot break it down, and the ink remains in the cytoplasmic vacuoles throughout the life of the macrophage (Fig. 15.16). As a result, most injected ink is trapped in macrophages in the skin region where the ink was originally injected (see Fig. 15.15). Most macrophages loaded with ink stay in the tissue, whereas others migrate to the perivascular spaces (see Fig. 15.16). In addition, small ink particles are removed from the injection site via blood and lymph vessels and could be observed in local lymph nodes.

FIGURE 15.15. Diagram of the role of dermal macrophages in the ink capture-release-recapture cycle in tattooed skin. The tattoo machine operates like a sewing machine, moving a set of needles up and down to deliver ink deep into the dermis. Resident dermal macrophages, which colonized the skin in early development from the erythro-myeloid progenitor cells of the yolk sac, phagocytize the ink, capturing it within cytoplasmic vacuoles throughout the life of the cell. The resident dermal macrophages are long-lived cells; however, these ink-laden cells sometimes die during adult life. The phagocytosed ink particles are then released into the extracellular matrix, where they are once again phagocytized by newly arrived monocyte-derived macrophages. When these macrophages die, the cycle of ink capture-release-recapture continues in the tattooed skin. Note that over time and with multiple cycles, ink is passed from one macrophage to another, and the edges of the tattoo become less sharp and *washed out*.

FIGURE 15.16. Photomicrograph of a biopsy specimen from tattooed skin. **a.** This low-magnification hematoxylin and eosin (H&E)-stained photomicrograph shows skin with injected black ink particles. They are visible below the epidermis (*Epi*) in the reticular layer (*RL*) of the dermis and near the interface with the papillary layer (*PL*). Note the presence of lymphocytes in the papillary layer of the dermis and areas around visible ink particles, representing a chronic immune response with lymphocyte infiltration. These changes are characteristic of an inflammatory reaction as this patient was allergic to the specific tattoo ink. $\times 40$. **b.** This photomicrograph shows an enlargement of the area marked by the *rectangle* in panel **a**. Most of the ink is phagocytosed by dermal macrophages (*M*), which are surrounded by lymphocytes and other immune system cells. Some of the macrophages have visible nuclei. Dermal macrophages are aggregated near the perivascular spaces near a small artery (*A*). The pattern of irregular connective tissue (*CT*) of the dermis is visible. $\times 240$. **c.** This high-magnification photomicrograph shows a nest of ink-laden macrophages in which the ink obscures their nuclei. Note that a few small pigment particles appear to be dispersed between collagen fibers (*CF*). These small particles could be in the process of removal from the tissue by lymphatic vessels or have not been recaptured yet by newly arrived macrophages during the continuous ink “capture-release-recapture” cycle. $\times 480$. (Specimen courtesy of Dr. Kevin Christensen, Winona Health.)

In the past, it was thought that ink responsible for the visible part of the tattoo resides mainly in dermal fibroblasts, perivascular macrophages, and the connective tissue between the collagen fibers (free ink particles). More recent studies have found that resident dermal macrophages are the only cells to take up pigment in the same way they engulf invading pathogens. As discussed earlier, resident dermal macrophages are long-lived cells; however, after a certain

time, these ink-laden dermal macrophages die and the ink particles are released into the extracellular matrix. These particles are once again phagocytized by newly arrived monocyte-derived macrophages (see Fig. 15.15). Therefore, the **cycle of ink capture, ink release, and ink recapture** occurs continuously in tattooed skin. This cycle is the basis of “tattoo aging,” where the tattoo loses its sharpness over time (see Fig. 15.15). The aging process is also aggravated by chronic sun exposure. **The tattoo does not remain histologically inert during one’s lifetime. The ink pigment causes chronic nonspecific macrophage activation and generates mild inflammatory changes. They can be observed in the tissue biopsy as moderate fibrosis of the papillary layer of the dermis, reactive capillary proliferation, and nonspecific lymphocytic infiltration (see Fig. 15.16).**

The ink capture-release-recapture cycle makes **tattoo removal** difficult. Removal can only be successful if the treatment (surgery, laser, dermabrasion) extends to the dermis. Although **laser therapy** breaks down the ink and kills the ink-laden macrophages, new monocyte-derived macrophages are recruited to the damaged tissue and recapture much of the released pigment. Combining laser surgery with the **transient ablation of the macrophages** could improve the procedure. In this combined treatment, the fragmented ink particles released to the dermis after laser treatment are not immediately phagocytized by macrophages, which increases their likelihood of being drained away via the lymphatic vessels.

Dermal T-Resident Memory Cells

Dermal T-resident memory (T_{rm}) cells. These recently discovered cells are **noncirculating memory T cells** present in the skin. Dermal $T_{s_{rm}}$ cells are generated after exposure to antigen and provide memory at the site of initial exposure. They are more potent effector cells compared with other circulating T cells. Dermal T_{rm} cells maintain immune surveillance of the skin and are crucial for initiating rapid, robust immune responses during infection. They lack molecules

enabling them to leave the skin and migrate to lymph nodes. They express specific markers of residency (CD69, CD103, CD49a).

■ HYPODERMIS

Layers of adipose tissue, smooth muscle, and, in some sites, striated muscle may be found just beneath the reticular layer.

Deep to the reticular layer is a layer of adipose tissue, the **panniculus adiposus**, which varies in thickness. This layer serves as a major energy storage site and also provides insulation. It is particularly thick in individuals who live in cold climates. This layer and its associated loose connective tissue constitute the **hypodermis** or **subcutaneous fascia**.

In the skin of the areolae, penis, scrotum, and perineum, **smooth muscle** cells form a loose plexus in the reticular layer. This arrangement accounts for the puckering or wrinkled appearance of the skin at these sites, particularly in the scrotum (see pages 890–893).

Individual smooth muscle cells or small bundles of smooth muscle cells that originate in this layer form the **arrector pili muscles** that connect the deep part of hair follicles to the more superficial dermis. Contraction of these muscles in humans produces the erection of hairs and puckering of skin called “goose flesh.” In other animals, the erection of hairs serves in both thermal regulation and fright reactions.

A thin layer of striated muscle, the **panniculus carnosus**, lies deep to the subcutaneous fascia in many animals. Although largely vestigial in humans, it remains well defined in the skin of the neck, face, and scalp, where it constitutes the **platysma** muscle and the other **muscles of facial expression**.

■ SENSORY NERVE RECEPTORS OF THE SKIN

The skin is endowed with sensory receptors of various types that are peripheral terminals of sensory nerves (Fig. 15.17).

It is also well supplied with motor nerve endings to the blood vessels, arrector pili muscles, and sweat glands.

FIGURE 15.17. Diagram of the sensory receptors in skin. a. Epidermal free endings. b. Merkel corpuscles containing Merkel cells and disc receptors of afferent myelinated nerve fiber. c. Pacinian corpuscle located in the deep layer of deep dermis and hypodermis. d. Krause end bulb serves as cold receptor. e. Meissner corpuscle in dermal papilla. f. Ruffini corpuscle in deep layers of the dermis. Note that sensory nerve fibers in receptors shown in c to f are encapsulated.

Free nerve endings are the most numerous neuronal receptors in the epidermis.

Free nerve endings in the epidermis terminate in the stratum granulosum. The endings are “free” in that they lack a

connective tissue or Schwann cell investment. Such neuronal endings subserve multiple sensory modalities including fine touch, heat, cold, and pain without apparent morphologic distinction. Networks of free dermal endings surround most hair follicles and attach to their external root sheath (Figs. 15.18 and 15.19). In this position, they are particularly sensitive to hair movement and serve as mechanoreceptors. This relationship imparts a sophisticated degree of specialization in the receptors that surround tactile hairs (vibrissae), such as the whiskers of a cat or rodent, in which each vibrissa has a specific representation in the cerebral cortex.

FIGURE 15.18. Pacinian and Meissner corpuscles in hematoxylin and eosin (H&E) preparations. **a.** In this photomicrograph, the concentric cellular lamellae of the Pacinian corpuscle are visible because of flat, fibroblast-like supportive cells. Although not evident within the tissue section, these cells are continuous with the endoneurium of the nerve fiber. The spaces between lamellae contain mostly fluid. The neural portion of the Pacinian corpuscle travels longitudinally through the center of the structure (*arrow*). Several nerves (*N*) are present adjacent to the corpuscle. $\times 85$. **b.** Three Meissner corpuscles (*MC*) are shown residing within the dermal papillae. Note the direct proximity of the corpuscle to the undersurface of the epidermis. $\times 150$. Inset. A higher magnification

of a Meissner corpuscle. The nerve fiber terminates at the superficial pole of the corpuscle. Note that supporting cells are oriented approximately at right angles to the long axis of the corpuscle. $\times 320$.

FIGURE 15.19. Hair follicle and other skin appendages. **a.** Diagram showing a hair follicle. Note the cell layers that form the hair shaft and the surrounding external and internal root sheaths. The sebaceous gland consists of the secretory portion and a short duct that empties into the infundibulum, the upper part of the hair follicle. The arrector pili muscle accompanies the sebaceous gland; contraction of this smooth muscle assists in gland secretion and discharges the sebum into the infundibulum of the hair follicle. Projection of the external root sheath near insertion of the arrector pili muscle forms the follicular bulge that contains epidermal stem cells. Nerve endings (*yellow*) surround the follicular bulge with nearby insertion of arrector pili muscle. The apocrine sweat gland also empties into the infundibulum. Note that eccrine sweat glands are independent structures and are not associated directly with the hair follicle. **b.** Photomicrograph of hematoxylin and eosin (H&E)-stained section of thin skin from human scalp. The growing end of a hair follicle consists of an expanded hair bulb (*HB*) of epithelial cells that is invaginated by a connective tissue dermal papilla. Hair matrix that fills the bulb consists of cells that differentiate into the hair shaft and the internal root sheath of the hair follicle (*HF*). Note that several oblique and longitudinal sections of the hair follicles are embedded in the adipose tissue (*AT*) of the hypodermis. Some of

them reveal a section of the hair. Sebaceous glands (*SG*) are visible in conjunction with the infundibulum of the hair follicle. $\times 60$. *APM*, arrector pili muscle.

Other nerve endings in the skin are enclosed in a connective tissue capsule. **Encapsulated nerve endings** include the following:

- **Pacinian corpuscles** detect pressure changes and vibrations applied on the skin surface.
- **Meissner corpuscles** are responsible for sensitivity to light touch.
- **Ruffini corpuscles** are sensitive to skin stretch and torque.

Pacinian corpuscles are deep pressure receptors for mechanical and vibratory pressure.

Pacinian corpuscles are large ovoid structures found in the deeper dermis and hypodermis (especially in the fingertips), in connective tissue in general, and in association with joints, periosteum, and internal organs. Pacinian corpuscles usually have macroscopic dimensions, measuring more than 1 mm along their long axis. They are composed of a myelinated nerve ending surrounded by a capsule structure (see Figs. 15.17 and 15.18a). The nerve enters the capsule at one pole with its myelin sheath intact. The myelin is retained for one or two nodes and is then lost. The unmyelinated portion of the axon extends toward the opposite pole from which it entered. Its length is covered by a series of tightly packed, flattened Schwann cell lamellae that form the inner core of the corpuscle. The remainder of the capsule, the outer core, is formed by a series of concentric lamellae; each lamella is separated from its neighbor by a narrow space containing lymph-like fluid (Plate 15.5, page 584). The appearance of the concentric lamellae as observed in the light microscope is reminiscent of the cut surface of a hemisected onion. Each lamella is composed of flattened cells that correspond to the cells of the endoneurium outside the capsule. In addition to fluid between the lamellae, collagen fibrils are present, although sparse, as are occasional capillaries.

Mohs micrographic surgery (MMS), also referred to as **Mohs surgery**, is a specialized microscopically guided surgical technique for removing certain types of skin cancers. This technique, developed by Dr. Frederic E. Mohs in the 1930s and refined over the following decades, utilizes uniquely prepared frozen sections of excised skin to guide the surgeon in excision of the entire lesion.

The surgical specimen, usually excised in the shape of a disc, is placed on a glass slide so that the surgical margin is pressed outward and toward the surface of the slide. It is important that the surgical margins be pulled into the same plane as the remainder of the specimen. To achieve this, a shallow, circumferential relaxing incision is made parallel to the resection edge of the skin. Four radial incisions are often necessary to produce a flat surgical margin (Figs. F15.2.1 and F15.2.2a). The edges of the specimen are marked with color ink for orientation. A frozen tissue embedding medium (commonly called optimal cutting temperature [OCT]) is poured on both the specimen and the metal stub. Next, the specimen (still a flattened surgical surface attached to the glass slide) is flipped so that it is attached surgical side up on the metal stub. Liquid nitrogen is applied to the metal stub to snap-freeze the specimen. The glass slide is then removed to expose the OCT-embedded surgical surface, and the frozen specimen is transferred to a cryostat (a microtome placed in a freezer compartment) for sectioning. The sections taken are very thin horizontal (“en face”) slices cut from the bottom-most layers of the resected specimen. These slices are mounted on a glass slide, stained with hematoxylin and eosin (H&E), and examined with a microscope by the surgeon (see Fig. F15.2.1).

FIGURE F15.2.1. Diagram illustrating steps in Mohs micrographic surgery in comparison with conventional surgical slide preparation. Mohs surgical technique allows unique histologic processing of excised tissue that is examined by the surgeon during the tumor removal procedure. In this

preparation, 100% of the continuous peripheral surgical margin is displayed on the same focal plane as the deep margin. Frozen sections are cut horizontally (“en face”) from the bottom-most layers of the resected specimen. If tumor cells are found in the surgical margin during microscopic examination, the surgeon is able to remove additional tissue within the specific area indicated by color ink markings on the slide that correspond to the patient skin incision. In conventional surgical slide preparation, the specimen is cut vertically in a “bread-loafing” fashion, and individual sections show only discontinuous peripheral and deep surgical margins. Cancer cells may be lost with the discarded tissue between sections. Also, it is difficult to orient the location of the tumor to the specific region on the patient’s skin. *OCT*, optimal cutting temperature.

FIGURE F15.2.2. Photomicrograph of a specimen removed from the skin of the upper lip during Mohs micrographic surgery. A small, round (0.5 cm in diameter) specimen from the skin has been excised from the patient diagnosed with basal cell carcinoma

and processed according to the tissue preparation procedure for Mohs frozen sections. a. This image shows the entire specimen with its clearly visible flattened surgical margin surface and underlying hypodermis in one focal plane. Note that 100% of the margin surface is visible. Four radial incisions are visible and stained with four different colors of ink for orientation. At this low magnification, a darker stained nodule indicates the presence of cancer cells in the surgical margin of the incision. $\times 8$. b. This higher magnification image of a flattened surgical margin shows features of the skin containing epidermis, dermis with hair follicles, and sebaceous glands. The structure of the nodule can be clearly visible. It contains well-outlined multiple cords and islands consisting of deeply stained basophilic epithelial cells. This nodular lesion is characteristic of basal cell carcinoma that grows downward into the dermis and has no connection with upper layers of the epidermis. $\times 20$. c. Higher magnification shows an island of cancer cells surrounded by connective tissue (*CT*) of the dermis. The island is composed of organized layers of cells resembling columnar cells of the stratum basale, hence their name basaloid cells (*BC*). In the periphery, basaloid cells are organized into parallel (palisade) arrangement with their long axis being perpendicular to the underlying basement membrane (*BM*). Their elongated nuclei are deeply basophilic and surrounded by a small rim of cytoplasm; occasional mitoses are also visible (*arrowhead*). Cells in the center of the island are spindle-shaped and more irregular. $\times 280$. (Specimen courtesy of Dr. Kevin Christensen, Winona Health.)

Flattening of the specimen as described earlier ensures that 100% of the true surgical margin is visible on the first cryostat cut. Such preparation of excised skin tumors allows for complete examination of the entire peripheral and deep margins of the specimen in one single focal plane (see Fig F15.2.2a). It differs from the conventional vertical (“bread-loafing”) sectioning of the specimen that does not allow the surgeon to see the continuous surgical edge of excised tissue (see Fig. F15.2.1).

Because the edges of the specimen are marked with color ink that is visible under the microscope, the surgeon is able to identify the precise location of any remaining cancer cells. The surgeon is able then to remove the corresponding area on the patient, allowing superior tissue conservation compared with standard blind excision. This makes the technique ideal for removing skin tumors from certain areas of the body including the face, hands, feet, and genitalia.

MMS only works for contiguously growing tumors, as multifocal lesions could potentially appear to have a negative margin. Fortunately, most primary skin cancers, including basal and squamous cell carcinomas, as well as melanomas, grow contiguously and are amenable to this technique. In MMS, the surgeon also acts

as the pathologist, both excising the tissue and progressively examining the processed slides. This allows for direct clinical pathologic correlation and precise mapping of the tumor. Once the tumor is completely removed, reconstruction of the defect can occur in the same day under local anesthesia in the outpatient setting.

Pacinian corpuscles respond to **pressure** and **vibration** by displacing the capsule lamellae. This displacement effectively causes depolarization of the axon.

Meissner corpuscles are localized within dermal papillae and serve as touch receptors.

Meissner corpuscles (see Figs. 15.17 and 15.18b) are touch receptors that are particularly responsive to **low-frequency stimuli** in the papillary layer of hairless skin (e.g., the lips and the palmar and volar surfaces, particularly those of the fingers and toes). Generally, they are tapered cylinders that measure about 150 μm along their long axis and are oriented perpendicular to the skin surface. Meissner corpuscles are present in the dermal papillae just beneath the epidermal basal lamina (Plate 15.5, page 584). Within these receptors, one or two unmyelinated endings of myelinated nerve fibers follow spiral paths in the corpuscle. The cellular component consists of flattened Schwann cells that form several irregular lamellae through which the axons course to the pole of the corpuscle. In H&E-stained slides of sagittal sections, this structure resembles a loose, twisted skein of wool. It is the Schwann cells that give this impression.

Ruffini corpuscles respond to mechanical displacement of adjacent collagen fibers.

Ruffini corpuscles are the simplest encapsulated mechanoreceptors. They have an elongated fusiform shape and measure 1–2 μm in length (see Fig. 15.17f). Structurally, they consist of a thin connective tissue capsule that encloses a fluid-filled space. Collagen fibers from the surrounding connective tissue pass through the capsule. The neural element consists of a single myelinated fiber that enters the capsule,

where it loses its myelin sheath and branches to form a dense arborization of fine axonal endings, each terminating in a small knob-like bulb. The axonal endings are dispersed and intertwined inside the capsule. The axonal endings respond to displacement of the collagen fibers induced by sustained or continuous mechanical stress; thus, they respond to **stretch** and **torque**. Ruffini corpuscles functionally belong to the family of rapidly adapting receptors (phasic receptors) that generate short action potentials at the beginning and end of a stimulus.

■ EPIDERMAL SKIN APPENDAGES

Skin appendages are derived from downgrowths of epidermal epithelium during development. They include the following:

- **Hair follicles** and their product, **hair**
- **Nail beds** and their product **nails**
- **Sebaceous glands** and their product, **sebum**
- **Eccrine sweat glands** and their product, **sweat**
- **Apocrine sweat glands** and their mixed product containing a form of sweat with a high concentration of carbohydrates, lipids, and proteins

Both hairs and sweat glands play specific roles in the regulation of body temperature. Sebaceous glands secrete an oily substance that may have protective functions. Apocrine glands produce a serous secretion containing pheromones that act as a sex attractant in other animals and possibly in humans. The epithelium of the skin appendages (especially hair follicles) can serve as a source of new epithelial stem cells for skin wound repair.

Hair Follicles and Hair

Each hair follicle represents an invagination of the epidermis in which a hair is formed.

Hair follicles and **hairs** are present over almost the entire body; they are absent only from the sides and palmar surfaces of the hands, sides, and plantar surfaces of the feet, the lips, and the region around the urogenital orifices. Hair distribution is influenced to a considerable degree by sex hormones; these include, in the male, the thick, pigmented facial hairs that begin to grow at puberty and the pubic and axillary hair that develops at puberty in both sexes. In the male, the hairline tends to recede with age; in both sexes, the scalp hair thins with age because of reduced secretion of estrogen and estrogen-like hormones.

FOLDER 15.3

FUNCTIONAL CONSIDERATIONS: SKIN COLOR

The **color of an individual's skin** is determined by several factors, including genetic makeup, hormonal and environmental influences, such as exposure to ultraviolet radiation. The most significant are **melanosome number** and **melanin content**.

Although the number of melanocytes is essentially the same in all individuals, the fate of the melanin produced by melanocytes differs. For example, because of the lysosomal activity of keratinocytes, melanin is degraded more rapidly in individuals with light skin than in individuals with dark skin. In the former, melanosomes are concentrated in the keratinocytes nearest the basal layer and are relatively sparse in the midregion of the stratum granulosum. In contrast, dark skin may exhibit melanosomes throughout the epidermis, including the stratum corneum.

In addition, melanin pigment comprises two chemically distinct forms. One form, **eumelanin**, is a brownish-black pigment. The other form, **pheomelanin**, is a reddish-yellow pigment. Each is genetically determined. Coloration is most apparent in hair because of the concentration of melanin pigment granules, but it is also reflected in skin coloration.

Exposure to **ultraviolet radiation**, particularly the sun's rays, is called **sun tanning**. It increases the number of melanocytes and accelerates the rate of melanin production, thus protecting against further radiation effects. Response to ultraviolet radiation is genetically determined, and the skin is more protected in individuals with dark skin color.

On the molecular level, exposure to UV radiation causes keratinocytes in the upper layers of the epidermis to activate the **p53 signaling cascade**, leading to the secretion of a variety of growth factors such as fibroblast growth factor 2 (FGF2),

epithelial growth factor kit ligand (KITL), endothelin 1 (EDN1), and α -melanocyte-stimulating hormone (α -MSH). These signaling molecules bind to their respective melanocyte receptors to activate their growth and differentiation by increasing the synthesis of the **paired box 3 (PAX3) protein** and **microphthalmia-associated transcription factor (MITF)**.

MITF is a main transcriptional activator of genes involved in pigment synthesis and melanosome formation and trafficking. Under MITF expression, melanocytes increase melanosome production, develop a more robust dendritic structure, and increase the rate of pigment donation to keratinocytes, which causes the skin to darken. In the absence of sunlight and UV exposure, keratinocytes secrete transforming growth factor β (TGF- β) to keep the melanocytes in a quiescent state. Recently, keratinocytes have been shown to release **exosomes** that may also be responsible for stimulation of melanin synthesis after UV exposure.

Increased pigmentation of the skin may also result from hormonal factors, for example, in Addison disease. Lack of pigmentation occurs in a condition known as **albinism**. In this hereditary condition, premelanosomes are produced by melanocytes, but because of the absence of tyrosinase, the transformation of L-tyrosine to L-3,4-dihydroxyphenylalanine (L-DOPA) and the subsequent transformation of L-DOPA into melanin fail to occur. Thus, there is no pigmentation in the skin or hair of these individuals.

Two genes encoding **Bcl2 apoptosis regulator** and **microphthalmia-associated transcription factor (MITF)** appear to be responsible for the **process of graying**. The expression of Bcl2 in melanocyte stem cells is essential to maintaining their population within the niche of the follicular bulge. **Deficiency in Bcl2 expression** causes apoptosis of melanocyte stem cells and a consequent decrease in the number of melanocytes. Melanocyte depletion occurs with age, resulting in a decreased rate of pigment donation to keratinocytes. Therefore, the skin becomes lighter with increased age, and the incidence of skin cancer also increases. Melanocyte depletion caused by defective self-maintenance of melanocyte stem cells is also linked to hair graying, the most obvious sign of aging in humans. Individuals with a mutation in the **Bcl2 gene** may become prematurely gray.

Other normal factors that affect skin coloration include the presence of **oxyhemoglobin** in the dermal vascular bed, which imparts a red hue; the presence of carotenes, an exogenous orange pigment taken up from foods and concentrated in tissues containing fat; and the presence of certain endogenous pigments. The latter include degradation products of hemoglobin, iron-containing

hemosiderin, and iron-free bilirubin, all of which impart color to the skin. Hemosiderin is a golden-brown pigment, whereas bilirubin is a yellowish-brown pigment. **Bilirubin** is normally removed from the bloodstream by the liver and eliminated via the bile. A yellowish skin color as a result of abnormal accumulation of bilirubin reflects liver dysfunction and is evidenced as **jaundice**.

The **hair follicle** is responsible for the production and growth of a hair. Coloration of the hair is attributable to the content and type of melanin that the hair contains. The follicle's histologic appearance varies depending on whether it is in a growing or resting phase. The growing follicle shows the most elaborate structure; thus, it is described here.

The hair follicle is divided into four regions:

- The **infundibulum** extends from the surface opening of the follicle to the level of the opening of its sebaceous gland. The infundibulum is a part of the **pilosebaceous canal**, which is used to discharge the oily substance **sebum**.
- The **isthmus** extends from the infundibulum to the level of insertion of the arrector pili muscle.
- The **follicular bulge** protrudes from the hair follicle near the insertion of the arrector pili muscle and contains **epidermal stem (ES) cells** (Fig. 15.19).
- The **inferior segment** in the growing follicle (see Fig. 15.19) is of nearly uniform diameter except at its base, where it expands to form the **bulb**. The base of the bulb is invaginated by a tuft of vascularized loose connective tissue called, not surprisingly, a **dermal papilla** (Plate 15.6, page 586).

Other cells forming the bulb, including those surrounding the connective tissue dermal papilla, are collectively referred to as the **hair matrix**, which consists simply of **matrix cells**. Matrix cells immediately adjacent to the dermal papilla represent the population of rapidly dividing and differentiating cells that migrated from the follicular bulge containing ES cells (Fig. 15.20). Division and proliferation of

these cells account for the growth of the hair. Scattered melanocytes are also present in this germinative layer. They contribute melanosomes to the developing hair cells in a manner analogous to that in the stratum basale of the epidermis. The dividing matrix cells differentiate into the keratin-producing cells of the hair and the internal root sheath.

FIGURE 15.20. Hair follicle and pathways of epidermal stem cell migration. This diagram shows the location and migration pathways of epidermal stem cells that reside in the follicular bulge. Under normal conditions, epidermal stem cells migrate upward to the sebaceous gland and downward to reach the hair matrix in the bulb of the follicle

(*black arrows*). Hair matrix is formed by differentiating cells that migrate along the external root sheath from the follicular bulge. As the differentiation progresses, cells leave the matrix; they form cell layers that differentiate into the hair shaft containing (1) medulla, (2) hair cortex, and (3) hair cuticle, and the internal root sheath containing (4) internal root sheath cuticle, (5) Huxley layer, and (6) Henle layer. During injury of the epidermis, the epidermal stem cells migrate from the follicular bulge toward the skin surface (*red arrow*) and participate in the initial resurfacing of damaged epidermis.

FOLDER 15.4

CLINICAL CORRELATION: CLINICAL SIGNIFICANCE OF SKIN COLOR VARIATION

Skin color and skin type are important concepts in dermatology and oncology. **Skin color** can affect the appearance of malignant and nonmalignant lesions, which may lead to missed or incorrect diagnoses. **Skin type**—how the skin reacts to various insults and events—can be useful in both the diagnosis and management of skin conditions. Clinicians and researchers recognize two types of skin color: **constitutive skin color**, which refers to the genetically determined distribution of melanin in the epidermis, and **facultative skin color**, which refers to the increases in melanin content that occur as a result of environmental factors, such as ultraviolet (UV) radiation exposure or hormonal influences.

Skin Classification Systems

There have been many attempts to classify skin color. In older systems, such as the **Classifications of Human Varieties** created by Swedish physician and taxonomist Carl Linnaeus in 1758, skin color, other physical characteristics, and geographic location were used to categorize people into four different races. It is now recognized that racial classifications based on skin color and other physical features are subjective and arbitrary and that race is a social rather than a biologic construct. In current medical practice, race is no longer used as a demographic variable similar to socioeconomic status or educational level.

Another classification system was created in the late 18th century by Austrian physician and anthropologist Felix von Luschan. The **von Luschan Chromatic Scale** classified human skin colors into 36 tones using glass tiles of varying colors. The obvious limitation of this chromatic scale is that it could not be

Classification systems based only on the subjective assessment of skin color and appearance were eventually replaced by systems that classify how the skin responds to UV radiation (called phototypic systems), esthetic procedures, and the effects of aging. The most widely accepted phototyping classification in clinical practice is the **Fitzpatrick Phototyping Scale**, developed by Harvard dermatologist Thomas B. Fitzpatrick in 1975. The Fitzpatrick phototypes, graded from I to VI, are based on the self-reported tendency to sunburn or tan as a result of sun exposure. Individuals are asked to answer questions about hair color, eye color, freckling, and their skin's reaction to sunlight exposure without sunblock after 1 day of sun exposure (Table F15.4.1). The Fitzpatrick phototypes are shown in Table F15.4.2.

TABLE F15.4.1

Question	Score					Score/ Question
	0	1	2	3	4	
What is the natural color of your hair (before aging)?	Sandy red	Blonde	Chestnut or dark blonde	Dark brown	Black	
What is the color of your eyes?	Light blue, gray, or green	Blue, gray, or green	Dark blue, green, or light brown (hazel)	Dark brown	Brownish-black	
What is the color of your sun unexposed skin areas?	Pink or reddish	Very pale	Pale with beige tint	Light brown	Dark brown	
Do you have freckles on unexposed areas?	Many	Several	Few	Incidental	None	
What happens to your skin if you stay in the sun for an extended period of time without sunblock?	Severe burns, painful, redness, blistering, followed by peeling	Moderate burns, blistering, followed by peeling	Burns sometimes followed by peeling	Rarely burns	No burns, never had a problem	
How well do you turn brown after sun exposure?	Hardly or not at all	Light color tan	Reasonable tan	Tan very easily	Turn dark very quickly	
Do you turn brown within a day of sun exposure?	Never	Seldom	Sometimes	Often	Always	
Is your face sensitive to the sun?	Very sensitive	Sensitive	Normal	Resistant	Very resistant, never had a problem	
When did you last expose your skin to the sun or artificial sun treatments (tanning beds)?	>3 months	In the last 2–3 months	In the last 1–2 months	<1 month	<2 weeks	
How often do you tan?	Never	Hardly ever	Sometimes	Often	Always	
Skin type (total score)						
Questionnaire score: Skin type I = 0–7 points; Skin type II = 8–16 points; Skin type III = 17–25 points; Skin type VI = 25–30 points; Skin type V and VI = 30–40 points						

TABLE F15.4.2 Fitzpatrick Skin Type Classification

Typical features						
	Type I	Type II	Type III	Type IV	Type V	Type VI
Skin color	Light, pale white	White, fair	Darker white	Light brown	Brown	Dark brown to black
Eye color	Blue/green/gray	Blue	Brown	Dark brown	Black	Black
Hair color	Blond	Blond/red hair	Light brown	Medium brown	Dark brown	Black
Tanning ability	Always burns, never tans, sensitive to ultraviolet (UV) exposure	Burns easily, tans poorly	Tans gradually to light brown after initial burn	Burns minimally, tans easily to moderately brown	Rarely burns, tans darkly easily	Never burns, always tans darkly, least sensitive to UV exposure

In recent years, the validity of the Fitzpatrick scale has been questioned because of its reliance on self-report and its use of skin color changes as a basis for the skin's reactivity to the sun. Darker skin may also be sensitive to the sun but may not visibly "burn" in response to sun exposure. Although the epidermis of a darker-skinned person contains a greater amount of melanin than that of a lighter-skinned person, melanin is not the only factor contributing to photoprotection. Research shows that additional mechanisms involving antioxidants, DNA repair, and cellular survival pathways also play important roles and are not determined by melanin content. Nevertheless, the Fitzpatrick scale remains the gold standard for skin classification systems.

Skin Color and Diagnosis of Skin Cancer

Clinicians and researchers in dermatology and oncology now acknowledge that the appearance of skin cancer can differ significantly according to skin color. Skin cancer can occur in people of any skin color, although the risk of skin cancer is decreased in those with darker skin. When skin cancer does occur in a person with darker skin, it tends to be diagnosed at a later stage, which correlates with a worse prognosis. Efforts are currently directed at educating everyone, regardless of skin color, about the risks of skin cancer and the need for photoprotection. In addition, medical educational materials, such as textbooks and websites, currently strive to include photos showing skin cancer and other dermatologic conditions in individuals with different skin colors.

The **internal root sheath** is a multilayered cellular covering that surrounds the deep part of the hair (Fig. 15.21). The internal root sheath has three layers:

FIGURE 15.21. Photomicrograph showing a transverse section of hair follicles from the skin of the scalp. This hematoxylin and eosin (H&E)-stained specimen shows several cross-sectional profiles of hair follicles (*HF*) randomly distributed throughout the section. Some of the follicles are missing a hair shaft in the center that was lost during slide preparation. The sebaceous glands (*SG*) are visible in close association with hair follicles. Arrector pili muscles (*APM*) encircled by the *dashed line* comprise smooth muscle fibers accompanying the sebaceous gland; they attach to the hair follicle near the follicular bulge (*FB*). During contraction, they assist in gland secretion and discharge the sebum into the infundibulum of the hair follicles. Nerves (*N*) are frequently found near arrector pili muscles. Projection of the external root sheath near the insertion of the arrector pili muscle forms the follicular bulge (*FB*) visible in this cross section in two follicles. The hair follicle, hair shaft, arrector pili muscle, and sebaceous gland form the pilosebaceous unit. They are separated by dense irregular connective tissue (*CT*) and adipocytes containing blood vessels (*BV*). The secretory components and ducts of the eccrine sweat glands are found between groups of pilosebaceous units. $\times 120$. *Inset* shows the hair follicle included in

the *dashed rectangle* at higher magnification. The cross section of the hair follicle is at the level of the follicular bulge (*FB*), which is a protrusion of the external root sheath (*ERS*) containing a niche of the epidermal stem cells. An internal root sheath (*IRS*) and hair shaft in the center of the follicle are also visible. Note the melanin pigment transferred from the bulbar melanocytes residing in the hair matrix to the cortex (*C*) and the medulla (*M*) of the hair shaft. $\times 120$. (Courtesy of Dr. Jamie Chapman, Tasmanian School of Medicine, University of Tasmania, Hobart, Australia.)

- **Henle layer** consists of a single outer layer of cuboidal cells. These cells are in direct contact with the outermost part of the hair follicle, which represents a downgrowth of the epidermis and is designated the **external root sheath**.
- **Huxley layer** consists of a single or double layer of flattened cells that form the **middle plate of the internal root sheath**.
- The **internal root sheath cuticle** consists of squamous cells whose outer free surface faces the hair shaft.

The **external root sheath** encloses the inner root sheath and is continuous with the epidermis of the skin (see Fig. 15.21). A periodic acid-Schiff (PAS)-positive basement membrane separates the external root sheath from the connective tissue surrounding the hair follicle called the **dermal sheath**. The thickness of the external root sheath increases from the base of the hair follicle to its surface opening at the infundibulum. In the upper part of the hair follicle, the external root sheath is similar to the epidermis. It contains **basal cells**, **melanocytes**, **keratinocytes**, and other cells present in the epidermis. The stratum granulosum is visible near the skin surface. Near the follicular bulge, the hair follicle contains a site for attachment of the arrector pili muscle (a smooth muscle that raises hair into a vertical position). Keratinocytes in the lower part of the external root sheath appear to have clear cytoplasm, which is attributed to the high glycogen content in their cytoplasm.

A niche of ES cells that resides within the follicular bulge of the external root sheath provides stem cells for hair growth and skin regeneration.

The progression of the external root sheath of the hair follicle upward toward the epidermal surface reveals the insertion site of the arrector pili muscle and the origin of the sebaceous duct and gland from the wall of the follicular canal (see Fig 15.19). Nerve endings surround the external root sheath at the level of arrector pili muscle insertion. In this general region resides an aggregate of relatively undifferentiated epithelial cells called the **follicular bulge**. Recent studies have identified the follicular bulge as a **niche of ES cells** (see Fig. 15.20). The ES cells can reside in this area indefinitely and undergo self-renewal or differentiation into specific cell lineages. Under normal conditions, ES cells are responsible for providing stem cells for the growth of hair follicles (the hair matrix, internal root sheath, cortex, and medulla) as well as sebaceous glands (see Fig. 15.20). The ES cells that normally reside in the follicular bulge do not contribute to the population of the basal stem cells of the epidermis. However, when the epidermis is injured or lost (such as in extensive skin burns and superficial skin wounds), the ES cells become reprogrammed, migrate toward the wound surface from their follicular niches, and participate in the initial resurfacing of the wound.

Hairs are composed of keratinized cells that develop from hair follicles.

Keratinization of the hair and internal root sheath occurs shortly after the cells leave the matrix in a region called the **keratogenous zone** in the lower third of the follicle. As the cortical cells pass through this zone, they differentiate, extrude their organelles, and become tightly packed with cross-linked keratin intermediate filaments. By the time the hair emerges from the follicle, it is entirely keratinized as **hard keratin**. The internal root sheath, consisting of soft keratin, does not emerge from the follicle with the hair but is broken down at about the isthmus level where sebaceous secretions enter the follicle. A thick basal lamina, called the **glassy membrane**, separates the hair follicle from the dermis. Surrounding the follicle is a dense irregular connective

tissue. The **arrector pili muscle** is attached near the follicular bulge, which, as indicated earlier, serves as an ES cell niche.

Hairs are elongated filamentous structures that project from the hair follicles. They are composed of heavily cross-linked hard keratins and consist of three layers (see Fig. 15.19):

- The **medulla** forms the central part of the shaft and contains a column of large, loosely connected keratinized cells containing soft keratin. The medulla is present only in thick hairs.
- The **cortex** is the largest layer and accounts for approximately 80% of the total mass of each hair. It is located outside the medulla and is composed of cortical cells filled with hard keratin intermediate filaments. Each filament is surrounded by an amorphous space containing **keratin-associated proteins (KAPs)**. These high-sulfur KAPs are responsible for forming the rigid hair shaft by extensive cross-linking of keratin intermediate filaments by disulfide bonds. The cortex determines texture, elasticity, and the color of hair. Melanin pigment responsible for the color of hair is produced by melanocytes present in the germinative layer (hair matrix) of the hair bulb.
- The **cuticle of the hair shaft** is the outermost layer of the hair. It contains several layers of overlapping, semitransparent keratinized squamous cells. These cells resemble fish scales or roof tiles with their free edges lying away from the hair follicle. The cuticle protects the hair from physical and chemical damage and determines its porosity.

Hair structure in humans is determined by multiple genetic factors that include 17 keratin genes (11 genes for type I and 6 genes for type II keratins) and more than 85 KAP genes.

Nails

Nails are plates of keratinized cells containing hard keratin.

The **nails** are specialized skin appendages composed of keratinized, flattened epithelial cells derived from the germinative zones of the nail bed. The slightly arched fingernails and toenails, more properly referred to as **nail plates**, are strongly attached to underlying **nail beds**. The nail bed consists of epithelial cells that are continuous with the stratum basale and stratum spinosum of the epidermis (Fig. 15.22 and Plate 15.6, page 586).

FIGURE 15.22. Photomicrograph of a sagittal section of distal phalanx with a nail. A nail is a keratinized plate located on the dorsal aspect of the distal phalanges. Beneath the free edge of the nail is a boundary layer, the hyponychium, which is continuous with the stratum corneum of the adjacent epidermis. The proximal end, the root of the nail, is overlapped by skin, the eponychium, which is also continuous with the stratum corneum of the adjacent epidermis. Deep to the nail is a layer of epithelium with underlying dermis. The proximal portion of this epithelium is referred to as the *nail matrix*. The bone in this section represents a distal phalanx. Numerous Pacinian corpuscles are present in the connective tissue of the palmar side of the finger. Note that even at this low magnification, the stratum lucidum is visible in the epidermis of the fingertip. $\times 10$.

The proximal part of the nail, the **nail root**, is buried in a fold of epidermis and covers the cells of the **germinative zone** or **matrix**. The matrix contains a variety of cells, including stem cells, epithelial cells, melanocytes, Merkel cells, and Langerhans cells. The stem cells of the matrix regularly divide, migrate toward the root of the nail, and there differentiate and produce the keratin of the nail. Nail keratin is a **hard keratin**, like that of the hair cortex. Unlike the soft keratin of the epidermis, it does not desquamate. It consists of densely packed keratin filaments embedded in a matrix of amorphous keratin with a high sulfur content, which is responsible for the hardness of the nail. The process of hard keratin formation, as with the hair cortex, does not involve keratohyalin granules. In addition, a cornified CE contains proteins similar to those found in the epidermis.

The continuous addition and keratinization of new cells at the root account for nail growth. As the nail plate grows, it moves over the nail bed. The average growth rate for fingernails is estimated at 2 to 3 mm/month and for toenails about 1 mm/month; thus, complete replacement of nail requires 6 months for fingernails and 18 months for toenails. On the microscopic level, the nail plate resembles the modified stratum corneum of the skin. It contains closely packed, terminally differentiated interdigitating keratinocytes called **onychocytes** lacking nuclei and organelles. In contrast to the stratum corneum, the nail plate contains less fat and water,

and surface onychocytes do not desquamate like keratinocytes on the skin surface.

The crescent-shaped white area near the root of the nail, the **lunula**, demarcates the distal portion of the germinative zone. Its color derives from the thick, opaque layer of partially keratinized matrix cells in this region. When the nail plate becomes fully keratinized, it is more transparent and takes on the coloring of the underlying vascular bed. The edge of the skin fold covering the root of the nail is the **eponychium** or **cuticle**. The cuticle is also composed of hard keratin; therefore, it does not desquamate. Because of its thinness, it tends to break off or, as with many individuals, it is trimmed and pushed back. A thickened epidermal layer, the hyponychium, secures the free edge of the nail plate at the fingertip.

FOLDER 15.5

FUNCTIONAL CONSIDERATIONS: HAIR GROWTH AND HAIR CHARACTERISTICS

Unlike the renewal of the surface epidermis, hair growth is not continuous but a cyclic process. A **period of growth (anagen)** in which a new hair develops is followed by a brief period in which **growth stops (catagen)**. Catagen is followed by a long (range 2–4 months) **rest period (telogen)** in which the follicle atrophies, and the hair is eventually lost. Epidermal stem cells found in the follicular bulge are capable of providing stem cells that give rise to mature anagen follicles. During the hair growth cycle, mature anagen hairs periodically undergo apoptosis and regress to the catagen stage. In this phase, cell division ceases, the hair matrix regresses, the dermal papilla retracts, capillary nourishment diminishes, and entire follicles retract toward the epidermal layer. As the base of the retracted follicle approximates the follicular bulge, the hair shaft is no longer supported by the nutrient-rich anagen bulb and eventually is ejected from the resting telogen follicle. This makes room for a new shaft that will grow during anagen regeneration.

Hairs in the anagen phase are susceptible to destruction by **laser hair removal (LHR)** procedures. Because of the cyclic nature of hair growth, repeated hair removal treatments are necessary to address new follicles entering the anagen phase. Professional and home-based laser and light devices are both

currently available for removal of “unwanted hair” (the term used in describing facial and body hair but not scalp hair).

Out of a total of 100,000 hairs present in the normal scalp, more than 80% is in the anagen phase. In the catagen phase, the germinative zone is reduced to an epithelial strand still attached to a remnant of the dermal papilla. In the telogen phase, the atrophied follicle may contract to one-half or less of its original length. The hair may remain attached to the follicle for several months during this stage and is called a **club hair** because of the shape of its proximal end.

Hairs in humans grow to a specific length, which varies with the individual. Hairs vary in size from long, coarse **terminal hairs** that may reach a meter or more in length (scalp hair and beard hair in males) to short, fine **vellus hairs** that may be visible only with the aid of a magnifying lens (vellus hairs of the forehead and anterior surface of the forearm). Terminal hairs are produced by large-diameter, long follicles; vellus hairs are produced by relatively small follicles. Length of hair depends on genetic influences, location in the body, climate, age, nutrition, and hormonal status.

Hair length is determined by the rate and duration of anagen period. Terminal hair follicles may spend up to several years in anagen and only a few months in telogen. Average hair growth is estimated at 0.4 mm/day (1.2 cm/month), but with aging, the rate of hair growth declines and hair diminishes in thickness. Gray hair appears as the result of decreased melanin production within the hair matrix.

In the balding individual, large terminal follicles are gradually converted into small vellus follicles after several growth cycles. The ratio of vellus follicles to terminal follicles increases as baldness progresses. The “completely bald” scalp is not hairless but is populated by vellus follicles that produce fine hairs and remain in telogen for relatively long periods.

Sebaceous Glands

Most sebaceous glands are associated with hair follicles and form pilosebaceous units.

Sebaceous glands are usually found in association with hair follicles in most areas of the body surface except for the palms and soles. They form the **pilosebaceous units** comprising four structures: the hair follicle, hair shaft, arrector pili muscle, and sebaceous gland. The association between these structures is well demonstrated on a transverse section of hair

follicles from the scalp (see Fig. 15.21). The highest density of sebaceous glands is found on the face. In some areas such as the eyelids (Meibomian and Zeis glands), areolae (pigmented regions surrounding the nipples of mammary glands), and vermilion border of the lips, sebaceous glands are not associated with a hair follicle and open directly onto the skin's surface.

FOLDER 15.6

CLINICAL CORRELATION: SWEATING AND DISEASE

Although many neural and emotional factors can alter the **composition of sweat**, altered sweat composition can also be a sign of disease. For example, elevated sodium and chloride levels in sweat can serve as an indicator of **cystic fibrosis**.

Individuals with cystic fibrosis have two to five times higher than normal amounts of sodium and chloride in their sweat.

In pronounced **uremia**, in which the kidneys are unable to rid the body of urea, the concentration of urea in sweat increases. In this condition, after the water evaporates, crystals may be discerned on the skin, especially on the upper lip. These include urea crystals and are called **urea frost**.

Sebaceous glands develop early in fetal development as outgrowths of the external root sheath of the hair follicle in the epidermis. The glands can be either unilobular or multilobular (Fig. 15.23 and Plate 15.4, page 582). During the second trimester of fetal development, sebaceous glands are fully functional, and their secretion contributes to the **vernix caseosa**, a cheese-like white creamy substance that coats the skin of a newborn.

FIGURE 15.23. Photomicrograph of a sebaceous gland. **a.** This micrograph shows the secretory lobules and their pilosebaceous canal of two sebaceous glands. The canal of the gland on the *left* is about to enter the hair follicle seen at the *top* of the micrograph. The canal of the sebaceous gland on the *right* has been sectioned in a manner that shows mostly the wall of the canal. $\times 60$. **b.** The secretory component of the lobule in the *lower box* of **a** is shown here at higher magnification. Note the light staining of the sebocytes because of the lack of staining of the sebum that they contain. These cells are actively producing sebum. The basal cells at the periphery of the lobule divide and replenish the population of new sebocytes. Also, the arrector pili muscle (*APM*) composed of smooth muscle fibers is visible in the periphery of the secretory lobule. $\times 120$. **c.** The secretory component of the lobule in the upper box of **a** is shown here at higher magnification. The sebocytes are now within the canal. Note their pyknotic nuclei, signifying the death of the cell. $\times 120$.

The development of sebaceous glands is highly regulated by several transcription factors such as Sox9, Blimp1, Wnt, BMP, and the hedgehog pathway. Proliferation, differentiation, and metabolism of these glands are regulated by sex hormones, particularly androgens. **Sebaceous gland activity increases shortly after birth but then diminishes in the first few postnatal months. Increased androgen levels at puberty coincide with an increase in sebaceous gland activity and sebum secretion. Sebum production decreases by about 23% per decade in males and 32% per decade in females.**

Sebocytes are terminally differentiated epithelial cells that produce and accumulate sebum.

Sebocytes are the major cells within sebaceous glands that produce and accumulate lipids. The oily and waxy substance called **sebum** is produced by fully mature sebocytes in a process termed **holocrine secretion**. In this process, the entire cell produces and becomes filled with the fatty product while it simultaneously undergoes programmed cell death (apoptosis). Ultimately, both the secretory product and cellular debris are discharged from the gland as sebum into the infundibulum of a hair follicle, which forms the **pilosebaceous canal** with the short duct of the sebaceous gland. New sebocytes are produced by mitosis of the basal cells at the periphery of the gland, and the cells of the gland remain linked to one another by

desmosomes and gap junctions regardless of their differentiation stage. The basal lamina of these cells is continuous with that of the epidermis and the hair follicle. The basal cells of the sebaceous gland contain sER, rER, free ribosomes, mitochondria, glycogen, and a well-developed Golgi apparatus. As the sebocytes move away from the basal layer and begin to produce their lipid secretory product, the amount of sER increases, reflecting the role of the sER in lipid synthesis and secretion. The sebocytes gradually become filled with numerous lipid droplets separated by thin strands of cytoplasm. The sebum production process takes about 8 days from the time of basal cell mitosis to the secretion of the sebum.

The complex mixture of oily substances in the sebum provides a personalized chemical signature unique for each individual.

Sebum represents a complex oily mixture that consists of triglycerides, diglycerides, and free fatty acids (57%); wax esters (26%); squalene (12%); cholesterol; and cholesterol esters (2%). Because of its complex composition, human sebum is remarkably specific as a result of individual genetic variations in enzyme concentrations, pH, and temperature. The secreted sebum provides each person with a highly individual and **unique chemical signature**. Animals with a highly developed sense of smell, such as dogs, may be able to identify individuals on the basis of this specific chemical signature. Besides contributing to the maintenance of a functional epidermal barrier and the well-defined function of the specialized sebaceous gland secretion from Meibomian glands in eyelids, the role of sebum in human skin remains elusive. Some theories suggest that it may play a role in protection against UV irradiation. Other studies suggest that it has both immune and communication functions because of the presence of antioxidants (especially vitamin E), anti-inflammatory and proinflammatory substances, antimicrobial peptides, and pheromones on the skin surface.

Differentiation, proliferation, and secretion of lipid substances from sebocytes are controlled by complex endocrine pathways. Androgens generally increase sebaceous gland

function, whereas estrogens have an inhibitory effect on sebum production. In addition, histamine, substance P, corticotropin-releasing hormone (CRH), and dietary substances (e.g., free fatty acids, sugar, and fat) can induce sebum production. The increase in sebum secretion and alterations in its lipid composition during puberty in males and females may cause the chronic inflammatory disease of the pilosebaceous unit known as *acne vulgaris*. The three major events leading to acne development include (1) excessive sebum production (seborrhea), (2) abnormal follicular keratinization of the pilosebaceous canal, and (3) proliferation of *Propionibacterium acnes* bacteria within the pilosebaceous unit. On histologic examination, acne is characterized by the retention of sebum in the isthmus of the hair follicle with variable lymphocytic infiltration. In severe cases, dermal abscesses may form in association with inflamed hair follicles.

Sweat Glands

Humans have approximately 4 million **sweat glands** that are classified on the basis of their structure and the nature of their secretion. Two types of sweat glands are recognized:

- **Eccrine sweat glands** are distributed over the entire body surface except for the vermilion border of the lips, nail beds, and part of the external genitalia (glans penis, clitoris, and labia minora). The maximum density of sweat glands is found in the palms of the hands, soles of the feet, skin of axillae, forehead, and trunk.
- **Apocrine sweat glands** are limited to the axilla, areola and nipple of the mammary gland, skin around the anus, and the external genitalia. The **ceruminous glands** of the external acoustic meatus and the **apocrine glands of eyelashes (glands of Moll)** are also apocrine-type glands.

Eccrine Sweat Glands

Eccrine sweat glands are simple coiled glands that regulate body temperature.

Eccrine sweat glands are independent structures and are not associated with the hair follicle that arises as a downgrowth from the fetal epidermis. Each eccrine gland is arranged as a blind-ended, simple, coiled tubular structure. It consists of two segments: a **secretory segment** located deep in the dermis or in the upper part of the hypodermis and a directly continuous, less coiled **duct segment** that leads to the epidermal surface (Fig. 15.24 and Plate 15.3, page 580).

FIGURE 15.24. Photomicrograph of an eccrine sweat gland. This photomicrograph of a hematoxylin and eosin (H&E)-stained section of human skin shows profiles of both the secretory component and the duct of an eccrine sweat gland. The secretory component appears as a double layer of cuboidal epithelial cells and peripherally, within the basal lamina, a layer of myoepithelial cells. The duct portion of the gland has a narrower outside diameter and lumen than the secretory portion of the gland. It consists of a double layer of small cuboidal cells without the myoepithelial cells. $\times 320$.

Eccrine sweat glands play a major role in **temperature regulation** through the cooling that results from the evaporation of water from sweat on the body surface. Eccrine sweat glands in the skin of the palm and soles increase gripping strength. The secretory portion of the glands produces a secretion similar in composition to an ultrafiltrate of blood. Resorption of some of the sodium and water in the duct results in the release of a hypotonic sweat at the skin surface. This hypotonic watery solution is low in protein and contains varying amounts of sodium chloride, urea, uric acid, and ammonia. Thus, the eccrine sweat gland also serves, in part, as an excretory organ.

Excessive sweating can lead to the loss of other electrolytes, such as potassium and magnesium as well as significant water loss. Normally, the body loses about 600 mL of water a day through evaporation from the lungs and skin. Under conditions of high ambient temperature, water loss can be increased in a regulated manner by an increased rate of sweating. **This thermoregulatory sweating first occurs on the forehead and scalp, extends to the face and the rest of the body, and occurs last on the palms and soles. Under conditions of emotional stress, however, the palms, soles, and axillae are the first surfaces to sweat. Control of thermoregulatory sweating is cholinergic, whereas emotional sweating may be stimulated by adrenergic portions of the sympathetic division of the autonomic nervous system.**

The secretory segment of the eccrine sweat gland contains three cell types.

Three cell types are present in the secretory segment of the gland: **clear cells** and **dark cells**, both of which are secretory epithelial cells, and **myoepithelial cells**, which are contractile epithelial cells (Fig. 15.25 and Plate 15.4, page 582). All of the cells rest on the basal lamina; their arrangement is that of a pseudostratified epithelium. These three cell types are described as follows:

FIGURE 15.25. Electron micrographs of an eccrine sweat gland. a. This micrograph shows myoepithelial cells (*My*) and two distinctive gland cell types, dark cells (*D*) and clear cells (*C*). The apical portion of the dark cell is broad; it faces the lumen (*L*) of the gland and contains numerous secretory granules. The *dashed line* marks the boundary of one dark cell. The clear cell is more removed from the lumen of the gland. Its base rests on the myoepithelial cells or directly on the basal lamina. Most of the free surface of the clear cell faces an intercellular canaliculus (*IC*). Clear cells contain numerous mitochondria, extensive infoldings of the plasma membrane, and large numbers of electron-dense glycogen inclusions. $\times 5,600$. b. At higher magnification, dark cells display rough-surfaced endoplasmic reticulum (rER) (*arrow*) and a Golgi apparatus (*G*) in addition to secretory granules. Clear cells show large amounts of folded membrane, mitochondria, and glycogen. The myoepithelial cells (*My*) contain large numbers of contractile actin filaments. *Arrowheads* (*upper right*) mark the boundary of a clear cell. $\times 17,500$. (Courtesy of Dr. John A. Terzakakis.)

- **Clear cells** are characterized by abundant glycogen. In the electron micrograph shown in Figure 15.25a, the glycogen is conspicuous; it would also stain intensely with the PAS method. In routine H&E preparations, the cytoplasm of clear cells stains poorly. Membranous organelles include numerous mitochondria, profiles of sER, and a relatively small Golgi apparatus. The plasma membrane is remarkably amplified at the lateral and apical surfaces by extensive cytoplasmic folds. In addition, the basal surface of the cell possesses infoldings, although they are considerably less complex than the cytoplasmic folds. The morphology of these cells indicates that they produce the watery component of sweat.
- **Dark cells** are characterized by abundant rER and secretory granules (see Fig. 15.25). The Golgi apparatus is relatively large, a feature consistent with the glycoprotein secretion of these cells. The apical cytoplasm contains mature secretory granules and occupies most of the luminal surface (see Fig. 15.25a). Clear cells have considerably less cytoplasmic exposure to the lumen; their secretion is largely via the lateral surfaces of the cell, which are in contact with intercellular canaliculi that allow the watery secretion to reach the lumen. Here it mixes with the proteinaceous secretion of the dark cells.

- **Myoepithelial cells** are limited to the basal aspect of the secretory segment. They lie between the secretory cells, with their processes oriented transversally to the tubule. The cytoplasm contains numerous contractile filaments (actin) that stain deeply with eosin, thus making them readily identifiable in routine H&E specimens. Contraction of these cells is responsible for rapid expression of sweat from the gland.

The duct segment of eccrine glands is lined by stratified cuboidal epithelium and lacks myoepithelial cells.

The **duct segment** of the gland continues from the secretory portion with coiling. In histologic sections, multiple duct profiles typically appear among the secretory profiles. As the duct passes upward through the dermis, it takes a gentle spiral course until it reaches the epidermis, where it then continues in a tighter spiral to the surface. When the duct enters the epidermis, however, the duct cells end, and the epidermal cells form the wall of the duct. Clinically, the dermal part of the eccrine duct is called **syrinx**, and the coiled intraepidermal part that opens onto the skin surface is called the **acrosyringium**. Benign tumors of the syrx are termed **syringomas**, and tumors of the acrosyringium are **poromas**. The acrosyringium is also a place of origin for **eccrine porocarcinoma**, a rare type of skin cancer.

The dermal part of the duct is composed of **stratified cuboidal epithelium**, consisting of a basal cell layer and a luminal cell layer. The duct cells are smaller and appear darker than the cells of the secretory portion of the gland. Also, the duct has a smaller diameter than the secretory portion. In contrast to the secretory portion of the eccrine gland, the duct portion does not possess myoepithelial cells. These features are useful in distinguishing the duct from the secretory portion in a histologic section (see Fig. 15.24).

The basal or peripheral cells of the duct have a rounded or ovoid nucleus and contain a prominent nucleolus. The cytoplasm is filled with mitochondria and ribosomes. The apical or luminal cells are smaller than the basal cells, but their

nuclei are similar in appearance. The most conspicuous feature of the luminal cells is the deeply stained, glassy (hyalinized) appearance of the apical cytoplasm. The glassy appearance is attributable to large numbers of aggregated tonofilaments in the apical cytoplasm.

Apocrine Sweat Glands

Apocrine glands are large-lumen tubular glands associated with hair follicles.

Apocrine sweat glands develop from the same downgrowths of epidermis that give rise to hair follicles. The connection to the follicle is retained, allowing the secretion of the gland to enter the follicle, typically at a level just above the entrance to the sebaceous duct. From here, the secretion makes its way to the surface.

Like eccrine glands, apocrine glands are coiled tubular glands, and they are sometimes branched. The secretory portion of the gland is located deep in the dermis or, more commonly, in the upper region of the hypodermis.

The secretory portion of apocrine glands has a wider lumen than that of eccrine glands and is composed of a single cell type.

The secretory portion of apocrine glands differs in several respects from that of eccrine glands. The most obvious difference, readily noted in the light microscope, is its very wide lumen (Fig. 15.26 and Plate 15.3, page 580). Unlike eccrine glands, apocrine glands store their secretory product in the lumen. The secretory portion of the gland is composed of simple epithelium. Only one cell type is present, and the cytoplasm of the cell is eosinophilic. The apical part of the cell often exhibits a bleb-like protrusion. It was once thought that this part of the cell pinched off and was discharged into the lumen as an apocrine secretion, thus the name of the gland. However, TEM studies confirm that the secretion is a **merocrine type**. The apical cytoplasm contains numerous small granules, the secretory components within the cell, which are discharged by exocytosis. Other features of the cell include numerous

lysosomes and lipofuscin pigment granules. The latter represent secondary and tertiary lysosomes. Mitochondria are also numerous. During the refractory phase, after expulsion of the secretion, the Golgi apparatus enlarges in preparation for a new secretory phase.

FIGURE 15.26. Photomicrograph of an apocrine sweat gland. This section of adult skin from the area around the anus shows several apocrine (anal) sweat glands, which are easily identified by the large lumen of their secretory components. This apocrine sweat gland is close to a hair follicle (*center* of photomicrograph) and deep to the

dense, irregular connective tissue of the dermis. $\times 45$. Inset. Higher magnification of secretory component shows the cell types of the apocrine gland. The gland consists of a simple epithelium whose cells are either cuboidal or columnar and myoepithelial cells located in the basal portion of the epithelial cell layer. $\times 230$.

Myoepithelial cells are also present in the secretory portion of the gland and are situated between the secretory cells and the adjacent basal lamina. As in eccrine glands, contraction of the processes of myoid cells facilitates expulsion of the secretory product from the gland.

The duct portion of apocrine glands is lined by stratified cuboidal epithelium and lacks myoepithelial cells.

The **duct of the apocrine gland** is similar to that of the eccrine duct; it has a narrow lumen. However, it continues from the secretory portion of the gland in a relatively straight path to empty into the follicle canal. Because of its straight course, the probability of viewing both the duct and the secretory portion of an apocrine gland in the same histologic section is reduced. Also, in contrast to the eccrine duct, resorption does not occur in the apocrine duct. The secretory product is not altered in its passage through the duct.

The duct epithelium is stratified cuboidal, usually two but sometimes three cell layers thick. The apical cytoplasm of the luminal cells appears hyalinized, a consequence of the aggregated tonofilaments in the apical cytoplasm. In this aspect, they resemble the luminal cells of the eccrine duct.

Apocrine glands produce a protein-rich secretion containing pheromones.

Apocrine glands produce a secretion that contains protein, carbohydrates, ammonia, lipid, and certain organic compounds that may color the secretion. However, the secretions vary with the anatomic location. In the axilla, the secretion is milky and slightly viscous. When secreted, the fluid is odorless; through bacterial action on the skin surface, it develops an acrid odor.

Apocrine glands become functional at puberty; as with axillary and pubic hair, their development depends on sex hormones. In the female, axillary and areolar apocrine glands undergo morphologic and secretory changes that parallel the menstrual cycle.

In many mammals, similar glands secrete pheromones, chemical signals used in marking territory, courtship behavior, and certain maternal and social behaviors. It is generally believed that apocrine secretions may function as pheromones in humans. Male pheromones (androstamol and androstamolone) in the secretion of apocrine glands have been shown to influence the female menstrual cycle. Furthermore, female pheromones (copulins) influence male perception of females and may also induce hormonal changes in males.

The sympathetic portion of the autonomic nervous system innervates both eccrine and apocrine sweat glands.

The cholinergic neurotransmitter **acetylcholine** stimulates **eccrine sweat glands**; paradoxically, it is discharged from sympathetic nerve fibers, which typically use norepinephrine and not acetylcholine (acetylcholine serves as a neurotransmitter in the parasympathetic nerve fibers). Thus, eccrine sweat glands have a functional cholinergic innervation but are anatomically sympathetic. The adrenergic neurotransmitter **norepinephrine** stimulates the **apocrine glands**. As described earlier, eccrine glands respond to heat and stress. Sympathetic innervation to the sweat glands is mediated by the thermoregulatory center of the hypothalamus. Apocrine glands are involved in emotional sweating because of stress, fear, pain, and sexual stimulation but do not respond to heat. **Hyperhidrosis** is a pathologic disorder affecting 0.6% - 5% of the population and is characterized by excessive sweat production above the quantity needed for thermoregulation. It can be idiopathic (primary hyperhidrosis) or be a result of another endocrine, neurologic, or infectious disorder. **Primary hyperhidrosis** is characterized by uncontrollable, excessive, and unpredictable sweating, which occurs at rest and is not related to temperature. The symptoms of hyperhidrosis can

significantly affect quality of life and lead to social embarrassment, loneliness, anxiety, and depression. Treatment options include topical and oral anticholinergic medications, surgical procedures (i.e., endoscopic thoracic sympathectomy), laser therapy, or botulinum toxin injection.

FOLDER 15.7

CLINICAL CORRELATION: SKIN REPAIR

The process of wound healing of the skin is classically described as either a primary or secondary union. Healing by **primary union (first intention)** occurs after surgical incisions in which wounds that are usually clean and uninfected have their edges approximated by surgical sutures. Healing by **secondary union (secondary intention)** occurs in traumatic wounds with separated edges, which are characterized by more extensive loss of cells and tissues. Wound healing in such cases involves generating a large amount of **granulation tissue**, which represents a specialized type of tissue formed during the repair process.

The repair of an incision or laceration of the skin requires stimulated growth of both the dermis and the epidermis. Dermal repair involves (1) blood clot formation; (2) removal of damaged collagen fibers, primarily through the effort of macrophage activity that is associated with inflammation; (3) formation of granulation tissue; (4) reepithelialization of the exposed surface; (5) proliferation and migration of fibroblasts and differentiation of myofibroblasts involved in wound contraction; and (6) deposition and remodeling of the extracellular matrix of underlying connective tissue. Healing by primary union following application of sutures reduces the extent of the repair area through maximal closure of a wound, minimizing scar formation. Surgical incisions are typically made along cleavage lines; the cut tends to parallel the collagen fibers, thus minimizing the need for excess collagen production and the inherent scarring that may occur.

Repair of the epidermis involves the proliferation of the basal keratinocytes in the stratum basale in the undamaged site surrounding the wound (Fig. F15.7.1). Mitotic activity is markedly increased within the first 24 hours. In a short time, the wound site is covered by a **scab** that represents dehydrated blood clot. The proliferating basal cells of the stratum basale begin migrating beneath the scab and across the wound surface. The migration rate may be as much as 0.5 mm/day, starting within 8–18 hours after wounding. Further proliferation and differentiation occur behind the migration front, leading to restoration of the multilayered epidermis. As new cells ultimately keratinize and

desquamate, the overlying scab is freed with the desquamating cells, which explains why a scab detaches from its periphery inward.

FIGURE F15.7.1. Photomicrograph showing a late stage in the epidermal repair of a skin wound. The initial injury was caused by an incision through the full thickness of the skin and partially into the hypodermis, which contains adipose cells (A). The epidermis has re-formed beneath the scab. The *asterisk* marks an artifact where epithelium separated during specimen preparation. The scab, which contains numerous dead neutrophils in its inferior aspect, is close to the point of release. The dermis at this stage shows little change during the repair process but

will ultimately reestablish itself to form a continuous layer. $\times 110$.

In cases in which the full thickness of the epidermal layer is removed either by trauma or in surgery, the parts of hair follicles, the follicular bulge that contains the niche of the epidermal stem cells, will produce cells that migrate over the exposed surface to reestablish a complete epithelial (epidermal) layer. Massive destruction of all of the epithelial structures of the skin, as in a third-degree burn or extensive full-thickness abrasion, prevents reepithelialization. Such wounds can be healed only by grafting the epidermis to cover the wounded area. In the absence of a graft, the wound would, at best, reepithelialize slowly and imperfectly by ingrowth of cells from the margins of the wound.

■ SKIN AGING

Skin aging is influenced by several intrinsic and extrinsic factors, including genetics, environmental exposure, hormonal changes, and metabolic factors, all of which lead to a loss of structural integrity and physiologic function. The complex cellular and biochemical processes of the skin become altered with age and affect the balance between remodeling, regeneration, and repair. Additionally, the protective immune barrier of aged skin is less efficient. On the histologic level, several structural changes are noticeable in aged skin:

- **Keratinocyte atrophy**, which leads to decreased thickness of the epidermal layer of the skin. A thinner epidermis with a flattened interface between the epidermis and dermis makes aged skin less resistant to shearing forces and prone to injuries. In addition, keratinocyte atrophy affects the production of proteins and lipid components of the epidermal water barrier, increasing transepidermal water loss in elderly individuals that increases skin dryness.
- **Diminishment of mononuclear phagocyte system cell activity**, which affects the immunologic response to pathogens. Langerhans cells in the epidermis are reduced in number, and their capacity to migrate to lymph nodes is diminished. Dermal dendritic cells also show changes in the skin aging

process. They exhibit impaired migration and phagocytic activity with decreased ability to interact with T cells. A possible decrease in the skin's T-resident memory (T_{rm}) cells may be related to the increased rate of infection seen in elderly individuals.

- **Reduction is the size and activity of dermal fibroblasts**, which adds to age-associated dermal thinning. Dermal fibroblasts from elderly individuals synthesize less procollagen and other structural extracellular matrix proteins. However, they have increased matrix metalloproteinase (MMP) expression that contributes to the remodeling/destruction of the extracellular matrix.
- **Collagen and elastic fibers fragmentation**, which is related to increased activity of MMPs. The total amount of collagen and elastin in the skin is reduced with age. Several MMPs (i.e., MMP-1, MMP-3, and MMP-9) specifically target elastin fibers and are responsible for their fragmentation. This results in reduced skin elasticity, causing wrinkling of aging skin.
- **Reduction in secretion of sweat and sebaceous glands**, which amplifies the effect of skin dryness. Both sweat and sebum contain antimicrobial peptides and lipids that control bacterial growth on the skin surface. Decreased secretion of these compounds affects the immunologic skin barrier in restricting the growth of pathogenic bacteria.
- **Subcutaneous adipose tissue reduction**, which occurs in the hypodermis and superficial fascia. Dermal adipose tissue chronically exposed to UV radiation reduces the number of adipocytes and is accompanied by a decrease in free fatty acids and triglycerides.

The process of skin aging is dependent to a degree on lifestyle choices, genetic factors, and environmental challenges, including UV exposure, tobacco smoking, and environmental pollution. Collectively, these changes render older individuals more susceptible to mechanical injury and infections. It is important to note that high levels of

pigmentation in keratinocytes are protective with regard to the cumulative effects of sun UV exposure and skin damage.

INTEGUMENTARY SYSTEM

OVERVIEW OF THE INTEGUMENTARY SYSTEM

- The **integumentary system** consists of skin and its derivatives (epidermal skin appendages).
- The **skin** has two layers: the **epidermis**, a superficial layer that consists mainly of a stratified squamous keratinized epithelium, and the **dermis**, a deeper layer of dense irregular connective tissue.
- Deep to the skin is the **hypodermis**, which contains variable amounts of adipose tissue.

EPIDERMIS

- The **epidermis** is composed primarily of **keratinocytes** (85%) that undergo differentiation to form stratified squamous keratinized epithelium.
- Four distinct layers (strata) of epidermis can be distinguished.
- The **stratum basale** is a single layer of small, mitotically active basal cells that are attached by hemidesmosomes to underlying connective tissue and by desmosomes to each other.
- The **stratum spinosum** contains several layers of larger keratinocytes that are attached to each other by **desmosomes** located at the ends of their cytoplasmic processes containing intermediate filaments (keratin filaments).

- The **stratum granulosum** is a distinct layer of flattened keratinocytes filled with **keratohyalin granules** (contain precursors to **filaggrin**, which aggregates **keratin filaments**) and lamellar bodies containing lipids, which, when secreted, are responsible for the formation of the epidermal **water barrier**.
- The **stratum corneum** is the most superficial layer of terminally differentiated squamous cells (with no nuclei) that are entirely filled with keratin filaments. These cells are constantly desquamating from the skin surface.
- Total epidermal turnover time is approximately **47 days**.

SPECIALIZED CELLS OF THE EPIDERMIS

- **Melanocytes** (5% of cells in epidermis) reside in the stratum basale and have long processes that extend between keratinocytes into the stratum spinosum.
- Melanocytes synthesize **melanin** pigment in **melanosomes** that is then transferred (**pigment donation**) to adjacent keratinocytes. The transferred pigment accumulates above nuclei of keratinocytes to protect nuclear DNA from UV radiation and damage.
- Other cells in the epidermis include **Langerhans cells** (2% - 5%), which are the antigen-presenting cells involved in signaling of the immune system, and **Merkel cells** (6% - 10%), which are mechanoreceptor cells associated with sensory nerve endings.

DERMIS

- The **dermis** is composed of two layers.
- The **papillary layer** is superficial and consists of loose connective tissue (collagen I and III) that contains

extensive plexus of blood, lymphatic vessels, and sensory nerve endings.

- The **reticular layer** is deeper and is composed of dense irregular connective tissue containing type I collagen, elastic fibers, and larger blood vessels.
- The **epidermal-dermal junction** has numerous finger-like connective tissue protrusions called **dermal papillae** that correspond to similar epidermal protrusions (**epidermal ridges**).
- **Dermal papillae** contain nerve endings and a network of blood and lymphatic capillaries.

SPECIALIZED CELLS OF THE DERMIS

- **Dermal fibroblasts** have **toll-like receptors (TLRs)** for pathogen recognition; when they encounter pathogens, they produce inflammatory cytokines and initiate an immune response.
- **Dermal dendritic cells** present antigens to the T cells or migrate to the lymph node to initiate an immune response.
- **Resident dermal macrophages** are yolk sac-derived antigen-presenting cells in the dermis that initiate an immune response to foreign substances, tissue damage, and pathogens.
- **Dermal T-resident memory (T_{rm}) cells** are noncirculating memory T cells that provide immunologic memory to initiate a rapid, robust immune response.

SENSORY NERVE RECEPTORS OF THE SKIN

- The epidermis contains **free nerve endings**, which detect fine touch, heat, cold, and pain.
- In addition, **Merkel corpuscle** (Merkel cell with a nerve ending) is a sensitive mechanoreceptor.

- The dermis contains several encapsulated nerve endings, such as Pacinian corpuscles to detect pressure and vibrations, Meissner corpuscles to detect light touch, and Ruffini corpuscles to detect skin stretch and torque.

HAIRS AND NAILS

- Hairs and hair follicles are present over almost the entire body.
- The hair follicle contains a reservoir of epidermal stem cells (follicular bulge) that are responsible for differentiation into hair-forming matrix cells.
- Hair is formed by the differentiation of matrix cells in the inferior segment of the hair follicle (bulb) to form the medulla, cortex (80% of hair mass), and cuticle of a hair shaft.
- The hair shaft is surrounded by the internal and external root sheath. The internal root sheath has three layers of cells: Henle layer, Huxley layer, and the internal root sheath cuticle. The external root sheath is continuous with the epidermis.
- Nails are plates of keratinized cells resting on nail beds containing hard keratin that is formed in a nail root at the proximal part of the nail. Keratinocytes proliferate there and differentiate to form hard keratin.
- As the nail plate grows, it moves over the nail bed with edges covered by skin folds.

GLANDS OF THE SKIN

- Sebaceous glands produce sebum that coats the hair and skin surface. Sebum is produced by holocrine secretion

by **sebocytes** and is discharged via the pilosebaceous canal into the hair follicle.

- **Apocrine sweat glands** secrete protein-rich sweat into the hair follicles, but they are restricted to specific regions of the body (axillae, perineum).
- Apocrine sweat glands are coiled tubular glands with a wide lumen. Their secretory parts contain **myoepithelial cells**, the contraction of which is responsible for expression of sweat.
- **Eccrine sweat glands** are not related to hair follicles. They produce sweat that is similar in composition to an ultrafiltrate of blood in the kidney.
- Eccrine sweat glands play a major role in **temperature regulation** through the cooling that results from the evaporation of water from sweat on the body surface. Their secretory parts also contain **myoepithelial cells**.

PLATE 15.1 ■ SKIN I

The skin, or integument, consists of two main layers: the **epidermis**, composed of stratified squamous epithelium that is keratinized, and the **dermis**, composed of connective tissue. Under the dermis is a layer of loose connective tissue called the **hypodermis**, which is also generally referred to as the **subcutaneous tissue** or, by gross anatomists, as the **superficial fascia**. Typically, the hypodermis contains large amounts of adipose tissue, particularly in an adequately nourished individual.

The epidermis gives rise to nails, hairs, sebaceous glands, and sweat glands. On the palms of the hands and soles of the feet, the epidermis has an outer keratinized layer that is substantially thicker than that over other parts of the body. Accordingly, the skin over the palms and soles is referred to as **thick skin**, in contrast to the skin over other parts of the body, which is referred to as **thin skin**.

There are no hairs in thick skin. In addition, the interface between the epidermis and the dermis is more complex in thick skin than in thin skin. The finger-like projections of the dermis into the base of the epidermis, the **dermal papillae**, are

much longer and more closely spaced in thick skin. This provides greater resistance to frictional forces acting on this skin.

Thick skin, human, hematoxylin and eosin (H&E) ×45.

In this sample of thick skin, the **epidermis** (*Ep*) is at the top; the remainder of the field consists of dermis, in which a large number of **sweat glands** (*SG*) can be observed. Although the layers of the epidermis are examined more advantageously at higher magnification, it is easy to see, even at this relatively low magnification, that about half of the thickness of the epidermis consists of a distinctive surface layer that stains more lightly than the remainder of the epidermis. This is the keratinized layer. The dome-shaped surface contours represent a cross section through the minute dermal ridges on the surface of thick skin that produce the characteristic fingerprints of an individual.

In addition to sweat glands, the dermis displays blood vessels (*BV*) and adipose tissue (*AT*). The ducts of the sweat glands (*D*) extend from the glands to the epidermis. One of the ducts is shown as it enters the epidermis at the bottom of an epithelial ridge. It will pass through the epidermis in a spiral course to open onto the skin surface.

Thin skin, human, H&E ×60.

A sample of thin skin is shown here to compare with the thick skin in the above figure. Note a very thin keratinized layer of epidermis (*Ep*) in comparison to thick skin. In addition to sweat glands, thin skin contains hair follicles (*HF*) and their associated **sebaceous glands** (*SG*). Each sebaceous gland opens into a hair follicle. Often, as in this tissue sample, the hair follicles and the glands, both sebaceous and sweat, extend beyond the dermis (*De*) and into the hypodermis. Note the blood vessels (*BV*) and adipose tissue (*AT*) in the hypodermis.

Epidermis, skin, human, H&E ×320; inset ×640.

The layers of the **epidermis** of **thin skin** are shown here at higher magnification. The cell layer that occupies the deepest

location is the **stratum basale** (*SB*). This is one cell deep. Just above this is a layer several cells in thickness, the **stratum spinosum** (*SS*). It consists of cells that have spinous processes on their surface. These processes meet with spinous processes of neighboring cells and, together, appear as intercellular bridges (*arrows, inset*). The next layer is the **stratum granulosum** (*SGr*), whose cells contain keratohyalin granules (*arrowhead, inset*). On the surface is the **stratum corneum** (*SC*). This consists of keratinized cells, that is, cells that no longer possess nuclei. The keratinized cells are flat and generally adhere to other cells above and below without evidence of cell boundaries. In thick skin, a fifth layer, the **stratum lucidum**, is seen between the stratum granulosum and the stratum corneum. The pigment in the cells of the stratum basale is melanin; some of this pigment (*P*) is also present in connective tissue cells of the dermis. Note blood vessels (*BV*) extending into dermal papillae.

AT, adipose tissue
 BV, blood vessels
 D, duct of sweat glands
 De, dermis
 Ep, epidermis
 HF, hair follicle
 P, pigment
 SB, stratum basale
 SC, stratum corneum
 SGI, sebaceous gland
 SGr, stratum granulosum
 SS, stratum spinosum
 SW, sweat gland
 arrowhead, granules in cell of stratum granulosum
 arrows, intercellular bridges

PLATE 15.2 ■ SKIN II

The epidermis contains four distinctive cell types: keratinocytes, melanocytes, Langerhans cells, and Merkel cells. Keratinocytes are the most numerous of these cells; they are generated in the **stratum basale** and move toward the surface. As they do so, they produce the intracellular protein **keratin** and the special extracellular lipid that serves as a water barrier in the upper layers of the epidermis. Histologically, the keratinocytes are the cells that show spinous processes in the **stratum spinosum**. The other three cell types are not readily identified in hematoxylin and eosin (H&E)-stained paraffin sections. The product of the melanocyte is, however, evident in H&E sections, and this is considered in the first two figures of this plate.

The skin contains a pigment, **melanin**, which protects the tissue against the harmful effects of ultraviolet light. It is formed by the melanocytes that then pass the pigment to the keratinocytes. More pigment is present in dark skin than in light skin; this can be seen by comparing light skin (*top figure*) and dark skin (*middle figure*). The epidermis and a small amount of the dermis are shown in each figure. Whereas the deep part of the dark skin contains considerable pigment, the amount of pigment in light skin is insufficient to be noticeable at this magnification. Cells for producing the pigment are present in both skin types and in approximately equal numbers. The difference is due to more rapid digestion of the pigment by lysosomes of keratinocytes in light skin. After prolonged exposure to sunlight, pigment is also produced in sufficient amounts to be seen in light skin.

Light skin, human, H&E $\times 300$.

In routine H&E-stained paraffin sections of light skin, such as this sample, the **melanocytes** are among the cells that appear as small, rounded, clear cells (CC) mixed with the other cells of the stratum basale. However, not all clear cells of the epidermis are melanocytes. For example, Langerhans cells may also appear as clear cells, but they are located more superficially in the stratum spinosum. Merkel cells may also appear as clear cells, thus making it difficult to identify these three cell types with certainty.

Dark skin, human, H&E $\times 300$.

In dark skin, most of the pigment is in the basal portion of the epidermis, but it is also present in cells progressing toward the surface and within the nonnucleated cells of the keratinized layer. The *arrows* indicate the **melanin pigment** in keratinocytes of the stratum spinosum and in the stratum corneum. In light skin, the melanin is broken down before it leaves the upper part of the stratum spinosum. Thus, pigment is not seen in the upper layers of the epidermis.

Dermis, skin, human, H&E and elastin stain $\times 200$; inset $\times 450$.

This figure is included because it shows certain features of the dermis, the connective tissue layer of the skin. The dermis is divided into two layers: the **papillary layer (PL)** of loose connective tissue and the **reticular layer (RL)** of denser connective tissue. The papillary layer is immediately under the epidermis. It includes the connective tissue papillae that project into the undersurface of the epidermis. The **reticular layer** is deep to the papillary layer. The boundary between these two layers is not demarcated by any specific structural feature except for the change in the histologic composition of the two layers.

This specimen was stained with H&E and also with a procedure to display elastic fibers (*EF*). They are relatively thick and conspicuous in the reticular layer (see also *inset*), where they appear as dark-blue profiles, some of which are elongate, whereas others are short. In the papillary layer, the elastic fibers are thinner and relatively sparse (*arrows*). The *inset* shows the typical eosinophilic staining of the thick collagenous fibers in the reticular layer. Although the collagenous fibers at the lower magnification of this figure are not as prominent, it is nevertheless possible to note that they are thicker in the reticular layer than in the papillary layer. The papillary layer is evidently more cellular than the reticular layer. Many of the small dark-blue profiles in the reticular layer represent oblique and cross sections through elastic fibers (see *inset*) and not nuclei of cells.

CC, clear cells
EF, elastic fibers

PL, papillary layer

RL, reticular layer

arrows, middle figure, pigment in different layers of epidermis;
lower figure, delicate elastic fibers

PLATE 15.3 ■ APOCRINE AND ECCRINE SWEAT GLANDS

Skin possesses three types of glands: eccrine, apocrine, and sebaceous. Eccrine sweat glands are distributed over the entire body surface except for the lips, glans penis, prepuce, clitoris, and labia minora. They are especially numerous in the thick skin of the hands and feet. Evaporation of the secreted sweat on the skin surface cools the body.

Apocrine sweat glands are localized in the axilla, areolae, perineal and perianal area, prepuce, scrotum, mons pubis, and labia majora. Many of the epithelial cells in the secretory segment of these glands exhibit an apical bleb-like protrusion that was earlier thought to represent their mode of secretion (i.e., pinching off of the bleb as the secretory product, thus the name apocrine). It is now known that secretion occurs as a merocrine process. The secretion is a clear, viscous product that becomes odiferous through the action of resident microbes on the skin surface. In the human, its role is unclear, but it is generally believed that the secretion may act as a sex attractant (pheromone). Apocrine glands are present at birth but do not fully develop and become functional until puberty. In the female, these glands undergo changes that parallel the menstrual cycle.

ORIENTATION MICROGRAPH: The adjacent orientation micrograph of the skin of the axilla shows both the large, branched tubular apocrine glands (*A*) and the smaller, simple tubular eccrine glands (*E*) in the hypodermis (*H*). Also evident is a tangentially cut hair follicle (*HF*). The overlying dermis (*D*) consists of dense connective tissue and includes part of a sebaceous gland (*SG*).

Apocrine sweat gland, skin, human, hematoxylin and eosin (H&E) $\times 33$.

Low-power micrograph showing the secretory segment of an **apocrine sweat gland**. The sectioned profiles seen here represent several coiled branches of a single gland surrounded by dense connective tissue (*DCT*). In the *upper part* of this image are two **sweat glands** (*SwG*)

also surrounded by dense connective tissue. Note the considerable difference in diameter and lumen size of the two types of glands.

Apocrine sweat gland, skin, human, H&E ×256.

The epithelium (*Ep*) of the **apocrine sweat gland** from the *boxed area to the left* is simple columnar. The individual cells vary in height, and some show bleb-like protrusions (*B*). At the base of the epithelium are the spindle-shaped myoepithelial cells. In some regions of the tubule, these cells have been cut longitudinally and thus appear as a deeply stained eosin band (*EB*). At other sites, the cells have been sectioned tangentially and appear as a series of parallel linear profiles (*MyC*).

Eccrine sweat gland, skin, human, H&E ×256.

In this micrograph, the **eccrine sweat gland** from above is seen at higher magnification. Both secretory and duct segments are present. The **secretory segment** (*SS*) has a wider diameter and larger lumen than the duct segment (*DS*). The epithelium of the secretory segment is simple columnar; the **duct segment** is two cell layers thick, namely, stratified cuboidal. Also, the secretory segment possesses a myoepithelial component.

Eccrine sweat gland, skin, human, H&E ×512.

At this very high magnification, two cross-sectioned profiles of the secretory segment (*SS*) and one profile of the duct segment (*DS*) from the *boxed area to the left* are shown. When the tubule wall of the secretory segment is cut in a perpendicular plane, the simple columnar nature of the epithelium (*Ep*) is evident. Because the tubule is so tortuous, more often the epithelium appears to be multilayered. The **myoepithelial cells** of the secretory segment appear here both as a circumferential band (*CB*) and in a cross-sectioned array (*CA*) in which they resemble the teeth of a saw blade. Occasionally, myoepithelial cell nuclei (*MyN*) are present. Such profiles give the appearance of a pseudostratified epithelium. The duct segment (*DS*) lacks the myoepithelium and also differs in that it is stratified cuboidal. See next plate.

A, apocrine gland
B, bleb-like protrusions
CA, cross-sectioned array
CB, circumferential band
D, dermis

MyN, myoepithelial cell nuclei
SG, sebaceous gland
SS, secretory segment
SwG, sweat glands

PLATE 15.4 ■ SWEAT AND SEBACEOUS GLANDS

Normally, the body loses ~600 mL of water a day through evaporation from the lungs and skin. Under conditions of high ambient temperature, water loss is increased by an increased rate of sweating. This *thermoregulatory sweating* first occurs on the forehead and scalp, extends to the face and the rest of the body, and occurs last on the palms and soles. *Emotional sweating*, however, occurs first on the palms and soles and in the axillae. Sweating is under both nervous control through the autonomic nervous system and hormonal control.

Sebaceous glands secrete sebum, an oily substance that coats the hair and skin surface. Sebaceous secretion is a *holocrine* secretion; the entire cell produces, and becomes filled with, the fatty secretory product while it simultaneously undergoes progressive disruption, followed by apoptosis, as the product fills the cell. Both secretory product and cell debris are discharged into the pilosebaceous canal.

Sweat gland, skin, human, hematoxylin and eosin (H&E) $\times 1,000$.

This section through a sweat gland shows five profiles of the ductal portion (*D*) and two profiles of the secretory portion (*SG*). The larger secretory segment is through a region either just below or above where a U turn was made; therefore, it shows two luminal profiles.

The lumina of both the ductal and the secretory units are marked by *asterisks*.

The **glandular unit** of the eccrine sweat gland contains two epithelial cell types and myoepithelial cells (*M*). *Arrowheads* show small cross sections of myoepithelial cell cytoplasm; *large arrows* show where more elongate profiles of myoepithelial cytoplasm are evident. The epithelial cells are of two types, designated dark cells and clear cells. Unfortunately, the characteristic dark cytoplasmic staining of the dark cells is not evident unless special precautions are taken to preserve the secretory granules in their apical cytoplasm. Nevertheless, note that the dark cells are closer to the lumen, whereas the clear cells are closer to the base of the epithelial layer, making contact with either the basal lamina or, more frequently, the myoepithelial cells. In addition, the clear cells are in contact with intercellular canaliculi. Several such intercellular canaliculi are shown in the secretory units (*small arrows*). This

figure also shows that the duct consists of two layers of small cuboidal cells.

Sebaceous gland, skin, human, H&E $\times 160$.

Sebaceous glands develop from the epithelial cells of the hair follicle and discharge their secretion into the follicle, from where it reaches the skin surface. The sebaceous secretion is rich in lipid, and this is reflected in the cells of the sebaceous gland. A section of a sebaceous gland and its related hair follicle is shown in this figure. At this level, the hair follicle consists of the external root sheath (*RS*) surrounding the hair shaft. The **sebaceous gland** (*Seb*) appears as a cluster of cells known as **sebocytes**, most of which display a washed-out or finely reticulated cytoplasm. This is because these cells contain numerous lipid droplets and the lipid is lost by dissolution in fat solvents during the routine preparation of the H&E-stained paraffin section. The opening of the sebaceous gland through the external root sheath (*eRS*) and into the hair follicle is shown in the *lower right*.

Sebaceous gland, skin, human, H&E $\times 280$.

The **sebaceous gland** and **pilosebaceous canal** are shown here at higher magnification. *Numbers 1 to 4* show a series of sebocytes filled with an increasingly greater amount of lipid and progressively closer to the opening of the pilosebaceous canal (*PSC*) as it enters into the hair follicle. The sebaceous secretion includes the entire cell, and therefore, sebocytes need to be replaced constantly in the functional gland. Cells at the periphery of the gland are basal cells (*BC*). Dividing cells in the basal layer replace those that are lost with the secretion.

BC, basal cells

CT, connective tissue

D, duct of eccrine sweat gland

eRS, junction between sebaceous gland and external root sheath

small arrows, intercellular canaliculi

PLATE 15.5 ■ INTEGUMENT AND SENSORY ORGANS

The skin is endowed with numerous sensory receptors of various types. These are the peripheral terminals of sensory nerves whose cell bodies are in the dorsal root ganglia. The receptors in the skin are described as **free nerve endings** and **encapsulated nerve endings**. Free nerve endings are the most numerous. They subserve fine touch, heat, and cold and are found in the basal layers of the epidermis and as a network around the root sheath of hair follicles. Encapsulated nerve endings include **Pacinian corpuscles** (deep pressure and vibration), **Meissner corpuscles** (touch, especially in the lips and thick skin of fingers and toes), and **Ruffini corpuscles** (sustained mechanical stress on the dermis).

Motor endings of the autonomic nervous system supply the blood vessels, the arrector pili muscles, and the apocrine and eccrine sweat glands.

Skin, fingertip, human, hematoxylin and eosin (H&E) $\times 20$.

This specimen is a section of thick skin from the fingertip, showing the **epidermis** (*Ep*) and the **dermis** (*De*) and, under the skin, a portion of the **hypodermis** (*Hy*). The thickness of the epidermis is largely due to the thickness of the stratum corneum. This layer is more lightly stained than the deeper portions of the epidermis. Note, even at this low magnification, the thick collagenous fibers in the reticular layer of the dermis. **Sweat glands** (*SG*) are present in the upper part of the hypodermis, and several sweat ducts (*D*) are seen passing through the epidermis. A feature of this specimen is that it depicts those sensory receptors that can be recognized in a routine low-power H&E-stained paraffin section. They are Meissner corpuscles and Pacinian corpuscles (*PC*). Several nerve bundles (*N*) are seen in proximity to the Pacinian corpuscles. Meissner corpuscles are in the upper part of the dermis, in the dermal papillae immediately under the epidermis. These corpuscles are small and difficult to identify at this low magnification; however, their location is characteristic. Knowing where they are located is a major step in finding Meissner corpuscles in a tissue section; they are shown at higher magnification in the figure below.

Pacinian corpuscles are seen in the lower part of the hypodermis. These corpuscles are large, slightly oval structures, and even at low

magnification, a layered or lamellated pattern can be discerned.

Pacinian corpuscle, skin, human, H&E $\times 320$.

At this higher magnification, the concentric layers or lamellae of the **Pacinian corpuscle** can be seen to be due to flat cells. These are fibroblast-like cells, and although not evident within the tissue section, these cells are continuous with the perineurium of the nerve fiber. The space between the cellular lamellae contains mostly fluid. The neural portion of the Pacinian corpuscle travels longitudinally through the center of the corpuscle. In this specimen, the corpuscle has been cross-sectioned; an *arrowhead* points to the centrally located nerve fiber.

Meissner's corpuscle, skin, human, H&E $\times 190$.

This high-magnification micrograph shows portions of the *upper left* field of the figure above in which two **Meissner corpuscles (MC)** are in direct proximity to the undersurface of the epidermis in adjacent dermal papillae. The section shows the long axis of the corpuscles. A Meissner corpuscle consists of an axon (sometimes two) taking a zigzag or flat spiral course from one pole of the corpuscle to the other. The nerve fiber terminates at the superficial pole of the corpuscle. Consequently, as seen here, the nerve fibers and supporting cells are oriented approximately at right angles to the long axis of the corpuscle. Meissner corpuscles are particularly numerous near the tips of the fingers and toes.

Meissner corpuscle, skin, human, H&E $\times 550$.

At the even higher magnification of this figure, the close apposition of **Meissner corpuscle** to the undersurface of the epidermis is well demonstrated throughout the entire area of the dermal papilla. The flat spiral path of the nerve fiber (not seen) and its supporting cells is evident here, as is the fibrous capsule (FC) that surrounds the ending.

D, ducts of sweat glands

De, dermis

Ep, epidermis

FC, fibrous capsule

Hy, hypodermis

MC, Meissner corpuscles

N, nerve bundles

PC, Pacinian corpuscles

SG, sweat glands

arrowhead, nerve fiber in the center of Pacinian corpuscle

PLATE 15.6 ■ HAIR FOLLICLE AND NAIL

Hairs are composed of keratinized cells that develop from hair follicles. Hairs are present over almost the entire body, being conspicuously absent only from the sides and palmar surfaces of the hands, from the sides and plantar surfaces of the feet, from the lips, and from the skin around the urogenital orifices. Coloration of the hair is due to the content and type of melanin that it contains. The follicle varies in appearance, depending on whether it is in a growing or a resting phase; the growing follicle is the more elaborate.

The **skin appendages** (adnexa), especially hair follicles and sweat glands, are particularly important in healing of skin wounds. They serve as the source of new epithelial cells when there is extensive loss of epidermis, as in deep abrasions and second-degree burns.

Hair follicle, skin, human, hematoxylin and eosin (H&E) $\times 300$; inset $\times 440$.

The growing end of a **hair follicle** consists of an expanded bulb of epithelial cells that is invaginated by a dermal papilla (*DP*) of connective tissue. The epithelial cells surrounding the papilla at the very tip of the follicle are not yet specialized; they constitute the **hair matrix** (*HM*), the region of the hair follicle where cell division occurs. As the cells leave the matrix, they form cell layers that will become the shaft of the hair and the internal and external root sheaths of the hair follicle.

The cells that will develop into the **shaft of the hair** are seen just to the right of the expanded bulb. They constitute the cortex (*C*), medulla (*M*), and cuticle (*asterisks*) of the hair. The cells of the cortex become keratinized. This layer will come to constitute most of the hair shaft as a thick cylinder. The medulla forms the centrally located axis of the hair shaft; it does not always extend through the entire length of the hair and is absent from some hairs. The cuticle consists of overlapping cells that ultimately lose their nuclei and become filled with keratin. The cuticle covers the hair shaft like a layer of overlapping shingles.

The **root sheath** (*RS*) has two parts: the external root sheath, which is continuous with the epidermis of the skin, and the internal root sheath, which extends only as far as the level at which sebaceous

glands enter the hair follicle. The internal root sheath is further divided into three layers: Henle layer, Huxley layer, and the cuticle of the internal root sheath. These layers are seen in the growing hair follicle and are shown at higher magnification in the *inset* with numbers 1 to 5: 1, cells of the external root sheath; 2, Henle layer; 3, Huxley layer; 4, cuticle of the internal root sheath; and 5, future cuticle of the hair.

Note that many of the cells in the hair matrix (*HM*) of the growing hair follicle contain melanin produced by melanocytes. The melanin, which is transferred to the cells forming cortex and medulla of the hair shaft, contributes to the color of the hair. Most of this pigment is inside the cell (*inset*); however, in very dark hair, some pigment is also extracellular.

The connective tissue surrounding the hair follicle forms a distinct layer referred to as the *sheath*, or *dermal sheath* (*DS*), of the hair follicle.

Nail, skin, human, H&E $\times 12$.

A **nail** is a keratinized plate located on the dorsal aspect of the distal phalanges. A section through a nail plate is shown here. The **nail** itself (*N*) is difficult to stain. Under the free edge of the nail is a boundary layer, the **hyponychium** (*Hypon*), which is continuous with the stratum corneum of the adjacent epidermis. The proximal end of the nail is overlapped by skin; here, the junctional region is called the **eponychium** (*Epon*) and is also continuous with the stratum corneum of the adjacent epidermis. Under the nail is a layer of epithelium, the proximal portion of which is referred to as the **nail matrix** (*NM*). The cells of the nail matrix function in the growth of the nail. Together, the epithelium under the nail and the underlying dermis (*D*) constitute the nail bed. The proximal portion of the nail, covered by the fold of the skin, is the root of the nail (*NR*).

The relationship of the nail to other structures in the fingertip is also shown in this figure. The bone (*B*) in the specimen represents a distal phalanx. Note that in this bone, there is an epiphyseal growth plate (*EP*) at the proximal extremity of the bone but not at the distal extremity. Numerous Pacinian corpuscles (*PC*) are present in the connective tissue of the palmar side of the finger. Also seen to advantage in this section is the stratum lucidum (*SL*) in the epidermis of the thick skin of the fingertip.

HISTOLOGY

■ OVERVIEW OF THE DIGESTIVE SYSTEM

The **digestive system** consists of the **alimentary canal** and its principal **associated organs**, namely, the tongue, teeth, salivary glands, pancreas, liver, and gallbladder. Major functions of the digestive system include transport of ingested

water and food along the alimentary canal; secretion of fluids, electrolytes, and digestive enzymes; digestion and absorption of digested products; and excretion of indigestible remains.

The lumen of the alimentary canal is physically and functionally external to the body.

As it passes through the alimentary canal, food is broken down physically and chemically so that the degraded products can be absorbed into the body. The various segments of the **alimentary canal** are morphologically specialized for specific aspects of digestion and absorption.

Approximately 2 L of water and food are ingested into the body each day (Fig. 16.1). After preliminary maceration, moistening, and formation into a **bolus** by the actions of the structures of the oral cavity and by secretion of the salivary glands, food passes rapidly through the pharynx to the esophagus. The rapid passage of food through the pharynx ensures that only a brief interruption occurs in the airway for passage of air. The food passes more slowly through the **gastrointestinal tract**, aided by the secretion of digestive juices that may amount to 7 L or so per day. During food transit through the stomach and small intestine, the major alterations associated with digestion, solubilization, and absorption occur. Most of these fluids and nutrients are absorbed chiefly through the wall of the small intestine, but a small portion is absorbed in the large intestine (see Fig. 16.1). **Undigested food** and other substances within the alimentary canal, such as mucus, bacteria, desquamated cells, and bile pigments, are excreted as solids (**feces**).

FIGURE 16.1. The alimentary canal and its function in secretion and absorption of fluids. This schematic diagram shows regions of the alimentary canal with associated exocrine glands that contribute to secretion of digestive juices. Almost all of the absorption of fluids, electrolytes, and nutrients occurs in the small intestine.

The alimentary mucosa is the surface across which most substances enter the body.

The alimentary **mucosa** performs numerous functions in its role as an interface between the body and the environment. These functions include the following:

- **Secretion.** The lining of the alimentary canal secretes, at specific sites, digestive enzymes, hydrochloric acid, mucin, and antibodies.
- **Absorption.** The epithelium of the mucosa absorbs metabolic substrates (e.g., the breakdown products of digestion) as well as vitamins, water, electrolytes, recyclable materials such as bile components and cholesterol, and other substances essential to the functions of the body.
- **Barrier.** The mucosa serves as a barrier to prevent the entry of noxious substances, antigens, and pathogenic organisms.
- **Immunologic protection.** Lymphatic tissue within the mucosa serves as the body's first line of immune defense.

The functions listed earlier are discussed at the beginning of the next chapter (see page 632). The digestive system is considered in three chapters that deal, respectively, with the oral cavity and pharynx (this chapter); the esophagus and gastrointestinal tract (see Chapter 17, Digestive System II: Esophagus and Gastrointestinal Tract, page 632); and the liver, gallbladder, and pancreas (see Chapter 18, Digestive System III: Liver, Gallbladder, and Pancreas, page 692).

■ ORAL CAVITY

The oral cavity consists of the mouth and its structures, which include the tongue, teeth, and their supporting

structures (periodontium); major and minor salivary glands; and tonsils.

The **oral cavity** is divided into a vestibule and the oral cavity proper. The **vestibule** is the space between the lips, cheeks, and teeth. The **oral cavity proper** lies behind the teeth and is bounded by the hard and soft palates superiorly, the tongue and the floor of the mouth inferiorly, and the entrance to the oropharynx posteriorly.

The three **major salivary glands** are paired structures, including:

- **Parotid gland**, the largest of the three glands, located in the infratemporal region of the head. Its excretory duct, the parotid (Stensen) duct, opens at the parotid papilla, a small elevation on the mucosal surface of the cheek opposite the second upper molar tooth.
- **Submandibular gland**, located in the submandibular triangle of the neck. Its excretory duct, the submandibular (Wharton) duct, opens at a small fleshy prominence (the sublingual caruncle) on each side of the lingual frenulum on the floor of the oral cavity.
- **Sublingual gland**, lying inferior to the tongue within the sublingual folds at the floor of the oral cavity. It has a number of small excretory ducts; some enter the submandibular duct, and others enter individually into the oral cavity.

The parotid and submandibular glands have relatively long ducts that extend from the secretory portion of the gland to the oral cavity. The sublingual ducts are relatively short.

The **minor salivary glands** are located in the submucosa of the oral cavity. They empty directly into the cavity via short ducts and are named for their location (i.e., buccal, labial, lingual, and palatine).

The tonsils consist of aggregations of lymphatic nodules that are clustered around the posterior opening of the oral and nasal cavities.

Lymphatic tissue is organized into a **Waldeyer tonsillar ring** of immunologic protection located at the shared entrance to the digestive and respiratory tracts. This lymphatic tissue surrounds the posterior orifice of the oral and nasal cavities and contains aggregates of lymphatic nodules that include the following:

- **Palatine tonsils**, or simply the **tonsils**, which are located at either side of the entrance to the oropharynx between the palatopharyngeal and palatoglossal arches
- **Tubal tonsils**, which are located in the lateral walls of the nasopharynx posterior to the opening of the auditory tube
- **Pharyngeal tonsil**, or **adenoid**, which is located on the roof of the nasopharynx
- **Lingual tonsil**, which is located at the base of the tongue on its superior surface

The oral cavity is lined by the oral mucosa that consists of masticatory mucosa, lining mucosa, and specialized mucosa.

The **masticatory mucosa** is found on the gingiva (gums) and the hard palate (Fig. 16.2). It has a **keratinized** and, in some areas, a **parakeratinized stratified squamous epithelium**. Parakeratinized epithelium is similar to keratinized epithelium, except that the superficial cells do not lose their nuclei and their cytoplasm does not stain intensely with eosin (Plate 16.1, page 620). The nuclei of the parakeratinized cells are pyknotic (highly condensed) and remain until the cell is exfoliated (Fig. 16.3). The keratinized epithelium of the masticatory mucosa resembles that of the skin but lacks a stratum lucidum. The underlying **lamina propria** consists of a thick papillary layer of loose connective tissue that contains blood vessels and nerves, some of which send bare axon endings into the epithelium as sensory receptors, and some of which end in Meissner corpuscles. Deep to the lamina propria is a reticular layer of denser connective tissue.

FIGURE 16.2. Roof of the oral cavity. The hard palate, which contains bone, is bisected into right and left halves by a raphe. Anteriorly, in the fatty zone, the submucosa of the hard palate contains adipose tissue; posteriorly, in the glandular zone, there are mucous glands within the submucosa. Neither the raphe nor the gingiva contains a submucosa; instead, the mucosa is attached directly to the bone. The soft palate has muscle instead of bone, and its glands are continuous with those of the hard palate in the submucosa.

FIGURE 16.3. Stratified squamous epithelium at the mucocutaneous junction of the lip. This photomicrograph shows a transition in the oral mucosa from a stratified squamous epithelium (*on the right*) to a stratified squamous parakeratinized epithelium (*on the left*). The flattened surface cells of the keratinized epithelium are devoid of nuclei. The layer of keratohyalin granule-containing cells is clearly visible in this type of epithelium. The flattened surface cells of the parakeratinized epithelium display the same characteristics as the keratinized cells, except they retain their nuclei, that is, they are parakeratinized. In addition, note the paucity of keratohyalin granules present in the subsurface cells. $\times 380$.

As in the skin, the depth and number of connective tissue papillae contribute to the relative immobility of the masticatory mucosa, thus protecting it from frictional and shearing stress. At the midline of the hard palate, in the **palatine raphe**, the mucosa adheres firmly to the underlying

bone. The **reticular layer** of the lamina propria blends with the periosteum; thus, there is no submucosa. The same is true of the gingiva. Where there is a submucosa underlying the lamina propria on the hard palate (see Fig. 16.2), it contains adipose tissue anteriorly (fatty zone) and mucous glands posteriorly (glandular zone) that are continuous with those of the soft palate. In the submucosal regions, thick collagenous bands extend from the mucosa to the bone.

Lining mucosa is found on the lips, cheeks, alveolar mucosal surface, floor of the mouth, inferior surfaces of the tongue, and soft palate. At these sites, it covers striated muscle (lips, cheeks, and tongue), bone (alveolar mucosa), and glands (soft palate, cheeks, inferior surface of the tongue). The lining mucosa has fewer and shorter papillae so that it can adjust to the movement of its underlying muscles.

Generally, the epithelium of the lining mucosa is nonkeratinized, although, in some places, it may be parakeratinized (see Fig. 16.3). The epithelium of the vermilion border of the lip (the reddish portion between the moist inner surface and the facial skin) is keratinized. The nonkeratinized lining epithelium is thicker than keratinized epithelium. It consists of only three layers:

- **Stratum basale**, a single layer of cells resting on the basal lamina
- **Stratum spinosum**, which is several cells thick
- **Stratum superficiale**, the most superficial layer of cells, also referred to as the *surface layer of the mucosa*

The cells of the mucosal epithelium are similar to those of the epidermis of the skin and include keratinocytes, Langerhans cells, melanocytes, and Merkel cells.

The lamina propria contains blood vessels, nerves that send bare axon endings into the basal layers of the epithelium, and encapsulated sensory endings in some papillae. The sharp contrast between the numerous deep papillae of the alveolar mucosa and the shallow papillae in the rest of the lining mucosa allows easy identification of the two different regions in a histologic section.

Because it is highly vascularized, absorption of drugs through the oral mucosa is often used as an alternative method of systemic drug delivery. Oral transmucosal delivery offers several advantages because the absorbed substance directly enters the systemic circulation, bypassing the gastrointestinal tract and portal circulation, thus bypassing metabolism in the liver. Several cardiovascular drugs, such as nitroglycerin; analgesics; sedatives; antinausea drugs; drugs for erectile dysfunction; and hormonal drugs are available as oral transmucosal formulations. Some of these medications are administered by placement under the tongue (sublingual administration); other medications are administered by placement between the cheek and gum (buccal administration).

A distinct **submucosa** underlies the lining mucosa, except on the inferior surface of the tongue. This layer contains large bands of collagen and elastic fibers that bind the mucosa to the underlying muscle; it also contains the many minor salivary glands of the lips, tongue, and cheeks. Occasionally, **sebaceous glands** not associated with a hair follicle are found in the submucosa just lateral to the corner of the mouth and in the cheeks opposite the molar teeth. They are visible to the eye and are called **Fordyce spots**. The submucosa contains the larger blood vessels, nerves, and lymphatic vessels that supply the subepithelial neurovascular networks in the lamina propria throughout the oral cavity.

Specialized mucosa is associated with the sensation of taste and is restricted to the dorsal surface of the tongue. It contains papillae and **taste buds** responsible for generating the chemical sensation of taste.

Oral mucosa forms an important **protective barrier** between the external environment of the oral cavity and the internal environments of the surrounding tissues. It is resistant to the pathogenic organisms that enter the oral cavity and to indigenous microorganisms residing there as microbial flora. Epithelial cells, migratory neutrophils, and saliva all contribute to maintaining the health of the oral cavity and protecting the oral mucosa from bacterial, fungal, and viral infections. The protective mechanisms include several **salivary antimicrobial peptides**, β -defensins expressed in the

epithelium, α -defensins expressed by neutrophils, and secretory immunoglobulin A (sIgA). However, in individuals with immunodeficiency or those undergoing antibiotic therapy, in which the balance between microorganisms and protective mechanisms is disrupted, oral infections are rather common.

■ TONGUE

The **tongue** is a muscular organ projecting into the oral cavity from its inferior surface. **Lingual muscles** (i.e., muscles of the tongue) are both extrinsic (having one attachment outside the tongue) and intrinsic (confined entirely to the tongue, without external attachment). The striated muscle of the tongue is arranged in bundles that generally run in three planes. They are divided into longitudinal, vertical, and transverse muscles, with each arranged at right angles to the other two. This arrangement of tongue muscles can be most clearly seen in the frontal section of the fetal head (Fig. 16.4a) and permits enormous flexibility and precision in the movements of the tongue, which are essential to human speech and its role in digestion and swallowing. This unique form of muscle organization is found only in the tongue, which allows easy identification of this tissue as lingual muscle. Variable amounts of adipose tissue are found among the muscle fiber groups (Fig. 16.4b).

FIGURE 16.4. Muscle organization in the developing and adult human tongue. a. This photomicrograph of Mallory trichome-stained

specimen shows the frontal section of the fetal head at the level of the developing oral cavity. The cross section of the tongue shows the organization of intrinsic muscles into longitudinal bundles (just deep to the surface of the tongue), transverse bundles (connecting lateral surfaces of the tongue), and vertical bundles (connecting superior [dorsal] surface with the base of the tongue). The extrinsic muscles attach the tongue into the floor of the mouth. Note the mandible on both sides of the tongue and the maxilla above with developing teeth (*DT*). $\times 40$. b. This sagittal section of the hematoxylin and eosin (H&E)-stained tongue shows the unique arrangement of visceral striated muscle within the body of the tongue. All three directions of muscle fibers are visible, including cross-sectional profiles of transverse muscles and longitudinal profiles of both vertical and longitudinal muscles. In the *upper left corner*, note a small artery and nerve (*circled by dashed line*) next to accumulations of adipocytes. Nerve bundles are often visible between muscle fibers. $\times 380$. (Courtesy Dr. Frank Daley, University of New England College of Osteopathic Medicine.)

Grossly, the **dorsal surface of the tongue** is divided into an anterior two-thirds and a posterior one-third by a V-shaped depression, the **sulcus terminalis** (Fig. 16.5). The apex of the V points posteriorly and is the location of the **foramen cecum**, the remnant of the site from which an evagination of the floor of the embryonic pharynx occurred to form the thyroid gland.

FIGURE 16.5. Human tongue. Circumvallate papillae are positioned in a V configuration, separating the anterior two-thirds of the tongue from the posterior third. Fungiform and filiform papillae are located on the anterior portion of the dorsal tongue surface. The uneven contour of the posterior tongue surface is attributable to the lingual tonsils. The palatine tonsil is at the junction between the oral cavity and the pharynx.

Papillae cover the dorsal surface of the tongue.

Numerous mucosal irregularities and elevations called **lingual papillae** cover the dorsal surface of the tongue anterior to the sulcus terminalis. The lingual papillae and their associated taste buds constitute the **specialized mucosa** of the oral cavity. Four types of papillae are described: filiform, fungiform, circumvallate, and foliate.

- **Filiform papillae** are the smallest and most numerous in humans. They are conical, elongated projections of connective tissue that are covered with highly keratinized stratified squamous epithelium (Fig. 16.6a and Plate 16.2, page 622). This epithelium does not contain taste buds. The papillae serve only a mechanical role. Filiform papillae are distributed over the entire anterior dorsal surface of the tongue, with their tips pointing backward. They appear to form rows that diverge to the left and right from the midline and that parallel the arms of the sulcus terminalis.

FIGURE 16.6. Lingual papillae. a. Structurally, the filiform papillae are posteriorly bent conical projections of the epithelium. These papillae do not possess taste buds and are composed of stratified squamous keratinized epithelium. $\times 45$. b. Fungiform papillae are slightly rounded, elevated structures situated among the filiform papillae. A highly vascularized connective tissue core forms the center of the fungiform papilla and projects into the base of the surface epithelium. Because of the deep penetration of connective tissue into the epithelium (*arrows*), combined with a very thin keratinized surface, the fungiform papillae appear as small red dots when the dorsal surface of the tongue is examined by gross inspection. $\times 45$. c. In a section, foliate papillae can be distinguished from fungiform papillae because they appear in rows separated by deep clefts (*arrows*). The foliate papillae are covered by stratified squamous nonkeratinized epithelium containing numerous taste buds on their lateral surfaces. The free surface epithelium of each papilla is thick and has a number of secondary connective tissue papillae projecting into its undersurface. The connective tissue within and under the foliate papillae contains serous glands (von Ebner glands) that open via ducts into the cleft between neighboring papillae. $\times 45$. d. Circumvallate papillae are covered by stratified squamous epithelium that may be slightly keratinized. Each circumvallate papilla is surrounded by a trench or cleft. Numerous taste buds are on the lateral walls of the papillae. The

dorsal surface of the papilla is smooth. The deep trench surrounding the circumvallate papillae and the presence of taste buds on the sides rather than on the free surface are features that distinguish circumvallate from fungiform papillae. The connective tissue near the circumvallate papillae also contains many serous-type glands that open via ducts into the bottom of the trench. $\times 25$.

- **Fungiform papillae**, as the name implies, are mushroom-shaped projections located on the dorsal surface of the tongue (Fig. 16.6b). They project above the filiform papillae, among which they are scattered, and are just visible to the unaided eye as small spots (see Fig. 16.5 and Plate 16.2, page 622). They tend to be more numerous near the tip of the tongue. **Taste buds** are present in the stratified squamous epithelium on the dorsal surface of these papillae.
- **Circumvallate papillae** are large, dome-shaped structures that reside in the mucosa just anterior to the sulcus terminalis (see Fig. 16.5). The human tongue has 8–12 of these papillae. Each papilla is surrounded by a moat-like invagination lined with stratified squamous epithelium that contains numerous taste buds (Fig. 16.6d). Ducts of **lingual salivary (von Ebner) glands** empty their serous secretion into the base of the moats. This secretion presumably flushes material from the moat to enable the taste buds to respond rapidly to changing stimuli.
- **Foliate papillae** consist of parallel low ridges separated by deep mucosal clefts (see Fig. 16.6c and Plate 16.3, page 624), which are aligned at right angles to the long axis of the tongue. They occur on the lateral edge of the tongue. In older individuals, the foliate papillae may not be recognized; in younger individuals, they are easily found on the posterior lateral surface of the tongue and contain many taste buds in the epithelium of the facing walls of neighboring papillae (see Fig. 16.5). Small serous glands empty into the clefts. In some animals, such as the rabbit, foliate papillae constitute the principal site of aggregation of taste buds.

The dorsal surface of the base of the tongue exhibits smooth bulges that reflect the presence of the lingual tonsil in the

lamina propria (see Fig. 16.5).

Taste buds are present on fungiform, foliate, and circumvallate papillae.

Humans have approximately 5,000 - 10,000 taste buds, of which about half are located on the sides of circumvallate papillae. In histologic sections, **taste buds** appear as oval, pale-staining bodies that extend through the thickness of the epithelium (Fig. 16.7). A small opening onto the epithelial surface at the apex of the taste bud is called the **taste pore**.

FIGURE 16.7. Diagram and photomicrograph of a taste bud. a. This diagram of a taste bud shows the neuroepithelial (sensory), supporting, and basal cells. One of the basal cells is shown in the process of dividing. Nerve fibers have synapses with the neuroepithelial cells. (Based on Warwick R, Williams PL, eds. *Gray's Anatomy*. 35th ed. Churchill Livingstone; 1973.) b. This high-magnification photomicrograph shows the organization of the cells within the taste bud. The sensory and supporting cells extend through the full length of the taste bud. The apical surface of these cells contains microvilli. The basal cells are located at the bottom of the

taste bud. Note that the taste bud opens at the surface by means of a taste pore. $\times 1,100$.

Three principal cell types are found in taste buds:

- **Neuroepithelial (sensory) cells** are the most numerous cells in the taste bud. These elongated cells extend from the basal lamina of the epithelium to the taste pore, through which the tapered apical surface of each cell extends microvilli (see Fig. 16.7). Near their apical surface, they are connected to neighboring neuroepithelial or supporting cells by tight junctions. At their base, they form a synapse with the processes of afferent sensory neurons of the **facial** (cranial nerve VII), **glossopharyngeal** (cranial nerve IX), or **vagus** (cranial nerve X) nerves. The turnover time of neuroepithelial cells is about 10 - 14 days.
- **Supporting cells** are less numerous. They are also elongated cells that extend from the basal lamina to the taste pore. Like neuroepithelial cells, they contain microvilli on their apical surface and possess tight junctions, but they do not synapse with the nerve cells. The turnover time of supporting cells is also about 10 days.
- **Basal cells** are small cells located in the basal portion of the taste bud, near the basal lamina. They are the stem cells for the two other cell types.

In addition to those associated with the papillae, taste buds are also present on the glossopalatine arch, the soft palate, the posterior surface of the epiglottis, and the posterior wall of the pharynx down to the level of the cricoid cartilage.

Taste is a chemical sensation in which various chemicals elicit stimuli from neuroepithelial cells of taste buds.

Taste is characterized as a chemical sensation in which various **tastants** (taste-stimulating substances) in food or beverages interact with taste receptors located at the apical surface of the neuroepithelial cells. There are three types of neuroepithelial cells that react to five basic stimuli: Type I

reacts to **salty** taste; type II reacts to **sweet**, **bitter**, and **umami** [*Jap. delicious*] tastes; and type III detects **sour** taste. All taste buds have the same three neuroepithelial cell types; however, their ratios in different regions of the tongue vary. The molecular action of tastants can involve opening and passing through ion channels (i.e., salt and sour), closing ion channels (sour), or acting on a specific G-protein-coupled taste receptor (i.e., bitter, sweet, and umami).

Loss or changes in taste (ageusia or dysgeusia) are unique clinical symptoms reported by individuals infected by the SARS-CoV-2 (COVID-19) virus. These taste abnormalities frequently coexist with smell disorders (see Chapter 19, Respiratory System, page 735). Expression of angiotensin-converting enzyme 2 (ACE2) on the cell surface is responsible for the cellular entry of the SARS-CoV-2 virus. Once the viral spike protein binds to ACE2, more spike proteins are activated by transmembrane protease serine 2 (TMPRSS2), thereby facilitating viral entry. In the tongue, both ACE2 and TMPRSS2 proteins are coexpressed in the taste buds of lingual papillae. ACE2 expression has not been found in the neurons or ganglia of nerves innervating neuroepithelial cells. A recent study localized coexpression of ACE2 and TMPRSS2 proteins to type II neuroepithelial cells, which have **sweet**, **bitter**, and **umami** taste receptors. Taste receptor types I and II for salty and sour taste, respectively, are not involved in the replication of the SARS-CoV-2 virus. Direct injury to type II neuroepithelial cells may explain the high incidence of ageusia or dysgeusia in individuals with SARS-CoV-2 infection. Almost 90% of patients regain taste function in 4–15 days, which is compatible with the life span of the neuroepithelial cells.

Stimulation of bitter, sweet, and umami receptors activates G-protein-coupled taste receptors that belong to T1R and T2R chemosensory receptor families.

Bitter, sweet, and umami tastes in type II neuroepithelial cells are detected by a variety of receptor proteins encoded by two **taste receptor genes (T1R and T2R)**. Their products are characterized as **G-protein-coupled taste receptors**.

- **Bitter taste** is detected by about 30 different types of **T2R chemosensory receptors**. Each receptor represents a single transmembrane protein coupled to its own **G-protein**. After receptor activation by the tastant, the G-protein stimulates the enzyme phospholipase C, leading to increased intracellular production of **inositol 1,4,5-trisphosphate (IP₃)**, a second messenger molecule. IP₃, in turn, activates **taste-specific Na⁺ channels** causing an influx of Na⁺ ions, thus depolarizing the neuroepithelial cell. Depolarization of the plasma membrane causes **voltage-gated Ca²⁺ channels** in neuroepithelial cells to open. An increase in the concentration of intracellular Ca²⁺ levels, either by an influx of extracellular Ca²⁺ into the cell (the effect of depolarization) or by its release from intracellular stores (direct IP₃ stimulation), results in the release of neurotransmitter molecules, which generate nerve impulses along the gustatory afferent nerve fiber (Fig. 16.8a).

FIGURE 16.8. Diagram of taste receptors and their signaling mechanisms. a. This diagram shows the signaling mechanism of

bitter, sweet, and umami receptors in the neuroepithelial cells. These cells selectively express only one class of receptor proteins; for simplicity, all three taste receptors are depicted in the apical cell membrane. See text for details. **b.** Signaling mechanism for the sour sensation is generated by H^+ protons that primarily block K^+ channels. The H^+ protons enter the cell via amiloride-sensitive Na^+ channels and through taste-specific H^+ channels (PKD1L3 and PKD2L1) exclusively expressed in cells involved in sour taste transduction. **c.** Salty sensation is generated from Na^+ ions that enter the neuroepithelial cells through amiloride-sensitive Na^+ channels. Intracellular Na^+ causes a depolarization of the membrane and activation of additional voltage-sensitive Na^+ and Ca^{2+} channels. Calcium-mediated release of neurotransmitters from synaptic vesicles results in the stimulation of gustatory nerve fibers. IP_2 , inositol-1,4-diphosphate; IP_3 , inositol 1,4,5-trisphosphate; PLC , phospholipase C.

- **Sweet taste** receptors are also G-protein-coupled receptors. In contrast to bitter taste receptors, they have two protein subunits, **T1R2** and **T1R3**. The sweet tastants bound to these receptors activate the same second messenger system cascade of reactions that the bitter receptors do (see Fig. 16.8a).
- **Umami taste** is linked to certain amino acids (e.g., L-glutamate, aspartate, and related compounds) and is common to asparagus, tomatoes, cheese, and meat. Umami taste receptors are very similar to sweet receptors; they are also composed of two subunits. One subunit, **T1R3**, is identical to that in the sweet receptor, but the second subunit formed by the **T1R1** protein is unique for umami receptors (see Fig. 16.8a). The transduction process is identical to that described previously for bitter taste pathways. Monosodium glutamate, added to many foods to enhance their taste (and the main ingredient of soy sauce), stimulates umami receptors.

The mechanism of transduction can be similar to several tastes (i.e., bitter or sweet); however, it is important to remember that neuroepithelial cells selectively express only one class of receptor proteins. Therefore, the messages about bitterness or sweetness from eating food are transferred to the central nervous system (CNS) along different nerve fibers.

Sodium ions and hydrogen protons, which are responsible for salty and sour taste, respectively, act directly on ion channels.

Signaling mechanisms, in the case of sour and salty tastes, are similar to other signaling mechanisms found in synapses and neuromuscular junctions.

- **Sour taste** in type III neuroepithelial cells is generated by H^+ protons that are formed by hydrolysis of acidic compounds. The H^+ proton primarily blocks **K^+ channels** that are responsible for generating the cell membrane potential that causes depolarization of the cell membrane. In addition, H^+ protons enter the cell through **amiloride-sensitive Na^+ channels** and through specification channels, called *PKD1L3* and *PKD2L1*, found in neuroepithelial cells exclusively involved in sour taste transduction. The entry of H^+ into the receptor cell activates **voltage-sensitive Ca^{2+} channels**. Influx of Ca^{2+} triggers migration of synaptic vesicles, their fusion, and transmitter release, which results in generating action potentials in apposed sensory nerve fiber (Fig. 16.8b).
- **Salty taste** that is stimulated by table salt ($NaCl$) is essentially derived from the taste of the sodium ions. The Na^+ enters the type I neuroepithelial cells through specific **amiloride-sensitive Na^+ channels** (the same that are involved in sour taste transmission). These channels are different from voltage-sensitive Na^+ channels that generate action potentials in nerve or muscle cells. The entry of Na^+ into a receptor cell causes depolarization of its membrane and activation of additional **voltage-sensitive Na^+ channels and voltage-sensitive Ca^{2+} channels**. As previously described, an influx of Ca^{2+} triggers migration and release of neurotransmitter from synaptic vesicles, which results in stimulating gustatory nerve fibers (Fig. 16.8c).

Some areas of the tongue are more responsive to certain tastes than others.

In general, taste buds at the tip of the tongue detect sweet stimuli, those immediately posterolateral to the tip detect salty stimuli, and those more posterolateral detect sour-tasting stimuli. Taste buds on the circumvallate papillae detect bitter and umami stimuli. However, studies with thermal stimulation of the tongue have shown that the classic taste maps as described earlier represent an oversimplified view of the distribution of taste receptors. Sensitivity to all tastes is distributed across the entire tongue, but some areas are more responsive to certain tastes than others.

The lingual tonsil consists of accumulations of lymphatic tissue at the base of the tongue.

The **lingual tonsil** is located in the lamina propria of the root or base of the tongue. It is found posterior to the sulcus terminalis (see Fig. 16.5). The lingual tonsil contains diffuse lymphatic tissue with lymphatic nodules containing germinal centers. These structures are discussed in Chapter 14, Immune System and Lymphatic Tissues and Organs (page 505).

FOLDER 16.1

CLINICAL CORRELATION: THE GENETIC BASIS OF TASTE

The general ability to taste as well as the ability to sense specific tastes are genetically determined. Studies in large populations demonstrate that taste variation is common. About 25% of the population, referred to as “**supertasters**,” have more than the normal number of lingual papillae and a high density of taste buds. Rare individuals in this group, such as wine, brandy, coffee, or tea tasters, have prodigious taste discrimination and taste memory. These individuals are characterized by their extreme sensitivity to the chemical phenylthiocarbamide (PTC) and its derivative 6-*N*-propylthiouracil (PROP); they typically report an intensely bitter taste after a drop of PTC/PROP solution is placed on the tip of their tongue. On the other side of the spectrum (about 25% of the population) are individuals known as “**nontasters**,” with a smaller-than-normal number of lingual papillae and a lower density of taste buds. When tested with PTC/PROP solution, these individuals are unaware of its bitter taste.

Many clinical conditions can affect taste perception. They include lesions in the nerves that transmit the taste sensation to the central nervous system (i.e., facial nerve, chorda tympani, and

lingual nerve); inflammations of the oral cavity; mucosal disorders, including radiation-induced inflammation of the lingual mucosa; nutritional deficiencies; endocrine disorders such as diabetes mellitus, hypogonadism, and pseudohypoparathyroidism; and hormonal fluctuations during menstruation and pregnancy. Some rare genetic disorders also affect taste sensation. **Type I familial dysautonomia (Riley - Day syndrome)** causes severe hypogeusia (decreased ability to detect taste) because of the developmental absence of taste buds and fungiform papillae. This sensory and autonomic neuropathy is an autosomal recessive disorder caused by a mutation in the DYS gene (also referred to as the IKBKAP gene) located on chromosome 9. In addition to hypogeusia, these individuals experience other symptoms related to developmental defects in the peripheral and autonomic nervous systems, including diminished lacrimation, defective thermoregulation, orthostatic hypotension, excessive sweating, loss of pain and temperature sensation, and absent reflexes. A test that detects the causative mutation in the DYS gene can be used to confirm the diagnosis of familial dysautonomia.

Epithelial crypts usually invaginate into the lingual tonsil. However, the structure of the epithelium may be difficult to distinguish because of the extremely large number of lymphocytes that normally invade it. Between nodules, the lingual epithelium has the characteristics of lining epithelium. Mucous lingual salivary glands may be seen within the lingual tonsil and may extend into the muscle of the base of the tongue.

The complex nerve supply of the tongue is provided by cranial nerves and the autonomic nervous system.

- **General sensation** for the anterior two-thirds of the tongue (anterior to the sulcus terminalis) is carried in the **mandibular division of the trigeminal nerve** (cranial nerve V). General sensation for the posterior one-third of the tongue is carried in the **glossopharyngeal nerve** (cranial nerve IX) and the **vagus nerve** (cranial nerve X).
- **Taste sensation** is carried by the **chorda tympani**, a branch of the facial nerve (cranial nerve VII) anterior to the sulcus terminalis, and by the **glossopharyngeal nerve** (cranial nerve IX) and **vagus nerve** (cranial nerve X) posterior to the sulcus.

- **Motor innervation** for the musculature of the tongue is supplied by the **hypoglossal nerve** (cranial nerve XII).
- Vascular and glandular innervation is provided by the **sympathetic** and **parasympathetic nerves**. They supply blood vessels and small salivary glands of the tongue. Ganglion cells are often seen within the tongue. These cells belong to postsynaptic parasympathetic neurons and are destined for the minor salivary glands within the tongue. The cell bodies of sympathetic postsynaptic neurons are located in the superior cervical ganglion.

■ TEETH AND SUPPORTING TISSUES

Teeth are a major component of the oral cavity and are essential for initiating the digestive process. Teeth are embedded in and attached to the alveolar processes of the maxilla and mandible. Children have 10 **deciduous (primary, milk) teeth** in each jaw on each side:

- A **medial (central) incisor**, the first tooth to erupt (usually in the mandible) at approximately 6 months of age (in some infants, the first teeth may not erupt until 12 or 13 months of age)
- A **lateral incisor**, which erupts at approximately 8 months
- A **canine tooth**, which erupts at approximately 15 months
- Two **molar teeth**, the first of which erupts at 10–19 months and the second of which erupts at 20–31 months

During a period of years, usually beginning at about age 6 and ending at about age 12 or 13, deciduous teeth are gradually replaced by 16 **permanent (secondary) teeth** in each jaw (Folder 16.2). Each side of both the upper and lower jaws consists of the following:

FOLDER 16.2

CLINICAL CORRELATION: CLASSIFICATION OF PERMANENT (SECONDARY) AND DECIDUOUS (PRIMARY) DENTITION

Three systems (dental notations) are currently used to classify permanent and deciduous teeth (Fig. F16.2.1):

FIGURE F16.2.1. Classification of permanent and deciduous teeth. Three systems of tooth classification are used. The *central panel* of the diagram shows the permanent teeth, whereas the *upper and lower panels* show the deciduous teeth. Dentition is divided into four quadrants: upper left (UL), upper right (UR), lower left (LL), and lower right (LR). Each quadrant includes eight permanent teeth or five deciduous teeth. In the American (universal) system (blue), permanent teeth are designated with Arabic numerals. The numbering begins from the wisdom tooth in the upper right quadrant designated as tooth number 1 and continues along all the teeth in the maxilla to tooth number 16, which designates the third upper left molar. The numbering progresses to the mandible, beginning at the third left lower molar designated as number 17 to the third lower right molar designated as number 32. In the American system, deciduous teeth are marked with capital letters designated for each

tooth. The pattern is the same as that for permanent teeth, so the numbering begins from the second upper right molar and finishes with the second lower right molar. In the International system (*red*), also referred to as the *two-digit system*, each tooth is designated with two numbers: The first number indicates the dentition quadrant, which is marked from 1 to 4 and from 5 to 8 in a clockwise direction beginning from the upper right quadrant for permanent and deciduous teeth, respectively. The second number specifies individual teeth in each quadrant beginning from the midline, where the medial incisors are designated as number 1 and third molars are designated as number 8. In the Palmer system (*yellow*), the dentition is divided into four quadrants with a right-angle bracket. The *vertical line* of the bracket divides the dentition into a right and a left side beginning at the midline. The *horizontal line* of the bracket divides the dentition into the upper and lower parts to designate teeth in the maxilla and mandible. In the Palmer system, permanent teeth are numbered with Arabic numerals beginning from the midline. The deciduous teeth are marked with capital letters, also starting from the midline. To mark a particular tooth with the Palmer system, two lines (vertical and horizontal) and the correct number or letter of the tooth are needed. (Table design courtesy of Dr. Wade T. Schultz.)

- *Palmer system (military system)*, which is primarily used in the United Kingdom. In this system, uppercase letters are used for the deciduous teeth, and Arabic numerals are used for the permanent teeth. Each quadrant in this system is designated by angled line symbols (┘, └, ┐, ┌): ┘ for upper right (UR), └ for upper left (UL), ┐ for lower right (LR), and ┌ for lower left (LL). For example, permanent canines are called number 3 in each quadrant, and the quadrant is designated by its angled line. In the era of electronic medical records, Palmer notation symbols are encoded in the standard Unicode transformation format (UTF-16), which has been employed in modern operating systems and programming languages.
- *International system (World Dental Federation [FDI] system or ISO 3950)*, which is the most commonly used notation worldwide, except the United States, which uses the American (universal) system, and the United Kingdom, where the Palmer notation is frequently used. The International system uses two Arabic numerals to designate the individual tooth. In this system, the first numeral indicates the location of the tooth in a specific quadrant. The permanent quadrants are designated UR = 1, UL = 2, LL = 3, and LR = 4; the deciduous quadrants are designated UR = 5, UL = 6, LL = 7, and LR = 8. The second numeral designates the individual tooth, which is numbered beginning from the dental midline. For example, in this system,

the permanent canines are named 13, 23, 33, and 43, and the deciduous canines would be 53, 63, 73, and 83.

- *American system (Universal system, UNS)*, which is the most commonly used notation in North America. In this system, the permanent dentition is designated by Arabic numerals, and the deciduous dentition is designated with uppercase letters. For permanent dentition, numbering begins in the UR quadrant, with the UR third molar designated number 1. Numbering continues across the maxillary arch to the UL third molar, designated tooth number 16. Tooth number 17 is the third molar located in the LL quadrant inferior and opposite tooth number 16. Then, the numbering progresses across the mandibular arch and terminates with tooth number 32, the LR third molar. *In this system, the sum of the numbers of opposing teeth adds up to 33.* For the deciduous dentition, the same pattern is followed, but the letters A-T are used to designate the individual teeth. Thus, in this system, the permanent canines are designated 6, 11, 22, and 27, and the deciduous canines C, H, M, and R.

Also note that in Figure F16.2.1, the *red* color outline demonstrates the relationship of the deciduous and permanent dentitions. Examination of the table reveals that deciduous molars are replaced with permanent premolars after exfoliation and that the permanent molars have no deciduous precursors.

- A **medial (central) incisor**, which erupts at age 7 or 8
- A **lateral incisor**, which erupts at age 8 or 9
- A **canine tooth**, which erupts at age 10 to 12
- Two **premolar teeth**, which erupt between ages 10 and 12
- Three **molar teeth**, which erupt at different times; the first molar usually erupts at age 6, the second molar in the early teens, and the third molar (**wisdom teeth**) during the late teens or early 20s

Incisors, canines, and premolars have one root each, except for the first premolar of the maxilla, which has two roots. Molars have either two roots (lower jaw) or three (upper jaw) and, on rare occasions, four roots. However, all teeth have the same basic structure.

Teeth consist of several layers of specialized tissues.

Teeth are made up of three specialized tissues:

- **Enamel**, a hard, thin, translucent layer of acellular mineralized tissue that covers the crown of the tooth
- **Dentin**, the most abundant dental tissue; it lies deep to the enamel in the crown and cementum in the root. Its unique tubular structure and biochemical composition support the more rigid enamel and cementum overlying the surface of the tooth.
- **Cementum**, a thin, pale yellowish layer of bone-like calcified tissue covering the dentin of the root of the teeth. Cementum is softer and more permeable than dentin and is easily removed by abrasion when the root surface is exposed to the oral environment.

Enamel

Enamel is the hardest substance in the body; it consists of 96% - 98% calcium hydroxyapatite.

Enamel is an acellular mineralized tissue that covers the crown of the tooth. Once formed, it cannot be replaced. Enamel is a unique tissue because, unlike bone, which is formed from connective tissue, it is a mineralized material derived from epithelium. Enamel is more highly mineralized and harder than any other mineralized tissue in the body; it consists of 96% - 98% of calcium hydroxyapatite. The enamel that is exposed and visible above the gum line is called the **clinical crown**; the **anatomic crown** describes all of the tooth that is covered by enamel, some of which is below the gum line. Enamel varies in thickness over the crown and may be as thick as 2.5 mm on the **cusps** (biting and grinding surfaces) of some teeth. The enamel layer ends at the **neck**, or cervix, of the tooth at the **cementoenamel junction** (Fig. 16.9); the **root** of the tooth is then covered by **cementum**, a bone-like material.

FIGURE 16.9. Diagram of a section of an incisor tooth and surrounding bony and mucosal structures. The three mineralized components of the tooth are dentin, enamel, and cementum. The central soft core of the tooth is the pulp. The periodontal ligament (membrane) contains bundles of collagenous fibers that bind the tooth to the surrounding alveolar bone. The clinical crown of the tooth is the portion that projects into the oral cavity. The anatomic crown is the entire portion of the tooth covered by enamel.

Enamel is composed of enamel rods that span the entire thickness of the enamel layer.

The nonstoichiometric carbonated calcium hydroxyapatite enamel crystals that form the enamel are arranged as rods that measure 4 μm wide and 8 μm high. Each enamel rod spans the full thickness of the enamel layer from the dentinoenamel junction to the enamel surface. When examined in cross section at higher magnification, the rods reveal a keyhole shape (Fig. 16.10); the ballooned part, or head, is oriented superiorly, and the tail is directed inferiorly toward the root of the tooth. The enamel crystals are primarily oriented parallel to the long axis of the rod within the head, and in the tail, they are oriented more obliquely (Figs. 16.10 and 16.11). The limited spaces between the rods are also filled with enamel crystals. Striations observed on enamel rods (contour lines of Retzius) may represent evidence of rhythmic growth of the enamel in the developing tooth. A wider line of hypomineralization is observed in the enamel of the deciduous teeth. This line, called the *neonatal line*, marks the nutritional changes that take place between prenatal and postnatal life.

FIGURE 16.10. Diagram showing the basic organization and structure of enamel rods. The enamel rod is a thin structure extending from the dentinoenamel junction to the surface of the enamel. Where the enamel is thickest, at the tip of the crown, the

rods are the longest, measuring up to 2,000 μm . On cross section, the rods reveal a keyhole shape. The upper, ballooned part of the rod, called the *head*, is oriented superiorly, and the lower part of the rod, called the *tail*, is directed inferiorly. Within the head, most of the enamel crystals are oriented parallel to the long axis of each rod. Within the tail, the crystals are oriented more obliquely.

FIGURE 16.11. Structure of young enamel. a. This electron micrograph shows enamel rods cut obliquely. *Arrows* indicate the boundaries between adjacent rods. $\times 14,700$. b. Parts of two adjacent rods are seen at higher magnification. *Arrows* mark the boundary between the two rods. The dark needle-like objects are young hydroxyapatite crystals; the substance between the hydroxyapatite crystals is the organic matrix of the developing enamel. As the enamel matures, the hydroxyapatite crystals grow, and the bulk of the organic matrix is removed. $\times 60,000$.

Although the enamel of an erupted tooth lacks cells and cell processes, it is not a static tissue. It is influenced by the secretion of the salivary glands, which are essential to its maintenance. The substances in saliva that affect teeth include

digestive enzymes, secreted antibodies, and a variety of inorganic (mineral) components.

Mature enamel contains very little organic material. Despite its hardness, enamel can be decalcified by acid-producing bacteria acting on food products trapped on the enamel surface. This is the basis of the initiation of dental caries. Fluoride added to the hydroxyapatite complex makes the enamel more resistant to acid demineralization. The widespread use of fluoride in drinking water, toothpaste, pediatric vitamin supplements, and mouthwashes significantly reduces the incidence of dental caries.

Enamel is produced by ameloblasts of the enamel organ, and dentin is produced by neural crest-derived odontoblasts of the adjacent mesenchyme.

The **enamel organ** is an epithelial formation that is derived from ectodermal epithelial cells of the oral cavity. The onset of tooth development is marked by proliferation of oral epithelium to form a horseshoe-shaped cellular band of tissue, the dental lamina, in the adjacent mesenchyme where the upper and lower jaws will develop. At the site of each future tooth, there is a further proliferation of cells that arise from the dental lamina, resulting in a rounded, cellular, bud-like outgrowth, one for each tooth, that projects into the underlying mesenchymal tissue. This outgrowth, referred to as the **bud stage**, represents the early enamel organ (Fig. 16.12a). Gradually, the rounded cell mass enlarges and then develops a concavity at the site opposite to which it arose from the dental lamina; this is referred to as the **cap stage** (Fig. 16.12b). Further growth and development of the enamel organ results in the **bell stage** (Fig. 16.12c and d). At this stage, the enamel organ consists of four recognizable cellular components:

FIGURE 16.12. Diagrams and photomicrographs of a developing tooth. **a.** In the bud stage, the oral epithelium invaginates into the underlying mesenchyme, giving rise to the enamel organ (primordium of enamel). Mesenchymal cells adjacent to the tooth bud begin to

differentiate, forming the dental papilla that protrudes into the tooth bud. b. Tooth bud in cap stage. In this stage, cells located in the concavity of the cap differentiate into tall, columnar cells (ameloblasts) forming the inner enamel epithelium. The condensed mesenchyme invaginates into the inner enamel epithelium, forming the dental papilla, which gives rise to the dentin and the pulp. c. In the bell stage, the connection with the oral epithelium is almost cut off. The enamel organ consists of a narrow line of outer enamel epithelium, an inner enamel epithelium formed by ameloblasts, several condensed layers of cells that form the stratum intermedium, and the widely spaced stellate reticulum. The dental papilla is deeply invaginated against the enamel organ. d. In this appositional dentin and enamel stage, the tooth bud is completely differentiated and independent from the oral epithelium. The relationship of the two mineralized tissues of the dental crown, enamel and dentin, is clearly visible. The surrounding mesenchyme has developed into bony tissue. e. In this stage of tooth eruption, the apex of the tooth emerges through the surface of the oral epithelium. The odontoblastic layer lines the pulp cavity. Note the developed periodontal ligaments that fasten the root of the tooth to the surrounding bone. The apex of the root is still open, but after eruption occurs, it becomes narrower. f. Functional tooth stage. Note the distribution of enamel and dentin. The tooth is embedded in the surrounding bone and gingiva. g. This photomicrograph of the developing tooth in the cap stage (comparable to b) shows its connection with the oral epithelium. The enamel organ consists of a single layer of cuboidal cells forming the outer enamel epithelium; the inner enamel epithelium has differentiated into columnar ameloblasts, and the layer of cells adjacent to the inner enamel epithelium has formed the stratum intermedium. The remainder of the structure is occupied by the stellate reticulum. The mesenchyme of the dental papilla has proliferated and pushed into the enamel organ. At this stage, the forming tooth is surrounded by condensed mesenchyme, called the *dental sac*, which gives rise to periodontal structures. $\times 300$. h. This photomicrograph shows the developing crown of an incisor, which is surrounded by the outer enamel epithelium and remnants of the stellate reticulum. It is comparable to d. The underlying lighter stained layer of dentin is a product of the odontoblasts. These tall columnar odontoblasts have differentiated from cells of the dental papilla. The pulp cavity is filled with dental pulp, and blood vessels permeate the pulp tissue. $\times 40$.

- **Outer enamel epithelium**, made up of a cell layer that forms the convex surface
- **Inner enamel epithelium**, made up of a cell layer that forms the concave surface
- **Stratum intermedium**, a cell layer that develops internal to the inner enamel epithelium

- **Stellate reticulum**, made up of cells that have a stellate appearance and occupy the inner portion of the enamel organ

The neural crest-derived **preodontoblasts** lined up within the “bell” adjacent to the inner enamel epithelial cells become columnar and have an epithelial-type appearance. They will become **odontoblasts** and form the dentin of the tooth. The inner enamel epithelial cells of the enamel organ will become **ameloblasts**. Along with the cells of the stratum intermedium, they will be responsible for enamel production. At the early stage, just before dentinogenesis and amelogenesis, the dental lamina degenerates, leaving the developing tooth primordium detached from its site of origin.

Dental enamel is formed by a matrix-mediated biomineralization process known as **amelogenesis**. The major stages of amelogenesis are described as follows:

- **Matrix production** or **secretory stage**. In the formation of mineralized tissues of the tooth, dentin is produced first. Next, partially mineralized enamel matrix (Fig. 16.13) is deposited directly on the surface of the previously formed dentin. The cells producing this partially mineralized organic matrix are called **secretory-stage ameloblasts**. These cells produce an organic proteinaceous matrix by the activity of the rough endoplasmic reticulum (rER), Golgi apparatus, and secretory granules, similar to the process by which osteoblasts produce bone. The secretory-stage ameloblasts continue to produce enamel matrix until the full thickness of the future enamel is achieved.

FIGURE 16.13. Diagram and photomicrograph showing the cellular relationships during enamel formation. **a.** In the initial secretory stage, dentin is produced first by odontoblasts. Enamel matrix is then deposited directly on the surface of the previously formed dentin by secretory-stage ameloblasts. The secretory-stage ameloblasts continue to produce enamel matrix until the full thickness of the future enamel is achieved. **b.** This photomicrograph of a hematoxylin and eosin (H&E)-stained section of a developing human tooth shows an early stage of enamel formation (amelogenesis). The secretory-stage ameloblasts lie directly adjacent to the developing enamel, which is being deposited on the layer of dentin. The beginning of enamel deposition is indicated by the *arrow*. As the first increment of enamel is formed, ameloblasts move away from the dentin surface. Basal domains of secretory-stage ameloblasts are adjacent to cells in the stratum intermedium (a part of the enamel organ). Dentin is secreted by odontoblasts. Note the *lightly stained layer* of the newly secreted organic matrix (predentin) is in close apposition to the apical surfaces of odontoblasts. Predentin further undergoes mineralization to mature dentin (*dark-stained layer*). The layer of odontoblasts separates enamel from the dental pulp. $\times 240$. (Courtesy of Dr. Arthur R. Hand.)

- **Matrix maturation.** Maturation of the partially mineralized enamel matrix involves the removal of organic material as well as the continued influx of calcium and phosphate into the maturing enamel. Cells involved in this second stage of enamel formation are called **maturation-stage ameloblasts**. Maturation-stage ameloblasts differentiate from secretory-stage ameloblasts and function primarily as a transporting

epithelium, moving substances into and out of the maturing enamel. Maturation-stage ameloblasts undergo cyclical alterations in their morphology that correspond to the cyclical entry of calcium into the enamel.

Secretory-stage ameloblasts are polarized columnar cells that produce enamel.

The **secretory-stage ameloblast** lies directly adjacent to the developing enamel. At the apical pole of each ameloblast is a process, **Tomes process**, which is surrounded by the developing enamel (Fig. 16.14). A cluster of mitochondria and an accumulation of actin filaments in the proximal terminal web in the base of the cell account for the eosinophilic staining of this region in hematoxylin and eosin (H&E)-stained paraffin sections (Figs. 16.15 and 16.16a). Adjacent to the mitochondria is the nucleus; in the main column of cytoplasm are the rER, Golgi, secretory granules, and other cell elements. Junctional complexes are present at both the apical and basal parts of the cell. They maintain the integrity and orientation of the ameloblasts as they move away from the dentinoenamel junction. Actin filaments joined to these junctional complexes are involved in moving the secretory-stage ameloblast over the developing enamel. The rod produced by the ameloblast follows in the wake of the cell. Thus, in mature enamel, the direction of the enamel rod is a record of the path taken earlier by the secretory-stage ameloblast.

FIGURE 16.14. Schematic diagrams of a partially formed tooth showing details of amelogenesis. **a.** The enamel is drawn to show the enamel rods extending from the dentinoenamel junction to the surface of the tooth. Although the full thickness of the enamel is formed, the full thickness of the dentin has not yet been established. The contour lines within the dentin show the extent to which the dentin has developed at a particular time, as labeled in the illustration. Note that the pulp cavity in the center of the tooth becomes smaller as the dentin develops. (Based on Schour I, Massler M. The neonatal line in the enamel and dentin of the human deciduous teeth and first permanent molar. *J Am Dent Assoc.* 1936;23:1948.) **b.** During amelogenesis, enamel formation is influenced by the path of the ameloblasts. The rod produced by the ameloblast forms in the wake of the cell. Thus, in mature enamel, the direction of the enamel rod is a record of the path taken earlier by the secretory-stage ameloblast. **c.** At the apical pole of the secretory-stage ameloblasts are Tomes processes, surrounded by the developing enamel. Junctional complexes at the apical pole and distal terminal web are also shown. Note the numerous matrix-containing secretory vesicles in the cytoplasm of the processes.

FIGURE 16.15. Enamel organ cells and odontoblasts in a developing tooth. This photomicrograph of a hematoxylin and eosin (H&E)-stained section of a developing human tooth shows ameloblasts and odontoblasts as they begin to produce enamel (*E*) and dentin (*D*), respectively. Enamel is deposited by the secretory-stage ameloblasts (*AM*) onto the previously formed dentin. The enamel appears *deep purple* in this image and is adjacent to the *reddish purple* layer of mature dentin (*D*). The blood vessels (*BV*) on the *right* belong to the enamel organ (*EO*), which is partially formed from the cells of the stratum intermedium. Basal domains of odontoblasts (*OD*) on the *left* are in contact with dental pulp (*DP*). The cytoplasm of odontoblasts is adjacent to predentin (*PD*). At this point, cytoplasmic processes of odontoblasts (*OP*) extend into dentinal tubules of predentin. $\times 280$. (Courtesy of Dr. Arthur R. Hand.)

FIGURE 16.16. Ameloblasts in secretory and maturation stages. a. This high-magnification photomicrograph of a hematoxylin and eosin (H&E)-stained specimen shows the secretory-stage ameloblasts (AM). Note the lightly stained Tomes processes (TP) of the apical part of ameloblasts and the deeply stained enamel just below. The distinct *pink lines* are related to the accumulation of actin filaments in ameloblasts. The *first line* between Tomes processes and the cytoplasm of ameloblasts represents the distal terminal web (DTW), and the *second line* at the base of ameloblasts is the proximal terminal web (PTW). The enamel organ (EO) containing blood vessels (BV) is adjacent to the layer of ameloblasts. Stroma of dental follicles (DF) is visible at the top of this image. $\times 480$. (Courtesy of Dr. Arthur R. Hand.) b. Colorized scanning electron micrograph of a freeze-fracture section of the tooth shows a layer of smooth-ended maturation-stage ameloblasts (MA, *green*) on the enamel surface (E, *orange*). At the basal pole of the ameloblasts are the cells of the papillary layer (PL) containing blood vessels (BV) and loose connective tissue (CT). A layer of stratum intermedium is no longer present during this stage of ameloblast maturation. During slide preparation, apical surfaces of ameloblasts were detached from the enamel. $\times 1,300$. (Courtesy of SPL/Photo Researchers, Inc., with permission.)

At their base, the secretory-stage ameloblasts are adjacent to a layer of enamel organ cells called the **stratum intermedium** (see Figs. 16.12b, c, and g and 16.13b). The plasma membrane of these cells, especially at the base of the ameloblasts, contains alkaline phosphatase, an enzyme active in calcification. Stellate enamel organ cells are external to the stratum intermedium and are separated from the adjacent blood vessels by a basal lamina.

Maturation-stage ameloblasts transport substances needed for enamel maturation.

The histologic feature that characterizes **maturation-stage ameloblasts** is the presence of a striated (or ruffled) border on their apical surface (Fig. 16.16b). At this stage, ameloblasts undergo **modulation**, a cyclic change in which the striated border appears, then disappears, and finally reappears. During the modulation, maturation-stage ameloblasts undergo extensive remodeling, which alternates between displaying a **striated border** or a **smooth border**. Maturation-stage ameloblasts with striated borders account for approximately 70% of all cells undergoing cyclic modulation. A well-developed striated border is responsible for secreting bicarbonate ions (HCO_3^-); it also contains plasma membrane Ca^{2+} -ATPases (PMCA) that extrude calcium ions (Ca^{2+}) into the maturing enamel. Maturation-stage ameloblasts with smooth-ended apical borders account for approximately 30% of this cell population. Although they have no detected Ca^{2+} -ATPase activity, they produce and secrete enzymes to degrade and reabsorb the extracellular matrix that is no longer necessary.

At this stage, there is no stratum intermedium in the enamel organ during enamel maturation. Cells from the underlying stratum intermedium, stellate reticulum, and outer dental epithelium collapse on each other and undergo reorganization, making it impossible to distinguish them as individual layers. Finally, the blood vessels invaginate into this newly reorganized layer to form the **papillary layer** containing stellate **papillary cells** that are adjacent to the maturation-stage ameloblasts.

The maturation-stage ameloblasts and the adjacent papillary cells are characterized by numerous mitochondria. Their presence indicates cellular activity that requires large amounts of energy and reflects the function of maturation-stage ameloblasts and adjacent papillary cells as a transporting epithelium.

Recent advances in the molecular biology of ameloblast gene products have revealed the enamel matrix to be highly heterogeneous. It contains proteins encoded by a number of

different genes. Listed as follows are the principal proteins in the extracellular matrix of the developing enamel:

- **Amelogenins**, important proteins in establishing and maintaining the spacing between enamel rods in the early stages of enamel development
- **Ameloblastins**, signaling proteins produced by ameloblasts from the early secretory to late maturation stages. Their function is not well understood; however, their developmental pattern suggests that ameloblastins play a much broader role in amelogenesis than the other proteins. Ameloblastins are believed to guide the enamel mineralization process by controlling elongation of the enamel crystals and to form junctional complexes between individual enamel crystals.
- **Enamelins**, proteins distributed throughout the enamel layer. These proteins undergo proteolytic cleavage as the enamel matures. Low-molecular-weight products of this cleavage are retained in the mature enamel, often localized on the surface of enamel crystals.
- **Tuftelins**, the earliest detected proteins located near the dentinoenamel junction. Their acidic and insoluble nature aids in the nucleation of enamel crystals. Tuftelins are present in **enamel tufts** and account for hypomineralization, that is, enamel tufts have a higher percentage of organic material than the remainder of the mature enamel.

The maturation of the developing enamel results in its continued mineralization so that it becomes the hardest substance in the body. Amelogenins and ameloblastins are removed during enamel maturation. Thus, mature enamel contains only enamelins and tuftelins. The ameloblasts degenerate after the enamel is fully formed, at about the time of tooth eruption through the gum.

Cementum

Cementum covers the root of the tooth.

The **root** is the part of the tooth that fits into the **alveolus** or jaw socket in the maxilla or mandible. **Cementum** is a thin layer of bone-like material that covers the roots of the teeth beginning at the cervical portion of the tooth at the cemento-enamel junction and continuing to the apex. Cementum is produced by **cementoblasts** (large cuboidal cells that resemble the osteoblasts of the surface of growing bone). Cementoblasts secrete an extracellular matrix called **cementoid** that undergoes mineralization. A layer of cementoblasts is present on the outer surface of the cementum, adjacent to the **periodontal ligament**. During cementogenesis, cementoblasts are incorporated into the cementum and become **cementocytes**, cells that closely resemble osteocytes in bone. Like bone, cementum is 65% mineral and contains the highest concentration of fluoride of any mineralized tissue. The lacunae and canaliculi in the cementum contain the cementocytes and their processes, respectively. They resemble structures in bone that contain osteocytes and osteocyte processes. Unlike bone, cementum is avascular. In addition, the lacunae are irregularly distributed throughout the cementum and their canaliculi do not form an interconnecting network.

Collagen fibers that project out of the matrix of the cementum and embed in the bony matrix of the socket wall form the bulk of the periodontal ligament. These fibers are another example of **Sharpey fibers** (Fig. 16.17). In addition, elastic fibers are also a component of the periodontal ligament. This mode of attachment of the tooth in its socket allows slight movement of the tooth to occur naturally. It also forms the basis of orthodontic procedures used to straighten teeth and reduce malocclusion of the biting and grinding surfaces of the maxillary and mandibular teeth. During corrective tooth movements, the alveolar bone of the socket is resorbed and resynthesized, but the cementum is not.

FIGURE 16.17. Electron micrograph of Sharpey fibers. Sharpey fibers extend from the periodontal ligament (*right*) into the cementum. They consist of collagen fibrils. Sharpey fibers within the cementum are mineralized; those within the periodontal ligament are not mineralized. $\times 13,000$.

Dentin

Dentin is a calcified material that forms most of the tooth substance.

Dentin lies deep to the enamel and cementum. It contains less hydroxyapatite than enamel, about 70%, but more than is found in bone and cementum. Dentin is secreted by **odontoblasts** that form an epithelial layer over the inner surface of the dentin, that is, the surface that is in contact with the pulp (Fig. 16.18). Like ameloblasts, odontoblasts are columnar cells that contain a well-developed rER, a large Golgi apparatus, and other organelles associated with the synthesis and secretion of large amounts of protein (Fig. 16.19). The apical surface of the odontoblast is in contact with the forming dentin; junctional complexes between the odontoblasts at that level separate the dentinal compartment from the pulp chamber.

FIGURE 16.18. Dental pulp and structure of dentin. This photomicrograph of a decalcified tooth shows the centrally located dental pulp, surrounded by dentin on both sides. The dental pulp is a soft-tissue core of the tooth that resembles embryonic connective tissue, even in the adult. It contains blood vessels and nerves. Dentin contains the cytoplasmic processes of the odontoblasts within dentinal tubules. They extend into the dentinoenamel junction. The cell bodies of the odontoblasts are adjacent to the unmineralized dentin called the *predentin*. $\times 120$. Left inset. Longitudinal profiles of the dentinal tubules. $\times 240$. Right inset. Cross-sectional profiles of dentinal tubules. The dark outline of the dentinal tubules, as seen in both *insets*, represents the peritubular dentin, which is the more mineralized part of the dentin. $\times 240$.

FIGURE 16.19. Electron micrograph of odontoblasts. The plasma membrane of one odontoblast has been marked with *arrows*. The cell contains a large amount of rough endoplasmic reticulum and a large Golgi apparatus. The odontoblast processes are not included in this image; one process would extend from the apical pole of each cell (*top*). The *black objects* in the Golgi region are abacus bodies. The tissue has been treated with pyroantimonate, which forms a black precipitate with calcium. $\times 12,000$.

The layer of odontoblasts retreats as the dentin is laid down, leaving odontoblast processes embedded in the dentin in narrow channels called **dentinal tubules** (see Fig. 16.18). The tubules and processes continue to elongate as the dentin continues to thicken by rhythmic growth. The rhythmic growth of dentin produces certain “growth lines” in the dentin (incremental lines of von Ebner and thicker lines of Owen) that mark significant developmental times such as birth (**neonatal line**) and when unusual substances such as lead are incorporated into the growing tooth. The study of growth lines has proved useful in forensic medicine.

Predentin is the newly secreted organic matrix, closest to the cell body of the odontoblast, which has yet to be mineralized. Although most of the proteins in the organic matrix are similar to those of bone, predentin contains two unique proteins:

- **Dentin phosphoprotein (DPP)**, a 45-kDa highly acidic phosphorylated protein, which is rich in aspartic acid and phosphoserine and binds large amounts of calcium. DPP is involved in the initiation of mineralization and the control of mineral size and shape.
- **Dentin sialoprotein (DSP)**, a 100-kDa proteoglycan that is rich in aspartic and glutamic acids, serine, glycine, and chondroitin 6-sulfate. DSP is also involved in the mineralization process.

An unusual feature of the secretion of collagen and hydroxyapatite by odontoblasts is the presence, in Golgi vesicles, of arrays of a formed filamentous collagen precursor. Granules believed to contain calcium attach to these precursors, giving rise to structures called **abacus bodies**

(Figs. 16.19 and 16.20). Abacus bodies become more condensed as they mature into secretory granules.

FIGURE 16.20. Golgi apparatus in an odontoblast. This electron micrograph shows a region of the Golgi apparatus containing numerous large vesicles. Note the abacus bodies (*arrows*) that contain parallel arrays of filaments studded with granules. $\times 52,000$.

Dentin is produced by odontoblasts.

Dentin is the first mineralized component of the tooth to be deposited. The outermost dentin, which is referred to as **mantle dentin**, is formed by subodontoblastic cells that produce small bundles of collagen fibers (von Korff fibers). The **odontoblasts** differentiate from cells at the periphery of the dental

papilla. The progenitor cells have the appearance of typical mesenchymal cells, that is, they contain little cytoplasm. During their differentiation into odontoblasts, the cytoplasmic volume and organelles characteristic of collagen-producing cells increase. The cells form a layer at the periphery of the dental papilla, and they secrete the organic matrix of dentin, or predentin, at their apical end (away from the dental papilla; Fig. 16.21). As the predentin thickens, the odontoblasts move or are displaced centrally (see Fig. 16.14). A **wave of mineralization** follows the receding odontoblasts; this mineralized product is dentin. As the cells move centrally, the odontoblastic processes elongate, the longest being surrounded by the mineralized dentin. In newly formed dentin, the wall of the dentinal tubule is simply the edge of the mineralized dentin. Over time, the dentin immediately surrounding the dentinal tubule becomes more highly mineralized; this more mineralized sheath of dentin is referred to as the **peritubular dentin**. The remainder of the dentin is called the **intertubular dentin**.

FIGURE 16.21. Odontoblast process of a young odontoblast. This electron micrograph shows a process of the odontoblast entering a dentinal tubule. The process extends into the predentin and, after passing the mineralization front (*arrows*), lies within the dentin. The collagen fibrils in the predentin are finer than the more mature, coarser fibrils of the mineralization front and beyond. $\times 34,000$.

Dental Pulp and Central Pulp Cavity (Pulp Chamber)

The dental pulp cavity is a connective tissue compartment bounded by the tooth dentin.

The **central pulp cavity** is the space within a tooth that is occupied by **dental pulp**, a loose connective tissue that is richly vascularized and supplied by abundant nerves. The pulp cavity takes the general shape of the tooth. The blood vessels and nerves enter the pulp cavity at the tip (apex) of the root at a site called the **apical foramen**. (The designations *apex* and *apical* in this context refer only to the narrowed tip of the root of the tooth rather than to a luminal [apical] surface, as used in describing secretory and absorptive epithelia.)

The blood vessels and nerves extend to the crown of the tooth, where they form vascular and neural networks beneath and within the layer of odontoblasts. Some bare nerve fibers also enter the proximal portions of the dentinal tubules and contact with the odontoblast processes. The odontoblast processes are believed to serve a transducer function in transmitting stimuli from the tooth surface to the nerves in the dental pulp. In teeth with more than one cusp, **pulpal horns** extend into the cusps and contain large numbers of nerve fibers. More of these fibers extend into the dentinal tubules than at other sites. Because dentin continues to be secreted throughout life, the pulp cavity decreases in volume with age.

Supporting Tissues of the Teeth

Supporting tissues of the teeth include the alveolar bone of the alveolar processes of the maxilla and mandible, periodontal ligaments, and gingiva.

The alveolar processes of the maxilla and mandible contain the sockets or alveoli for the roots of the teeth.

The **alveolar bone proper**, a thin layer of compact bone, forms the wall of the alveolus (see Fig. 16.9) and is the bone to which the periodontal ligament is attached. The rest of the alveolar process consists of supporting bone.

The surface of the alveolar bone proper usually shows regions of bone resorption and bone deposition, particularly when a tooth is being moved (Fig. 16.22). Periodontal disease usually leads to loss of alveolar bone, as does the absence of functional occlusion of a tooth with its normal opposing tooth.

FIGURE 16.22. Schematic diagram of gingiva. This schematic diagram of gingiva corresponds to the *rectangular area* of the orientation diagram. The gingival epithelium is attached to the enamel of the tooth. Here, the junction between epithelium and connective tissue is smooth. Elsewhere, the gingival epithelium is deeply indented by connective tissue papillae, and the junction between the two is irregular. The *black lines* represent collagen fibers from the cementum of the tooth and from the crest of the alveolar bone that extend toward the gingival epithelium. Note the shallow papillae in the lining mucosa (alveolar mucosa) that contrast sharply with those of the gingiva.

The **periodontal ligament** is the fibrous connective tissue joining the tooth to its surrounding bone. This ligament is also called the **periodontal membrane**, but neither term describes its structure and function adequately. The **periodontal ligament** provides for the following:

- Tooth attachment (fixation)
- Tooth support
- Bone remodeling (during movement of a tooth)
- Proprioception
- Tooth eruption

A histologic section of the periodontal ligament shows that it contains areas of both dense and loose connective tissues. The dense connective tissue contains collagen fibers and fibroblasts that are elongated parallel to the long axis of the collagen fibers. The fibroblasts are believed to move back and forth, leaving behind a trail of collagen fibers. Periodontal fibroblasts also contain internalized collagen fibrils that are digested by the hydrolytic enzymes of the cytoplasmic lysosomes. These observations indicate that the fibroblasts not only produce collagen fibrils but also resorb collagen fibrils, thereby adjusting continuously to the demands of tooth stress and movement.

The loose connective tissue in the periodontal ligament contains blood vessels and nerve endings. In addition to fibroblasts and thin collagenous fibers, the periodontal ligament also contains thin, longitudinally disposed **oxytalan**

fibers. They are attached to bone or cementum at each end. Some appear to be associated with the adventitia of blood vessels.

The gingiva is the part of the mucous membrane commonly called the *gums*.

The **gingiva** is a specialized part of the oral mucosa located around the neck of the tooth. It is firmly attached to the teeth and underlying alveolar bony tissue. An idealized diagram of the gingiva is presented in Figure 16.22. The gingiva is composed of two parts:

- **Gingival mucosa**, which is synonymous with the masticatory mucosa described earlier
- **Junctional epithelium**, or **attachment epithelium**, which adheres firmly to the tooth. A basal lamina-like material is secreted by the junctional epithelium and adheres firmly to the tooth surface. The cells then attach to this material via hemidesmosomes. The basal lamina and the hemidesmosomes are together referred to as the **epithelial attachment**. In young individuals, this attachment is to the enamel; in older individuals, where passive tooth eruption and gingival recession expose the roots, the attachment is to the cementum.

Above the attachment of the epithelium to the tooth, a shallow crevice called the **gingival sulcus** is lined with **crevicular epithelium** that is continuous with the attachment epithelium.

The term **periodontium** refers to all the tissues involved in the attachment of a tooth to the mandible and maxilla. These include the crevicular and junctional epithelium, the cementum, the periodontal ligament, and the alveolar bone. **Periodontitis** is an inflammatory oral disease that leads to the destruction of periodontal tissue involved in the attachment of the tooth. Although conventional therapies are available to control the inflammatory process, they are unable to restore damaged periodontal structures. With the discovery of multipotent periodontal ligament stem cells (PDLSCs), periodontal regenerative treatment that could restore the physiologic

function of teeth by rebuilding damaged periodontal supporting tissues, including alveolar bone, gingiva, periodontal ligaments, and the cementum, may become possible. PDLSCs in humans can be obtained from healthy permanent and deciduous teeth. When isolated human PDLSCs are transplanted into laboratory animals, they differentiate into periodontal ligaments, alveolar bone, cementum, peripheral nerves, and blood vessels.

■ SALIVARY GLANDS

The major salivary glands are paired glands with long ducts that empty into the oral cavity.

The **major salivary glands**, as noted earlier, consist of the paired parotid, submandibular, and sublingual glands. The parotid and the submandibular glands are actually located outside the oral cavity; their secretions reach the cavity by ducts. The **parotid gland** is located subcutaneously, below and in front of the ear in the space between the ramus of the mandible and the styloid process of the temporal bone. The **submandibular gland** is located under the floor of the mouth, in the submandibular triangle of the neck. The **sublingual gland** is located on the floor of the mouth anterior to the submandibular gland.

The **minor salivary glands** are located in the submucosa of different parts of the oral cavity. They include the **lingual**, **labial**, **buccal**, **molar**, and **palatine glands**.

The embryologic development of the major salivary glands is a complex process requiring multidirectional signaling between invaginating epithelium and mesenchyme.

Each salivary gland arises from the developing oral cavity epithelium. The parotid glands develop first from invagination of the oral ectodermal lining the stomodeum (primitive oral cavity), whereas the submandibular and sublingual glands arise later from oral endoderm (near the junction between the ectoderm of the stomodeum and the endoderm of the gut tube).

Initially, the gland forms a solid cord of cells that enters the mesenchyme. The invaginated epithelium interacts with the adjacent mesenchyme, and through multidirectional signaling networks, these interactions influence the growth and differentiation of the gland tissue. Under the influence of fibroblast growth factor-10 (FGF10), the proliferation of epithelial cells eventually produces highly branched epithelial cords with bulbous ends. Degeneration of the innermost cells of the cords and bulbous ends leads to their canalization. The cords become ducts, and the bulbous ends become **secretory acini**. Finally, the glands develop a dense irregular connective tissue capsule. In addition, both sympathetic and parasympathetic innervations are necessary for the proper development, growth, and maintenance of salivary gland tissue.

Any disruption in signaling networks between the developing glandular epithelium and mesenchyme, as well as disruption of autonomic nervous system innervation, may lead to **salivary gland aplasia** (lack of its development). Craniofacial abnormalities such as cleft palate, skeletal dysplasias, and branchial cleft anomalies are also associated with either unilateral or bilateral salivary gland aplasia and hypoplasia (arrested development).

Secretory Gland Acini

Secretory acini are organized into lobules.

The major salivary glands are surrounded by a capsule of moderately dense connective tissue from which septa divide the secretory portions of the gland into lobes and lobules. The septa contain the larger blood vessels and excretory ducts. The connective tissue associated with the groups of secretory acini blends imperceptibly into the surrounding loose connective tissue. The minor salivary glands do not have a capsule.

Numerous lymphocytes and plasma cells populate the connective tissue surrounding the acini in both the major and minor salivary glands. Their significance in the secretion of salivary antibodies is described later.

Acini are of three types: serous, mucous, or mixed.

The basic secretory unit of salivary glands, the **salivon**, consists of the acinus, intercalated duct, and excretory duct (Fig. 16.23). The **acinus** is a blind sac composed of secretory cells. The term *acinus* [*L, berry or grape*] refers to the secretory unit of the salivary glands. The acini of salivary glands contain **serous cells** (protein secreting), **mucous cells** (mucin secreting), or both. The relative frequencies of the three types of acini are the primary characteristic by which the major salivary glands are distinguished. Thus, three types of acini are described:

FIGURE 16.23. Diagram comparing the components of the salivon in the three major salivary glands. The four major parts of the

salivon—the acinus, intercalated duct, striated duct, and excretory duct—are color coded. The three columns on the *right* of the salivon compare the length of the different ducts in the three salivary glands. The *red-colored* cells of the acinus represent serous-secreting cells, and the *yellow-colored* cells represent mucus-secreting cells. The ratio of serous-secreting cells to mucus-secreting cells is depicted in the acini of the various glands.

- **Serous acini**, which contain only serous cells and are generally spherical
- **Mucous acini**, which contain only mucous cells and are usually more tubular
- **Mixed acini**, which contain both serous and mucous cells. In routine H&E preparations, mucous acini appear to have a cap of serous cells, in which the cytoplasm extends into the narrowed and highly convoluted intercellular space between the mucous cells. Because of their appearance in histologic sections, such caps are called **serous demilunes** [*Fr. half-moon*] and represent an artifact of fixation.

Serous demilunes are artifacts of the traditional fixation method.

As noted earlier, each mixed acinus, such as those found in the sublingual and submandibular glands, contains serous- and mucus-producing cells. In routine preparations for both light and electron microscopies, serous cells have traditionally been regarded as the structures that make up the **demilune**. Recent electron microscopic studies now challenge this classic interpretation of the demilune. Rapid freezing of the tissue in liquid nitrogen, followed by rapid-freeze substitution with osmium tetroxide in cold acetone, reveals that both mucous and serous cells are aligned in the same row to surround the lumen of the secretory acinus. No serous demilune is found (Fig. 16.24a). Sections prepared from the same specimen by conventional methods show swollen **mucous cells** with enlarged secretory granules. The serous cells have been squeezed out by swollen mucous cells to form typical demilunes. Most of the cell cytoplasm is relocated to the peripheral region of the acinus with slender cytoplasmic processes interposed between the mucous cells (Fig. 16.24b). These findings indicate that

the demilune observed in light or electron microscopy is an **artifact of the routine fixation method** (see Fig. 16.24). The process of demilune formation can be explained by the expansion of mucinogen, a major component of secretory granules, during routine fixation. This expansion increases the volume of the mucous cells and displaces the serous cells from their original position, thus creating the demilune effect. A similar phenomenon is sometimes seen in the intestinal mucosa, in which swollen goblet cells displace adjacent absorptive cells.

FIGURE 16.24. Relationship of serous-secreting cells and mucus-secreting cells in a mixed acinus. **a.** This drawing indicates the relationship of the mucous and serous cells as observed in the electron microscope after the rapid-freezing method. The serous cells extend from the basal lamina to the lumen of the acinus. **b.** In this drawing, serous cells are shown occupying the periphery of the acinus to form the so-called *serous demilune*. This feature is visible in routine preparations using immersion fixation. The swollen mucous cells have forced out the serous cells, leaving small remnants of the cytoplasm between the mucous cells.

CLINICAL CORRELATION: DENTAL CARIES

Dental caries is an infectious microbial disease of teeth that results in the destruction of affected calcified tissues, that is, enamel, dentin, and cementum. Carious lesions generally occur under masses of bacterial colonies referred to as “dental plaque.” The onset of dental caries is primarily associated with bacterial colonies of *Streptococcus mutans*, whereas lactobacilli are associated with an active progression of the disease. These bacterial colonies metabolize carbohydrates, producing an acidic environment that demineralizes the underlying tooth structure. Frequent sucrose ingestion is strongly associated with the development of these acidogenic bacterial colonies.

Trace amounts of **fluoride**, from sources such as water supplies (0.5–1.0 ppm is optimal), toothpaste, and even diet, can improve resistance to the effects of cariogenic bacteria. Fluoride improves the acid resistance of the tooth structure, acts as an antimicrobial agent, and promotes remineralization of small carious lesions. Resistance to acid breakdown of enamel is facilitated by the substitution of fluoride ion for the hydroxyl ion in the hydroxyapatite crystal. This decreases enamel crystal solubility in acid.

Treatment of cavitated lesions, or “tooth cavities” (Fig. F16.3.1), includes excavation of the infected tooth tissue and replacement with dental materials, such as amalgam, composite, and glass ionomer cements. Microbial invasion of tooth structure can reach the “pulp” of the tooth and elicit an inflammatory response. In this case, endodontic treatment, or a “root canal,” is generally recommended, with subsequent placement of a crown to add strength to the compromised coronal tooth structure.

FIGURE F16.3.1. Photomicrographs of carious lesions. a. Photomicrograph of an unstained ground section of a tooth showing a carious lesion (CL) that has penetrated the entire thickness of the enamel (E) and spread laterally at the amelodentinal junction. D, dentin. b. The lesion here is more advanced. The enamel (E) has been undermined and weakened, causing fracture and a resulting cavity. At this point, bacteria can invade and penetrate into the exposed dental tubules, resulting in destructive liquefaction foci in the dentin (D) and, ultimately, exposure of the pulp. $\times 16$. (From Eveson JW, Scully C. *Color Atlas of Oral Pathology*. Times Mirror International Publishers; 1995.)

Serous cells are protein-secreting cells.

Serous cells have a pyramidal shape, with a relatively wide basal surface facing the basal lamina and a small apical surface facing the lumen of the acinus. They contain large amounts of rER, free ribosomes, a prominent Golgi apparatus, and numerous spherical secretory granules (Fig. 16.25). As in most protein-secreting cells that store their secretions in

zymogen granules, the granules are located in the apical cytoplasm. Most other organelles are located in the basal or perinuclear cytoplasm. In H&E sections, the basal cytoplasm of the serous cell stains with hematoxylin because of the presence of the rER and free ribosomes, whereas the apical region stains with eosin, in large part because of the presence of secretory granules.

FIGURE 16.25. Electron micrograph of the apical portion of parotid gland serous cells. As indicated by the *box* in the orientation photomicrograph, only the apical portions of parotid gland serous acinus are shown in this electron micrograph. The cells are polarized, with their product packaged within the secretory vesicles (SV) near the lumen (L) of the acinus. The cells display rough endoplasmic reticulum (rER) and several profiles of the Golgi apparatus (G). Immature secretory vesicles (IV) are present close to the Golgi apparatus. At the apical pole of the cells are junctional

complexes (*JC*). The intercellular space (*IC*) is dilated, and profiles of sectioned lateral plications are seen. *M*, mitochondria. $\times 15,000$.

When examined with the transmission electron microscope (TEM), the base of the serous cell may display infoldings of the plasma membrane and basolateral folds in the form of processes that interdigitate with similar processes of adjacent cells. The serous cells are joined near their apical surface by junctional complexes to neighboring cells of the acinus (see Fig. 16.25).

Mucous cells are mucin-secreting cells.

As in other mucus-secreting epithelia, the **mucous cells** of the mucous salivary acini undergo cyclic activity. During part of the cycle, mucus is synthesized and stored within the cell as **mucinogen granules**. When the product is discharged after hormonal or neural stimulation, the cell begins to resynthesize mucus. After discharge of most or all of the mucinogen granules, the cell is difficult to distinguish from an inactive serous cell. However, most mucous cells contain large numbers of mucinogen granules in their apical cytoplasm, and because the mucinogen is lost in H&E-stained paraffin sections, the apical portion of the cell usually appears empty. In TEM preparations, the rER, mitochondria, and other components are seen chiefly in the basal portion of the cell; this part of the cell also contains the nucleus, which is typically flattened against the base of the cell (Fig. 16.26). In rapid-freeze preparations (Fig. 16.27), cells are rounded and clearly isolated from each other. The nuclei are round and centrally located. The apical portion of the mucous cell contains numerous mucinogen granules and a large Golgi apparatus, in which large amounts of carbohydrates are added to a protein base to synthesize the glycoprotein of the mucin. Mucous cells possess apical junctional complexes, the same as those seen between serous cells.

FIGURE 16.26. Low-magnification electron micrograph of a mucous acinus. The mucous cells contain numerous mucinogen granules. Many of the granules have coalesced to form larger irregular masses that will ultimately discharge into the lumen (*L*) of the acinus. Myoepithelial cell processes (*MyC*) are evident at the periphery of the acinus. $\times 5,000$.

FIGURE 16.27. Electron micrographs of mixed acini. **a.** Low-magnification electron micrograph of the sublingual gland, prepared by the rapid-freezing and freeze-substitution method, shows the arrangement of the cells within a single acinus. The mucous cells have well-preserved round mucinogen granules. The mucous and serous cells are aligned to surround the acinus lumen. Serous demilunes are not evident. $\times 6,000$. **b.** Electron micrograph of the sublingual gland prepared by traditional fixation in formaldehyde. Note the considerable expansion and coalescence of the mucinogen granules and the formation of a serous demilune. $\times 15,000$. (Courtesy of Dr. Shohei Yamashina.)

Secretion from salivary glands is largely dependent upon signals from the parasympathetic nerves. The protein content of the saliva is increased by sympathetic innervation and modified by neuropeptides (i.e., nerve growth factor [NGF], substance P).

Myoepithelial cells are contractile cells that embrace the base of the acinar secretory cells.

Myoepithelial cells are contractile cells with numerous processes. Owing to their shape and interwoven processes forming a basket around the acinus, they are commonly referred to as “basket cells.” Other descriptions compare them to “an octopus sitting on a rock.” They lie between the basal plasma

membrane of the epithelial cells and the basal lamina of the epithelium (Fig. 16.28). They are not unique to the salivary gland and can be found in the secretory portion of most excretory glands, such as mammary, lacrimal, and sweat glands.

FIGURE 16.28. Schematic illustration of a mixed acinus of the salivary gland with its intercalated duct. The acinus of the salivary gland represents a blind sac composed of secretory acinar cells that are either serous (protein-secreting) or mucous (mucin-

secreting) cells or both. Serous acini contain only serous cells, mucous acini contain only mucous cells, and mixed acini contain both serous and mucous cells. The illustration shows a mixed acinus with *yellow* mucous cells and *red* serous cells and its intercalated duct lined by *light pink* ductal cells. Note the myoepithelial cells that envelop the acinus (like an octopus sitting on a rock) extend onto the intercalated duct. This drawing clearly shows the basal lamina (*magenta*) as semitransparent sheath at the bottom of the acinus covering both acinar cells and overlying the myoepithelial cells. Basal lamina also extends over ductal cells and myoepithelial cells in the intercalated duct. Myoepithelial cells thus lie between the basal plasma membrane of the acinar and ductal cells and the basal lamina of the epithelium. The cytoplasm of myoepithelial cells possesses contractile elements (similar to that in smooth muscles), which can be seen in electron microscopies (EMs) as dense bodies. The myoepithelial cells and their overlapping processes are attached to each other and to acinar and ductal cells by desmosomes and gap junctions and to the basal lamina by hemidesmosomes. During contraction, myoepithelial cells compress the acinus to aid in the expulsion of saliva and its passage through the intercalated duct.

Myoepithelial cells also underlie the cells of the proximal portion of the duct system (intercalated and striated ducts), where they are oriented along the long axes of ducts. In both locations, the contraction of the myoepithelial cells is instrumental in reducing the acinus's luminal volume and shortening the length of the duct system (pumping effect) in moving secretory products toward the excretory duct.

Myoepithelial cells are sometimes difficult to identify in H&E sections. The nucleus of the cell is often seen as a small, round profile near the basement membrane. The contractile filaments stain with eosin and are sometimes recognized as a thin eosinophilic band adjacent to the basement membrane. On electron micrographs, cells exhibit electron density owing to the accumulation of contractile elements with visible cytoplasmic densities (dense bodies) similar to that found in muscle cells (Fig. 16.29). Myoepithelial cells produce and maintain a basement membrane; thus, their cytoplasm contains typical organelles, such as mitochondria, rER, Golgi apparatus, and occasional collections of glycogen particles. They secrete basement membrane-related proteins (type IV collagen and laminin) and other interstitial matrix proteins. The feature distinguishing them from smooth muscle cells is that

myoepithelial cells are attached to acinar and ductal cells and to each other by desmosomes and gap junctions and to the basal lamina by hemidesmosomes.

FIGURE 16.29. Electron micrograph of the basal portion of an acinus. This electron micrograph shows the basal portion of two secretory cells from a submandibular gland. A myoepithelial cell process is also evident. Note the location of the myoepithelial cell process on the epithelial side of the basal lamina. The cytoplasm of the myoepithelial cell contains contractile filaments and cytoplasmic densities or dense bodies (*arrows*) similar to those seen in smooth muscle cells. The cell on the *left* with the small nucleus is a lymphocyte. Having migrated through the basal lamina, it is also located within the epithelial compartment. *Arrowheads*, cell boundaries; *asterisks*, basolateral folds. $\times 15,000$.

Primary Sjögren syndrome is a systemic autoimmune inflammatory disease that involves salivary and lacrimal glands, resulting in dry mouth and dry eyes. A histologic section of the salivary gland from an affected individual shows focal lymphocytic infiltration of the gland with an increased number of macrophages and plasma cells. In advanced stages,

normal secretory acini are replaced by lymphocytes. Recent studies also indicate the alteration of the myoepithelial cells. The amount of α -smooth muscle actin (α -SMA) that is responsible for contractile properties of myoepithelial cells in salivary glands is significantly reduced in patients with primary Sjögren syndrome when compared with healthy individuals. This may cause a loss of mechanical support for acini and the duct system and contribute to the reduction of salivary flow.

Salivary Ducts

The lumen of the salivary acinus is continuous with that of a **duct system** that may have as many as three sequential segments:

- **Intercalated duct**, which leads from the acinus
- **Striated duct**, so-called because of the presence of “striations,” the infoldings of the basal plasma membrane of the columnar cells that form the duct
- **Excretory ducts**, which are the larger ducts that empty into the oral cavity

The degree of development of the intercalated ducts and striated ducts varies, depending on the nature of the acinar secretion (see Fig. 16.23). Serous glands have well-developed intercalated ducts and striated ducts that modify the serous secretion by both the absorption of specific components from the secretion and the secretion of additional components to form the final product. Mucous glands, in which the secretion is not modified, have very poorly developed intercalated ducts that may not be recognizable in H&E sections. Moreover, they do not display striated ducts.

Intercalated ducts are located between a secretory acinus and a larger duct.

Intercalated ducts are lined by low cuboidal epithelial cells that usually lack any distinctive feature to suggest a function other than that of a conduit. However, the cells of intercalated ducts possess carbonic anhydrase activity. In

serous-secreting glands and mixed glands, they have been shown to

- **secrete HCO_3^-** into the acinar product and
- **absorb Cl^-** from the acinar product.

As noted earlier, intercalated ducts are most prominent in those salivary glands that produce a watery serous secretion. In mucus-secreting salivary glands, the intercalated ducts, when present, are short and difficult to identify.

Striated duct cells have numerous infoldings of the basal plasma membrane.

Striated ducts are lined by a simple cuboidal epithelium that gradually becomes columnar as it approaches the excretory duct. The infoldings of the basal plasma membrane are seen in histologic sections as “striations.” Longitudinally oriented, elongated mitochondria are enclosed in the infoldings. Basal infoldings associated with elongated mitochondria are a morphologic specialization associated with reabsorption of fluid and electrolytes. The striated duct cells also have numerous basolateral folds that are interdigitated with those of adjacent cells. The nucleus typically occupies a central (rather than basal) location in the cell. Striated ducts are the sites of

- **reabsorption of Na^+** from the primary secretion and
- **secretion of K^+ and HCO_3^-** into the secretion.

More Na^+ is resorbed than K^+ is secreted, so the secretion becomes hypotonic. When the secretion is very rapid, more Na^+ and less K^+ appear in the final saliva because the reabsorption and secondary secretion systems cannot keep up with the rate of primary secretion. Thus, the saliva may become isotonic to hypertonic.

The diameter of striated ducts often exceeds that of the secretory acinus. Striated ducts are located in the parenchyma of the glands (they are **intralobular ducts**) but may be

surrounded by small amounts of connective tissue in which blood vessels and nerves can be seen running in parallel with the duct.

Excretory ducts travel in the interlobular and interlobar connective tissue.

Excretory ducts constitute the principal ducts of each of the major glands. They ultimately connect to the oral cavity. The epithelium of small excretory ducts is a simple cuboidal. It gradually changes to pseudostratified columnar or stratified cuboidal. As the diameter of the duct increases, stratified columnar epithelium is often seen, and as the ducts approach the oral epithelium, stratified squamous epithelium may be present. The parotid duct (Stensen duct) and the submandibular duct (Wharton duct) travel in the connective tissue of the face and neck, respectively, for some distance from the gland before penetrating the oral mucosa.

Major Salivary Glands

Parotid gland

The parotid glands are composed of pure serous acini.

The paired serous **parotid glands** are the largest of the major salivary glands. The parotid duct travels from the gland, which is located below and in front of the ear, to enter the oral cavity opposite the second upper molar tooth. The secretory units in the parotid are serous and surround numerous, long, narrow intercalated ducts. Striated ducts are large and conspicuous (Fig. 16.30a).

FIGURE 16.30. Photomicrographs of the three major salivary glands. a. The parotid gland in the human is composed entirely of serous acini and their ducts. Typically, adipose cells are also distributed throughout the gland. The *lower portion* of the figure reveals an excretory duct within a connective tissue septum. $\times 120$. Inset. Higher magnification of the serous acinar cells. $\times 320$. b. The submandibular glands contain both serous and mucous acini. In humans, the serous components predominate. The mucus-secreting acini are readily discernible at this low magnification because of their light staining. The remainder of the field is composed largely of serous acini. Various ducts—excretory, striated, and intercalated—are evident in the field. $\times 120$. Left inset. Higher magnification of an acinus revealing a serous demilune surrounding mucus-secreting cells. $\times 360$. Right inset. Higher magnification of a striated duct. These ducts have columnar epithelium with visible basal striations. $\times 320$. c. The sublingual gland also contains both serous and mucous elements. Here, the mucous acini predominate. The mucous acini are conspicuous because of their light staining. Critical examination of the mucous acini at this relatively low magnification reveals that they are not spherical structures but, rather, elongated or tubular structures with branching outpockets. Thus, the acinus is rather large, and much of it is usually not seen within the plane of a single section. The ducts of the sublingual gland that are observed with the greatest frequency in a section are the interlobular ducts. $\times 120$. Inset. The serous component of the gland is composed largely of demilunes (*asterisks*), artifacts of conventional fixation. $\times 320$.

Large amounts of adipose tissue often occur in the parotid gland; this is one of its distinguishing features (Plate 16.5, page 628). The facial nerve (cranial nerve VII) passes through the parotid gland; large cross sections of this nerve may be encountered in routine H&E sections of the gland and are useful in identifying the parotid. Mumps, a viral infection of the parotid gland, can damage the facial nerve.

Submandibular gland

The submandibular glands are mixed glands that are mostly serous in humans.

The large, paired, mixed submandibular glands are located under either side of the floor of the mouth, close to the mandible. A duct from each of the two glands runs forward and medially to a papilla located on the floor of the mouth just lateral to the frenulum of the tongue. Some mucous acini capped by serous demilunes are generally found among the predominant serous

acini. Intercalated ducts are less extensive than in the parotid gland (Fig. 16.30b and Plate 16.4, page 626).

Sublingual gland

The small sublingual glands are mixed glands that are mostly mucus secreting in humans.

The **sublingual glands**, the smallest of the paired major salivary glands, are located on the floor of the mouth anterior to the submandibular glands. Their multiple small sublingual ducts empty into the submandibular duct as well as directly onto the floor of the mouth. Some of the predominant mucous acini exhibit serous demilunes, but purely serous acini are rarely present (Fig. 16.30c and Plate 16.6, page 630). Intercalated ducts and striated ducts are short, difficult to locate, or sometimes absent. The mucous secretory units may be more tubular than purely acinar.

Saliva

Saliva includes the combined secretions of all the major and minor salivary glands.

Most **saliva** is produced by the salivary glands. The composition of saliva produced by each of the three major salivary glands is slightly different. The parotid glands produce the most serous fluid; the sublingual glands produce slightly more viscous fluid; and the submandibular glands produce the most viscous and mucinous saliva. A smaller amount of saliva is produced by general transudation from the epithelial lining of the oral cavity; minor salivary glands dispersed in the oral mucosa; and by the gingival sulcus and tonsillar crypts. One of the unique features of saliva is the large and variable volume produced. The volume (per weight of gland tissue) of saliva exceeds that of other digestive secretions by as much as 40 times. The large volume of saliva produced is undoubtedly related to its many functions, only some of which are concerned with digestion.

Saliva performs both protective and digestive functions.

The salivary glands produce about 1,500 mL of saliva a day. **Saliva** has numerous functions relating to metabolic and nonmetabolic activities:

- Moistening the oral mucosa, which helps controls water intake. Lack of saliva signals thirst.
- Moistening dry foods to aid chewing and swallowing
- Providing a medium for dissolved and suspended food materials that chemically stimulate taste buds
- Buffering the contents of the oral cavity because of its high concentration of bicarbonate ions
- Digesting carbohydrates with the digestive enzyme α -amylase, which breaks 1,4 glycosidic bonds and continues to act in the esophagus and stomach
- Controlling the bacterial flora of the oral cavity by the use of lysozyme (muramidase), an enzyme that lyses the muramic acid in certain bacteria (e.g., staphylococci)

The unique composition of saliva is summarized in Table 16.1.

TABLE 16.1 Composition of Unstimulated Saliva	
Organic Constituents	Mean (mg/mL)
Protein	220.0
Amylase	38.0
Mucin	2.7
Muramidase (lysozyme)	22.0
Lactoferrin	0.03
ABO group markers	0.005
EGF	3.4
sIgA	19.0
IgG	1.4
IgM	0.2
Glucose	1.0
Urea	20.0

Uric acid	1.5
Creatinine	0.1
Cholesterol	8.0
cAMP	7.0
Inorganic Constituents	
Sodium	15.0
Potassium	80.0
Thiocyanate	
Smokers	9.0
Nonsmokers	2.0
Calcium	5.8
Phosphate	16.8
Chloride	5.0
Fluoride	Traces (according to intake)

cAMP, cyclic adenosine monophosphate; *EGF*, epithelial growth factor; *Ig*, immunoglobulin; *sIgA*, secretory immunoglobulin A.

Modified from Jenkins GN. *The Physiology and Biochemistry of the Mouth*. 4th ed. Blackwell Scientific Publications; 1978.

Saliva contains water, various proteins, and electrolytes.

Saliva contains chiefly water, proteins and glycoproteins (enzymes and antibodies), and electrolytes. It has a high potassium concentration that is approximately 7 times that of blood; a sodium concentration of approximately one-tenth that of blood; a bicarbonate concentration of approximately 3 times that of blood; and significant amounts of calcium, phosphorus, chloride, thiocyanate, and urea. Lysozyme and α -amylase are the principal enzymes present (see Table 16.1).

Saliva is a source of calcium and phosphate ions essential for normal tooth development and maintenance.

Calcium and phosphate in the saliva are essential for the mineralization of newly erupted teeth and the repair of precarious lesions of the enamel in erupted teeth. In addition, saliva serves several other roles in protecting the teeth. Proteins in saliva cover the teeth with a protective coat

called the **acquired pellicle**. Antibodies and other antibacterial agents retard bacterial action that would otherwise lead to tooth decay. Patients whose salivary glands are irradiated, as in the treatment of salivary gland tumors, fail to produce normal amounts of saliva; these patients typically develop numerous **dental caries**. Anticholinergic drugs used to treat some forms of heart disease also significantly reduce salivary secretion and induce the development of dental caries.

FOLDER 16.4

CLINICAL CORRELATION: SALIVARY GLAND TUMORS

Tumors of salivary glands usually occur in the major salivary glands (parotid, submandibular, and sublingual); however, a small percentage occurs in the minor glands located within the oral mucosa, palate, uvula, floor of the mouth, tongue, pharynx, larynx, and paranasal sinuses. Approximately 80% of salivary gland tumors are benign. Most originate in the parotid gland (Fig. F16.4.1a). The palate is the most common site of minor salivary gland tumors.

FIGURE F16.4.1. Pleomorphic adenoma of the parotid gland. **a.** This photograph shows an individual with a parotid mass located near the angle of the mandible. **b.** This low-magnification photomicrograph shows the features of a pleomorphic adenoma. (Courtesy of Dr. Kerry D. Olsen.) Note that normal parotid tissue (basophilic-stained areas in the *lower part*) is separated by the fibrous capsule of a nodule containing connective-like tissue that

resembles the extracellular matrix of cartilage. $\times 40$. Higher magnification *inset* shows a nest of cancer cells separated by lighter eosinophilic-stained stroma that resembles extracellular matrix of the hyaline cartilage. $\times 200$. (Courtesy of Dr. Joaquín J. García.)

The most common benign tumor is the **pleomorphic adenoma**, which accounts for 65% of all salivary gland tumors. It is characterized by epithelial tissue containing ductal and myoepithelial cells intermingled with areas, resembling ground substance of connective tissues (e.g., in cartilage). These connective-like tissues are produced by myoepithelial cells (Fig. F16.4.1b).

Most individuals with benign tumors present with painless swelling of the involved gland. Because of nerve involvement, signs such as numbness or weakness of innervated muscle are also reported. For instance, paralysis of facial muscles or persistent facial pain may be present in some individuals with parotid tumors.

The most common treatment is surgical removal of the tumor. For parotid gland tumors, a total parotidectomy (excision of parotid gland) is often necessary. Postoperative radiation therapy is also used when the tumor is cancerous. Complications of surgical treatment of parotid gland tumors include facial nerve dysfunction and **Frey syndrome** (also known as *gustatory sweating*).

Saliva performs immunologic functions.

As noted, saliva contains antibodies, salivary **immunoglobulin A (IgA)**. IgA is synthesized by plasma cells in the connective tissue surrounding the secretory acini of the salivary glands, and both dimeric and monomeric forms are released into the connective tissue matrix (Fig. 16.31). A **polymeric immunoglobulin receptor (pIgR)** protein is synthesized by the salivary gland cells and inserted into the basal plasma membrane, where it serves as a receptor for dimeric IgA.

FIGURE 16.31. Diagram of different forms of immunoglobulin A (IgA). This drawing shows the monomer of IgA (*top*). The dimer of IgA is a product of the plasma cell and contains a J chain (*J*) connecting two monomers (*middle*). The secretory component (*SC*), a product of proteolytically cleaved pIgR, is added to the dimer to form secretory IgA (sIgA; *bottom*). *pIgR*, polymeric immunoglobulin receptor; *sIgA*, secretory immunoglobulin A.

When dimeric IgA binds to the receptor, the **pIgR - dIgA complex** is internalized by receptor-mediated endocytosis and carried through the acinar cell to the apical plasma membrane. Here, pIgR is proteolytically cleaved and the extracellular part of the receptor that is bound to dIgA is released into the lumen as **secretory IgA (sIgA)**. This process of synthesis and secretion of IgA is essentially identical to that which occurs in the more distal parts of the gastrointestinal tract, where sIgA is transported across the absorptive columnar epithelium of the small intestine and colon (see page 658).

DIGESTIVE SYSTEM I: ORAL CAVITY AND ASSOCIATED STRUCTURES

OVERVIEW OF THE DIGESTIVE SYSTEM

- The **digestive system** consists of the **alimentary canal**, its associated organs (tongue and teeth), and exocrine glands (salivary glands, liver, pancreas).
- The major functions of the digestive system are transport of ingested water and food through the alimentary canal; secretion of fluids, electrolytes, and digestive enzymes; digestion and absorption of digested products; and excretion of undigested remains.
- Because the lumen of the alimentary canal is physically and functionally external to the body, the alimentary **mucosa** (lining of the digestive system) provides immunologic protection and acts as a barrier between the lumen and the internal body environment.

ORAL CAVITY

- The **oral cavity** consists of the mouth, which includes the tongue, teeth, and their supporting structures; major and minor salivary glands; and tonsils.
- **Oral mucosa** lines the oral cavity. Depending on its location, it is divided into **masticatory mucosa** (gingiva and hard palate), a stratified squamous keratinized or parakeratinized epithelium; **lining mucosa** (remaining parts of the oral cavity, except for the dorsum of the tongue), a stratified squamous nonkeratinized epithelium; and **specialized mucosa** (dorsal surface of the tongue), which contains lingual papillae.

TEETH

- Humans have 32 permanent **teeth**; each tooth has a root embedded in the alveolar bone and a **clinical crown** that projects into the oral cavity. The centrally located **pulp cavity** contains loose connective tissue, vessels, and nerves.
- The tooth has three specialized tissues: visible **enamel** covering its anatomic crown; **cementum**, found on the root for the attachment of periodontal ligaments; and **dentin**, which lies deep to enamel and cementum.
- **Enamel** is produced by **ameloblasts** (during **enamel organ** embryonic tooth development) and is composed of parallel **enamel rods**; enamel production is regulated by specific proteins (e.g., amelogenins, ameloblastins, enamelines).
- **Cementum** is a bone-like structure that covers the root of the tooth. Collagen fibers project from the cementum and form the **periodontal ligaments** connecting the tooth to the **alveolus** (socket).
- **Dentin** is initially deposited by odontoblasts as **predentin**, which, under the influence of **dentin phosphoprotein (DPP)** and **dentin sialoprotein (DSP)**, is

mineralized to dentin. It has tubules containing elongated processes of odontoblasts.

TONGUE

- The specialized mucosa on the dorsal surface of the tongue has four types of projecting **lingual papillae**: **filiform** (made of stratified squamous keratinized epithelium), **foliate**, **fungiform**, and **circumvallate** (lined by stratified squamous nonkeratinized epithelium).
- The foliate, fungiform, and circumvallate papillae contain **taste buds** on their surface with neuroepithelial (sensory) cells for the detection of five basic tastes: sweet, salty, bitter, sour, and umami.
- **Sweet**, **bitter**, and **umami tastes** are detected by G-protein-coupled taste receptors, and **sour** and **sweet tastes** act on Na^+ and K^+ channels.
- The **lingual tonsil** represents aggregation of diffuse lymphatic tissue and lymphatic nodules at the base of the tongue.

SALIVARY GLANDS

- The **salivon** is the basic secretory unit of any salivary gland and consists of the acinus, intercalated duct, and excretory duct.
- The **acinus** is the secretory part of the salivon. Acini are spherical, containing **serous cells** (protein secreting); more tubular, containing **mucous cells** (mucin secreting); or mixed, with both types of cells. Mixed acini in routine preparation have **serous demilunes** (artifacts of fixation). Myoepithelial cells are present at the base of secretory cells.
- Secretion from the acinus is drained by the **intercalated duct** (lined by simple cuboidal epithelium), which merges

into the **striated duct** (simple columnar epithelium with distinct basal striations) and finally into the **excretory duct** (stratified cuboidal or columnar epithelium), which is surrounded by connective tissue.

- Cells of striated ducts have numerous infoldings of the basal plasma membrane that contain mitochondria. The infoldings are specialized for reabsorption of electrolytes from the secretion.
- The **major salivary glands** are the paired parotid, submandibular, and sublingual glands.
- **Parotid glands** contain only serous acini with adipose tissue distributed throughout the gland.
- **Submandibular glands** contain predominantly serous but also mucous acini.
- **Sublingual glands** are also mixed but primarily contain elongated mucous acini. The serous component is visible as **demilunes**.
- **Saliva** is produced by salivary glands and has protective and digestive functions. It contains water, proteins and glycoproteins (enzymes and antibodies), and electrolytes.

PLATE 16.1 ■ LIP AND MUCOCUTANEOUS JUNCTION

The lips are the entry point of the alimentary canal. Here, the thin **keratinized epithelium** of the facial skin changes to the thick **parakeratinized epithelium** of the oral mucosa. At the mucocutaneous junction, the *red* portion of the lips is characterized by deep penetration of connective tissue papillae into the base of the **stratified squamous keratinized epithelium**. The blood vessels and nerve endings in these papillae are responsible for both the color and exquisite touch sensitivity of the lips.

ORIENTATION MICROGRAPH: A hematoxylin and eosin (H&E)-stained sagittal section through the upper lip in this low-power orientation photomicrograph to the *right* (×8) reveals the skin of the face, the red margin of the lip, and the transition to the oral mucosa (*OM*). The *marked rectangles* indicate representative areas of each of these sites, shown at higher magnifications in

upper, middle, and lower rows of figures on the adjacent plate. Note the change in thickness of the epithelium from the exterior or facial portion of the lip (the *vertical surface on the left*) to the interior surface of the oral cavity (the surface beginning with *rectangle marked lower* and continuing upward along the right surface of the lip) in this micrograph.

Keratinized epithelium, lip, human, H&E $\times 120$.

The keratinized epithelium (EP) of the face is relatively thin and has the general features of thin skin found in other sites.

Associated with it are hair follicles (*HF*), sebaceous glands (*SG*), and blood vessels (*BV*).

Keratinized epithelium, lip, human, H&E $\times 380$.

The *circled area* in the figure on the *left* is shown at a higher magnification. The *reddish brown* material in the basal cells is the pigment melanin (*M*), and the *dark blue* near the surface is the stratum granulosum (*SG*) with its deep blue-stained keratohyalin granules.

Red margin, lip, human, H&E $\times 120$.

The epithelium of the **red margin** of the lip is much thicker than that of the face. The stratum granulosum is still present; thus, the epithelium is keratinized. The feature that accounts for the coloration of the red margin is the deep penetration of the connective tissue papillae into the epithelium (*arrowheads*). The thinness of the epithelium combined with the extensive vascularity of the underlying connective tissue, particularly the extensive venous blood vessels (*BV*), allows the color of the blood to show through.

Red margin, lip, human, H&E $\times 380$.

The sensitivity of the red margin to stimuli such as light touch is due to the presence of an increased number of sensory receptors. In fact, each of the two deep papillae seen in the figure on the *left*

contains a Meissner corpuscle (*MC*), one of which is more clearly seen in this figure.

Mucocutaneous junction, lip, human, H&E $\times 120$.

The transition from the keratinized red margin to the fairly thick stratified squamous parakeratinized epithelium of the oral mucosa

is evident in this figure. Note how the stratum granulosum suddenly ends. This is more clearly shown at higher magnification in the figure on the *right*.

Mucocutaneous junction, lip, human, H&E $\times 380$.

Beyond the site where the stratum granulosum cells disappear, nuclei are seen in the superficial cells up to the surface (*arrows*). The epithelium is also much thicker at this point and remains so throughout the oral cavity.

BV, venous blood vessels
EP, epithelium
HF, hair follicle
M, melanin pigment

MC, Meissner corpuscle

OM, oral mucosa

SG, stratum granulosum

SG1, sebaceous gland

arrowheads, connective tissue papillae

arrows, nuclei of superficial cells up to surface

PLATE 16.2 ■ TONGUE I

The tongue is a muscular organ projecting into the oral cavity from its inferior surface. It is covered with a mucous membrane that consists of **stratified squamous epithelium**, keratinized in parts, resting on loose connective tissue. The undersurface of the tongue is relatively uncomplicated. The mucosa of the dorsal surface, however, is modified to form three types of papillae: **filiform**, **fungiform**, and **circumvallate**. The circumvallate papillae form a V-shaped row that divides the tongue into a body and a root; the dorsal surface of the body, that is, the portion anterior to the circumvallate papillae, contains filiform and fungiform papillae. Parallel ridges bearing taste buds are found on the sides of the tongue and are particularly evident in infants. When sectioned at right angles to their long axis, they appear as papillae and, although not true papillae, are called **foliate papillae**.

The tongue contains both intrinsic and extrinsic voluntary striated muscles. The **striated muscles** of the tongue are arranged in three interweaving planes, with each arrayed at right angles to the other two. This arrangement is unique to the tongue. It provides enormous flexibility and precision in the movements of the tongue that are essential to human speech as well as to its role in digestion and swallowing. The arrangement also allows easy identification as lingual muscle.

Dorsal surface, tongue, monkey, hematoxylin and eosin (H&E) $\times 65$; inset $\times 130$.

This figure shows the dorsal surface of the tongue with the **filiform papillae** (*Fil P*). They are the most numerous of the three types of papillae. Structurally, they are bent, conical projections of the epithelium, with the point of the projection directed posteriorly. These papillae do not possess taste buds and are composed of stratified squamous keratinized epithelium.

The **fungiform papillae** are scattered about as isolated, slightly rounded, elevated structures situated among the filiform papillae. A fungiform papilla is shown in the *inset*. A large connective tissue core (primary connective tissue papilla) forms the center of the fungiform papilla, and smaller connective tissue papillae (secondary connective tissue papillae) project into the base of the surface epithelium (*arrowhead*). The connective tissue of the papillae is highly vascularized. Because of the deep penetration of connective tissue into the epithelium, combined with a very thin keratinized

surface, the fungiform papillae appear as small red dots when the dorsal surface of the tongue is examined by gross inspection.

Ventral surface, tongue, monkey, H&E $\times 65$.

The ventral surface of the tongue is shown in this figure. The smooth surface of the **stratified squamous epithelium** (*Ep*) contrasts with the irregular surface of the dorsum of the tongue. Moreover, the epithelial surface on the ventral surface of the tongue is usually not keratinized. The connective tissue (*CT*) is immediately deep to the epithelium; deeper still is the striated muscle (*M*). The numerous connective tissue papillae that project into the base of the epithelium of both ventral and dorsal surfaces give the epithelial-connective tissue junction an irregular profile. Often, these connective tissue papillae are cut obliquely and then appear as small islands of connective tissue within the epithelial layer (see the previous figure).

The connective tissue extends as far as the muscle without changing character, and no submucosa is recognized. The muscle (*M*) is striated and is unique in its organization, that is, the fibers travel in three planes. Therefore, most sections will show bundles of muscle fibers cut longitudinally, at right angles to each other, and in cross section. Nerves (*N*) that innervate the muscle are also frequently observed in the connective tissue septa between the muscle bundles.

The surface of the tongue behind the vallate papillae (the root of the tongue) contains lingual tonsils (not shown). These are similar in structure and appearance to the palatine tonsils illustrated in Plate 14.1 (page 526).

CT, connective tissue

Ep, epithelium

Fil P, filiform papillae

M, striated muscle bundles

N, nerves

arrowhead (inset), secondary connective tissue papilla

PLATE 16.3 ■ TONGUE II—FOLIATE PAPILLAE AND TASTE BUDS

The papillae and their associated taste buds constitute the specialized mucosa of the oral cavity. Although filiform papillae do not have taste buds, the other three types, namely, foliate, fungiform, and circumvallate, contain taste buds in their epithelium. The fungiform (i.e., mushroom-shaped) papillae (see *inset* on Plate 16.2, page 622) are most numerous near the tip of the tongue. Taste buds are present in the epithelium on their dorsal surface. The taste buds in the epithelium covering the circumvallate and foliate papillae are located in deep clefts that separate the papillae from adjacent mucosa or from each other, respectively. Ducts of lingual salivary glands (von Ebner glands; a component of the minor salivary glands) empty their serous secretions into the moat surrounding each circumvallate papilla. The secretions flush material from the moat to allow the taste buds to respond to new stimuli. Similarly, ducts of small serous glands empty into the clefts between foliate papillae. Taste buds in section appear as oval, pale-staining bodies that extend through the thickness of the epithelium. A small opening at the epithelial surface is called the taste pore. Taste buds react to only five stimuli: sweet, salty, bitter, sour, and umami. Sensitivity to all tastes is distributed across the entire tongue; however, taste receptors appear to be more concentrated in specific areas of the tongue; taste buds at the tip of the tongue detect sweet stimuli, those immediately posterolateral to the tip detect salty stimuli, and those on the circumvallate papillae detect bitter and umami stimuli.

Foliate papillae, tongue, human, hematoxylin and eosin (H&E) ×50.

Foliate papillae consist of a series of parallel ridges that are separated by narrow, deep mucosal clefts (see Fig. 16.5, page 592). They are aligned at right angles to the long axis of the tongue on its posterior lateral edge. In younger individuals, they are readily observed by gross inspection. However, with age, foliate papillae may not be recognized. This micrograph shows three papillae; each is separated from its neighbor by a narrow cleft (*C*). The surface of these papillae is covered by a thick stratified nonkeratinized epithelium (*SE*). The basal surface of the epithelium is extremely uneven owing to the presence of deep, penetrating connective tissue papillae (*CTP*). In contrast, the

epithelium lining the clefts (*Ep*) is relatively thin and uniform. It contains numerous taste buds. These are the light-staining objects seen in the cleft epithelium. Underlying the epithelium is a layer of loose connective tissue (*LCT*) and a central core of dense connective tissue. Within this core and between bundles of muscle fibers beneath the papillae are **lingual serous glands** (*LSG*). These glands, like the serous glands associated with the circumvallate papillae, have ducts (*D*) that empty into the base of the clefts between papillae.

Taste buds, tongue, human, H&E $\times 500$.

This higher magnification micrograph shows the **taste buds** located within the cleft epithelium. The taste buds typically appear as oval, pale-staining structures that extend through much of the thickness of the epithelium. Beneath the taste bud are nerve fibers (*NF*) that are also lightly stained. At the apex of the taste bud, there is a small opening in the epithelium, which is the taste pore (*TP*).

Taste bud, tongue, human, H&E $\times 1,100$.

This micrograph shows to advantage the **taste pore** (*TP*), the cells of the taste bud, and its associated nerve fibers (*NF*). The cells with large, round nuclei are **neuroepithelial sensory cells** (*NSC*). They are the most numerous cells of the taste bud. At their apical surface, they possess microvilli that extend into the taste pore. At their basal surface, they form a synapse with the afferent sensory fibers that make up the underlying nerve. Among the sensory cells are **supporting cells** (*SC*). These cells contain microvilli on their apical surface. Also present in the taste bud at its base are small cells simply referred to as **basal cells** (*BC*), one of which is identified here. They are the stem cells for the supporting and neuroepithelial cells, which have a turnover life of about 10 days.

BC, basal cells
C, cleft
CTP, connective tissue papillae
D, ducts
Ep, epithelium lining the clefts
LCT, loose connective tissue
LSG, lingual serous glands
NF, nerve fibers

NSC, neuroepithelial sensory cells
SC, supporting cells
SE, stratified nonkeratinized epithelium
TP, taste pore

PLATE 16.4 ■ SUBMANDIBULAR GLAND

Like the parotid glands, the submandibular glands are located outside the oral cavity. They are located under either side of the floor of the mouth near the mandible. A duct runs forward and medially from each of the two glands to a papilla located on the floor of the mouth just lateral to the frenulum of the tongue. The secretory components of the submandibular glands are the acini, which are of three types: **serous acini**, which are protein secreting like those of the parotid gland; **mucous acini**, which secrete mucin; and acini containing both serous- and mucus-secreting cells. In the case of the **mixed acini**, the mucous cells are capped by serous cells, which are typically described as demilunes. Research suggests that the demilune is an artifact of tissue preparation and that all of the cells are aligned to secrete into the acinus lumen. Traditional fixation in formaldehyde appears to expand the mucous cells with the consequent squeezing of the serous cells to form their cap-like position.

ORIENTATION MICROGRAPH: This micrograph reveals a portion of the submandibular gland. A single well-defined lobe (*L*) is seen in the *upper part* of the micrograph. Within the central portion of the gland, there is a dense connective tissue core (*DCT*) containing the larger arteries (*A*), veins (*V*), and excretory ducts (*ED*) of the gland. The submandibular gland is a mixed gland; those regions containing serous acini (*SA*) are darkly stained, whereas regions containing mucous acini (*MA*) are lighter in appearance.

Submandibular gland, human, hematoxylin and eosin (H&E) $\times 175$.

This micrograph reveals the various components of the submandibular gland. The **serous acini (SA)** are darkly stained in contrast to the lighter staining **mucous acini (MA)**. Furthermore, the serous acini are generally spherical in shape. The mucous acini are more tubular or elongated and sometimes can be seen to branch. The secretion from the acini enters an intercalated duct. They are the smallest ducts and are of relatively short length. They

reside within the lobule but are often difficult to find because of their shortness. These ducts, in turn, empty into the larger **striated duct** (*SD*). This type of duct is better demonstrated in the next micrograph. Their contents then empty into an **excretory duct** (*ED*), which is recognized by a stratified or pseudostratified epithelium. Other features of note in this micrograph are arteries (*A*) and veins (*V*), which are found coursing in the connective tissue with the larger ducts. Also evident in this micrograph is an area containing an accumulation of lymphocytes and plasma cells (*LP*).

Submandibular gland, human, H&E $\times 725$.

The *boxed area* in the previous micrograph is shown here at higher magnification. It includes several **mucous acini** (*MA*) on the *left side* of the micrograph, a number of **serous acini** (*SA*) on the *right side* of the micrograph, and in the *center*, two **mixed acini** (*MxA*) consisting of mucus- and serous-secreting cells. Characteristically, the mucus-secreting cells have a pale-staining cytoplasm with their nuclei flattened at the base of the cell. In contrast, the serous-secreting cells are deeply stained and exhibit round nuclei. In addition, the lumen (*Lu*) of the acini associated with the mucus-secreting cells is relatively wide; the lumen of the serous acini is relatively narrow and difficult to find. An additional point that should be made is that the serous cells of the mixed acini generally appear as a cap in relation to the mucous cells. These cells are referred to as *demilunes*. In evaluating some of those acini that appear to be serous in nature, it is possible that they simply represent a tangential section of a demilune. A **striated duct** (*SD*) is also included in the micrograph. It is so named because of the faint striations that can be seen in the basal cytoplasm. These ducts, as noted, receive secretion from the intercalated ducts and empty into the larger excretory ducts.

A, arteries
DCT, dense connective tissue core
ED, excretory ducts
L, lobe
LP, lymphocytes and plasma cells
Lu, lumen
MA, mucous acini
MxA, mixed acini
SA, serous acini
SD, striated duct

V, vein

PLATE 16.5 ■ PAROTID GLAND

The parotid glands are the largest of the major salivary glands. They are composed of alveoli containing only serous secretory cells. Adipose tissue often occurs in the parotid gland and may be one of its distinguishing features. The facial nerve (cranial nerve VII) passes through the parotid gland; large cross sections of this nerve, often found in routine hematoxylin and eosin (H&E) sections of the gland, may also be of help in identifying the parotid. Mumps, a viral infection of the parotid gland, can damage the facial nerve.

Parotid gland, human, H&E $\times 160$.

The parotid gland in the human is composed entirely of serous acini (A) and their ducts. However, numerous adipose cells (AC) are usually distributed throughout the gland. Both the serous acini and their duct system in the parotid gland are comparable in structure and arrangement to the same components in the submandibular gland. Within the lobule, the striated ducts (StD) are readily observed. They exhibit a simple columnar epithelium. The intercalated ducts are smaller; at the low magnification of this figure, they are difficult to recognize. A few intercalated ducts (ID) are indicated. The lower portion of the figure reveals an excretory duct (ED) within a connective tissue septum (CT). The epithelium of this excretory duct exhibits two layers of nuclei and is either pseudostratified or, possibly, already true stratified epithelium.

Parotid gland, monkey, glutaraldehyde-osmium tetroxide fixed, H&E $\times 640$.

The serous cells are optimally preserved in this specimen and reveal their secretory (zymogen) granules. The granules appear as fine dot-like objects within the cytoplasm. The acinus in the upper right of the figure has been cut in cross section and reveals the acinar lumen (AL). The small rectangle drawn in the acinus represents an area comparable to the electron micrograph shown in Figure 16.25. The large acinar profile to the left of the striated duct (StD) shows that the acini are not simple spheres but, rather, irregular elongated structures. Because of the small size of the

acinar lumen and the variability in sectioning an acinus, the lumen is seen infrequently.

A cross-sectional profile of an intercalated duct (*ID*) appears on the *left* of the micrograph; note its simple cuboidal epithelium. A single flattened nucleus is present at the top of the duct and may represent one of the myoepithelial cells that are associated with the beginning of the duct system as well as with the acini (*A*). The large duct occupying the *center* of the micrograph is a **striated duct** (*StD*). It is composed of columnar epithelium. The striations (*S*) that give the duct its name are evident. Also of significance is the presence of plasma cells (*PC*) within the connective tissue surrounding the duct. These cells produce the immunoglobulins taken up and resecreted by the acinar cells, particularly secretory IgA (sIgA).

A, acinus
AC, adipose cell
AL, acinar lumen
CT, connective tissue
ED, excretory duct
ID, intercalated duct

StD, striated duct

PLATE 16.6 ■ SUBLINGUAL GLAND

The sublingual glands are the smallest of the paired major salivary glands. Their multiple small ducts empty into the submandibular ducts as well as directly onto the floor of the mouth. The sublingual gland resembles the submandibular gland in that it contains both serous and mucous elements. In the sublingual gland, however, the mucous acini predominate. Some of the predominant mucous acini have serous demilunes, but purely serous acini are rarely present.

Saliva includes the combined secretions of all the major and minor salivary glands. The functions of saliva include *moistening* dry foods to aid swallowing, *dissolving* and *suspending* food materials that chemically stimulate taste buds, *buffering* the contents of the oral cavity through its high concentration of bicarbonate ion, digestion of carbohydrates by the digestive enzyme α -amylase (which breaks the 1-4 glycoside bonds and continues to act in the esophagus and stomach), and *controlling* the bacterial *flora* of the oral cavity because of the presence of the antibacterial enzyme *lysozyme*.

Saliva is a source of calcium and phosphate ions essential for normal tooth development and maintenance. It also contains antibodies, notably salivary secretory immunoglobulin A (sIgA). Salivation is part of a reflex arc that is normally stimulated by the ingestion of food, although sight, smell, or even thoughts of food can also stimulate salivation.

Sublingual gland, human, hematoxylin and eosin (H&E) $\times 160$.

This figure shows a **sublingual gland** at low power. The mucous acini (*MA*) are conspicuous because of their light staining. Critical examination of the mucous acini at this relatively low magnification reveals that they are not spherical structures but, rather, elongated or tubular structures with branching outpockets. Thus, the acinus is rather large, and much of it is usually not seen within the plane of a single section.

The serous component of the gland is composed largely of **demilunes**, but occasional serous acini are present. As noted earlier, some of the serous demilunes may be sectioned in a plane that does not include the mucous component of the acinus, thus giving the appearance of a serous acinus.

The ducts of the sublingual gland that are observed most frequently in a section are the intralobular ducts. They are the equivalent of

the striated duct of the submandibular and parotid glands but lack the extensive basal infoldings and mitochondrial array that creates the striations. One of the **intralobular ducts** (*InD*) is evident in this figure (*upper right*). The area within the *rectangle* includes part of this duct and is shown at higher magnification in the next figure.

Sublingual gland, human, H&E $\times 400$.

Note that through a fortuitous plane of section, the lumen of a **mucous acinus** (*MA*) (*upper right*) is seen joining an intercalated duct (*ID*). The juncture between the acinus and the beginning of the **intercalated duct** is marked by an *arrowhead*. The intercalated duct is composed of a flattened or low columnar epithelium similar to that seen in the other salivary glands. The intercalated ducts of the sublingual gland are extremely short, however, and thus are usually difficult to find. The intercalated duct seen in this micrograph joins with one or more other intercalated ducts to become the **intralobular duct** (*InD*), which is identified by its columnar epithelium and relatively large lumen. The point of transition from intercalated to intralobular duct is not recognizable in the micrograph, however, because the duct wall has only been grazed and the shape of the cells cannot be determined.

Examination of the acini at this higher magnification also reveals the serous demilunes (*SD*). Note how they form a cap-like addition to the mucous end pieces. The cytologic appearance of the mucous cells (*MC*) and serous cells is essentially the same as that described for the submandibular gland. The area selected for this higher magnification also reveals isolated cell clusters that bear some resemblance to serous acini. It is likely, however, that these cells are actually mucous cells that either have been cut in a plane parallel to their base and do not include the mucinogen-containing portions of the cell or are in a state of activity in which, after depletion of their granules, the production of new mucinogen granules does not yet suffice to give the characteristic “empty” mucous cell appearance.

An additional important feature of the connective tissue stroma is the presence of numerous lymphocytes and plasma cells. Some of the plasma cells are indicated by the *arrows*. The plasma cells are associated with the production of salivary IgA and are also present in the other salivary glands.

ID, intercalated duct

HISTOLOGY

■ OVERVIEW OF THE ESOPHAGUS AND GASTROINTESTINAL TRACT

The portion of the **alimentary canal** that extends from the proximal part of the esophagus to the distal part of the anal canal is a hollow tube of varying diameter. This tube has the same basic structural organization throughout its length. Its wall is formed by four distinctive layers. From the lumen outward (Fig. 17.1), they are as follows:

FIGURE 17.1. General organization of the alimentary canal. This composite diagram shows the wall structure of the alimentary canal in four representative organs: esophagus, stomach, small intestine, and large intestine. Note that villi, a characteristic feature of the small intestine, are not present in other parts of the alimentary canal. Mucosal glands are present throughout the length of the alimentary canal but sparingly in the esophagus and oral cavity. Submucosal glands are present in the esophagus and duodenum. The extramural glands (liver and pancreas) empty into the duodenum (first part of the small intestine). Diffuse lymphatic tissues and nodules are found in the lamina propria throughout the entire length of the alimentary canal (shown here only in the large intestine). Nerves, blood vessels, and lymphatic vessels reach the alimentary canal via the mesenteries or via adjacent connective tissue (tunica adventitia as in the retroperitoneal organs).

- **Mucosa**, consisting of a lining epithelium, an underlying connective tissue called the **lamina propria**, and the **muscularis mucosae**, composed of smooth muscle
- **Submucosa**, consisting of dense irregular connective tissue
- **Muscularis externa**, consisting, in most parts, of two layers of smooth muscle
- **Serosa**, a serous membrane consisting of a simple squamous epithelium, the mesothelium, and a small amount of underlying connective tissue. An **adventitia** consisting only of connective tissue is found where the wall of the tube is directly attached or fixed to adjoining structures (i.e., body wall and certain retroperitoneal organs).

Mucosa

The structure of the **esophagus** and **gastrointestinal tract** varies considerably from region to region; most of the variation occurs within the mucosa. The epithelium differs throughout the alimentary canal and is adapted to the specific function of each part of the tube. The mucosa has three principal functions: **protection**, **absorption**, and **secretion**. The histologic characteristics of these layers and their functions are described later in this chapter in relation to specific regions of the digestive tube.

The epithelium of the mucosa serves as a barrier that separates the lumen of the alimentary canal from the rest of the organism.

The epithelial barrier separates the external luminal environment of the tube from the tissues and organs of the body. The barrier aids in the protection of the individual from the entry of antigens, pathogens, and other noxious substances. In the esophagus, a

stratified squamous epithelium provides protection from physical abrasion by ingested food. In the gastrointestinal portion of the alimentary tract, tight junctions between the simple columnar epithelial cells of the mucosa serve as a selectively permeable barrier. Most epithelial cells transport products of digestion and other essential substances such as water through the cell and into the extracellular space beneath the tight junctions.

The absorptive function of the mucosa allows the movement of digested nutrients, water, and electrolytes into the blood and lymph vessels.

The **absorption** of digested nutrients, water, and electrolytes is possible because of projections of the mucosa and submucosa into the lumen of the digestive tract. These surface projections greatly increase the surface area available for absorption and vary in size and orientation. They consist of the following structural specializations (see Fig. 17.1):

- **Plicae circulares** are circumferentially oriented submucosal folds present along most of the length of the small intestine.
- **Villi** are mucosal projections that cover the entire surface of the small intestine, the principal site of absorption of the products of digestion.
- **Microvilli** are tightly packed, microscopic projections of the apical surface of intestinal absorptive cells. They further increase the surface available for absorption.

In addition, the **glycocalyx** consists of glycoproteins that project from the apical plasma membrane of epithelial absorptive cells. It provides an additional surface for adsorption and includes enzymes secreted by the absorptive cells that are essential for the final steps of digestion of proteins and sugars. The epithelium selectively absorbs the products of digestion both for its own cells and for transport into the vascular system for distribution to other tissues.

The secretory function of the mucosa provides lubrication and delivers digestive enzymes, hormones, and antibodies into the lumen of the alimentary tube.

Secretion is carried out largely by glands distributed throughout the length of the digestive tube. The various secretory products provide mucus for protective lubrication as well as buffering of the tract lining and substances that assist in digestion, including enzymes,

hydrochloric acid, peptide hormones, and water (see Fig. 17.1). The mucosal epithelium also secretes antibodies that it receives from the underlying connective tissue.

The glands of the alimentary tract (see Fig. 17.1) develop from invaginations of the luminal epithelium and include the following:

- **Mucosal glands** that extend into the lamina propria
- **Submucosal glands** that deliver their secretions either directly to the lumen of mucosal glands or via ducts that pass through the mucosa to the luminal surface
- **Extramural glands** that lie outside the digestive tract and deliver their secretions via ducts that pass through the wall of the intestine to enter the lumen. The liver and pancreas are extramural digestive glands (see Chapter 18, Digestive System III: Liver, Gallbladder, and Pancreas, page 692) that greatly increase the secretory capacity of the digestive system. They deliver their secretions into the **duodenum**, the first part of the small intestine.

The lamina propria contains glands, vessels that transport absorbed substances, and components of the immune system.

As noted, the **mucosal glands** extend into the lamina propria throughout the length of the alimentary canal. In addition, in several parts of the alimentary canal (e.g., the esophagus and anal canal), the lamina propria contains aggregations of mucus-secreting glands. In general, they lubricate the epithelial surface to protect the mucosa from mechanical and chemical injury. These glands are described later in this chapter in relation to specific regions of the digestive tube.

In segments of the digestive tract in which absorption occurs, principally in the small and large intestines, the absorbed products of digestion diffuse into the **blood and lymphatic vessels** of the lamina propria for distribution. Typically, the blood capillaries are of the fenestrated type and collect most of the absorbed metabolites. In the small intestine, lymphatic capillaries are numerous and receive some absorbed lipids and proteins.

- The **lymphatic tissues** in the lamina propria function as an integrated immunologic barrier that protects against pathogens and other antigenic substances that could potentially enter through the mucosa from the lumen of the alimentary canal. Lymphatic tissues present in the lamina propria are as follows:

- **Diffuse lymphatic tissue** consisting of numerous lymphocytes and plasma cells located in the lamina propria and lymphocytes transiently residing in the intercellular spaces of the epithelium
- **Lymphatic nodules** with well-developed germinal centers
- **Eosinophils**, macrophages, and, sometimes, neutrophils

The diffuse lymphatic tissue and the lymphatic nodules are referred to as **gut-associated lymphatic tissue (GALT)**. In the distal small intestine, the **ileum**, extensive aggregates of nodules, called **Peyer patches**, occupy much of the lamina propria and submucosa. They tend to be located on the side of the tube opposite the attachment of the mesentery. Aggregated lymphatic nodules are also present in the appendix.

The muscularis mucosae forms the boundary between mucosa and submucosa.

The **muscularis mucosae**, the deepest portion of the mucosa, consists of **smooth muscle** cells arranged in an inner circular and outer longitudinal layer. Contraction of this muscle produces movement of the mucosa, forming ridges and valleys that facilitate absorption and secretion. This localized movement of the mucosa is independent of the peristaltic movement of the entire wall of the digestive tract.

Submucosa

The submucosa consists of a dense irregular connective tissue layer containing blood and lymphatic vessels, a nerve plexus, and occasional glands.

The **submucosa** contains the larger blood vessels that send branches to the mucosa, muscularis externa, and serosa. The submucosa also contains lymphatic vessels and a nerve plexus. The extensive nerve network in the submucosa contains visceral sensory fibers of mainly sympathetic origin, parasympathetic (terminal) ganglia, and preganglionic and postganglionic parasympathetic nerve fibers. The nerve cell bodies of parasympathetic ganglia and their postganglionic nerve fibers represent the **enteric nervous system**, the third division of the autonomic nervous system. This system is primarily responsible for innervating the smooth muscle layers of the alimentary canal and can function totally independently of the central nervous system. In the submucosa, the network of unmyelinated nerve fibers and ganglion cells constitute the **submucosal plexus** (also called **Meissner plexus**).

As noted, glands occur occasionally in the submucosa in certain locations. For example, they are present in the esophagus and the initial portion of the duodenum. In histologic sections, the presence of these glands often aids in identifying the specific segment or region of the tract.

Muscularis Externa

In most parts of the digestive tract, the **muscularis externa** consists of two concentric and relatively thick layers of smooth muscle. The cells in the inner layer form a tight spiral, described as a **circularly oriented layer**; those in the outer layer form a loose spiral, described as a **longitudinally oriented layer**. Located between the two muscle layers is a thin connective tissue layer. Within this connective tissue lies the **myenteric plexus** (also called the **Auerbach plexus**), containing nerve cell bodies (ganglion cells) of postganglionic parasympathetic neurons, neurons of the enteric nervous system, and satellite cells as well as blood vessels and lymphatic vessels.

Contractions of the muscularis externa mix and propel the contents of the digestive tract.

Contraction of the inner circular layer of the **muscularis externa** compresses and mixes the contents by constricting the lumen; contraction of the outer, longitudinal layer propels the contents by shortening the tube. The slow, rhythmic contraction of these muscle layers under the control of the enteric nervous system produces **peristalsis** (i.e., waves of contraction). Peristalsis is marked by constriction and shortening of the tube, which moves the contents through the intestinal tract.

A few sites along the digestive tube exhibit variations in the muscularis externa. For example, in the wall of the proximal portion of the esophagus (pharyngoesophageal sphincter) and around the anal canal (external anal sphincter), striated muscle forms part of the muscularis externa. In the stomach, a third, obliquely oriented layer of smooth muscle is present deep into the circular layer. Finally, in the large intestine, part of the **longitudinal smooth muscle layer** is thickened to form three distinct, equally spaced longitudinal bands called **teniae coli**. During contraction, the teniae facilitate shortening of the tube to move its contents.

The circular smooth muscle layer forms sphincters at specific locations along the digestive tract.

At several points along the digestive tract, the **circular muscle layer** is thickened to form **sphincters** or **valves**. From the oropharynx distally, these structures include the following:

- **Pharyngoesophageal sphincter**. Actually, the lowest part of the cricopharyngeus muscle is physiologically referred to as the **superior (upper) esophageal sphincter**. It prevents the entry of air into the esophagus.
- **Inferior (lower) esophageal sphincter**. As its name implies, this sphincter is located at the lower end of the esophagus; its action is reinforced by the diaphragm that surrounds this part of the esophagus as it passes into the abdominal cavity. It creates a pressure difference between the esophagus and the stomach that prevents reflux of gastric contents into the esophagus. **Abnormal relaxation of this sphincter allows the acidic contents of the stomach to return (reflux) into the esophagus. If not treated, this condition may progress to gastroesophageal reflux disease (GERD), characterized by inflammation of the esophageal mucosa (reflux esophagitis), strictures, and difficulty in swallowing (dysphagia) with accompanying chest pain.**
- **Pyloric sphincter**. Located at the junction of the pylorus of the stomach and duodenum (gastroduodenal sphincter), this sphincter controls the release of **chyme**, the partially digested contents of the stomach, into the duodenum. **Nitric oxide synthase (NOS), which produces nitric oxide (NO), is responsible for physiologic relaxation of the pyloric sphincter. Deficiency in NOS causes smooth muscle spasm of the pyloric sphincter and subsequent hypertrophic pyloric stenosis. This condition occurs most commonly during the first 2-12 weeks of life and results in obstruction in flow of chyme into the duodenum, which causes projectile vomiting (without bile) after feeding. If untreated, it may lead to dehydration and hypochloremic, hypokalemic metabolic alkalosis. Hypertrophy of the pyloric muscle can be diagnosed by ultrasonography and is also easily palpable as an “olive” in the right upper quadrant of the abdomen. Laparoscopic pyloromyotomy that involves transection of pyloric muscle without disruption of underlying mucosa remains the primary surgical treatment.**
- **Ileocecal valve**. Located at the junction of the small and large intestines, it prevents reflux of the contents of the colon with its high bacterial count into the distal ileum, which normally has a low bacterial count.
- **Internal anal sphincter**. This, the most distally located sphincter, surrounds the anal canal and prevents passage of the feces into the

anal canal from the undistended rectum.

Serosa and Adventitia

Serosa or adventitia constitutes the outermost layer of the alimentary canal.

The **serosa** is a serous membrane consisting of a layer of simple squamous epithelium, called the **mesothelium**, and a small amount of underlying connective tissue. It is equivalent to the visceral peritoneum described in gross anatomy. The serosa is the most superficial layer of those parts of the digestive tract that are suspended in the peritoneal cavity. As such, the serosa is continuous with both the **mesentery** and lining of the abdominal cavity.

Large blood and lymphatic vessels and nerve trunks travel through the serosa (from and to the mesentery) to reach the wall of the digestive tract. Large amounts of adipose tissue can develop in the connective tissue of the serosa (and in the mesentery).

Parts of the digestive tract do not possess a serosa. These include the thoracic part of the esophagus and portions of structures in the abdominal and pelvic cavities that are fixed to the cavity wall—descending, horizontal, and ascending part of duodenum; ascending and descending colon; rectum; and anal canal. These structures are attached to the abdominal and pelvic walls by connective tissue, the **adventitia**, which blends with the connective tissue of the wall.

■ ESOPHAGUS

The esophagus is a fixed muscular tube that delivers food and liquid from the pharynx to the stomach.

The **esophagus** courses through the neck and mediastinum, where it is attached to adjacent structures by connective tissue. As it enters the abdominal cavity, it is free for a short distance, approximately 1–2 cm. The overall length of the esophagus is about 25 cm. On cross section (Fig. 17.2), the lumen in its normally collapsed state has a branched appearance because of longitudinal folds. When a bolus of food passes through the esophagus, the lumen expands without mucosal injury.

FIGURE 17.2. Photomicrograph of the esophagus. This low-magnification photomicrograph shows a hematoxylin and eosin (H&E)-stained section of the esophagus with its characteristically folded wall, giving the lumen an irregular appearance. The mucosa consists of a relatively thick stratified squamous epithelium, a thin layer of lamina propria containing occasional lymphatic nodules, and muscularis mucosae. Mucous glands are present in the submucosa; their ducts, which empty into the lumen of the esophagus, are not evident in this section. External to the submucosa in this part of the esophagus is a thick muscularis externa made up of an inner layer of circularly arranged smooth muscle and an outer layer of longitudinally arranged smooth muscle. The adventitia is seen just external to the muscularis externa. $\times 8$.

The **mucosa** that lines the length of the esophagus has a nonkeratinized stratified squamous epithelium (Fig. 17.3 and Plate 17.1, page 670). In many animals, however, the epithelium is keratinized, reflecting a coarse food diet. In humans, the surface cells may exhibit some keratohyalin granules, but keratinization does not normally occur. The underlying lamina propria is similar to the lamina propria throughout the alimentary tract; diffuse lymphatic tissue is scattered throughout, and lymphatic nodules are present, often in proximity to ducts of the esophageal mucous glands (see page 638). The deep layer of the mucosa, the **muscularis mucosae**, is composed of longitudinally organized smooth muscle that begins near the level of the cricoid cartilage. It is unusually thick in the proximal portion of the esophagus and presumably functions as an aid in swallowing.

FIGURE 17.3. Photomicrograph of the esophageal mucosa. This higher magnification photomicrograph shows the mucosa of the wall of the esophagus in a hematoxylin and eosin (H&E) preparation. It consists of stratified squamous epithelium, lamina propria, and muscularis mucosae. The boundary between the epithelium and the lamina propria is distinct, although uneven, because of the connective tissue papillae. The basal layer of the epithelium stains intensely, appearing as a dark band because the basal cells are smaller and have a high nucleus-to-cytoplasm ratio. Note that the loose

connective tissue of the lamina propria is very cellular, containing many lymphocytes. The deepest part of the mucosa is the muscularis mucosae, which is arranged in two layers (inner circular and outer longitudinal) similar in orientation to the muscularis externa. $\times 240$.

The **submucosa** consists of dense irregular connective tissue that contains the larger blood and lymphatic vessels, nerve fibers, and ganglion cells. The nerve fibers and ganglion cells make up the **submucosal plexus (Meissner plexus)**. Glands are also present (see page 634). In addition, diffuse lymphatic tissue and lymphatic nodules are present mostly in the upper and lower parts of the esophagus where submucosal glands are more prevalent.

The **muscularis externa** consists of two muscle layers, an inner circular layer and an outer longitudinal layer (Plate 17.1, page 670). It differs from the muscularis externa found in the rest of the digestive tract in that the upper one-third is striated muscle, a continuation of the muscle of the pharynx. Striated muscle and smooth muscle bundles are mixed and interwoven in the muscularis externa of the middle third of the esophagus; the muscularis externa of the distal third consists only of smooth muscle, as in the rest of the digestive tract. A nerve plexus, the **myenteric (Auerbach) plexus**, is present between the outer and inner muscle layers. As in the submucosal plexus (Meissner plexus), nerves and ganglion cells are present here. This plexus innervates the muscularis externa and produces peristaltic activity.

As noted, the esophagus is fixed to adjoining structures throughout most of its length; thus, its outer layer is composed of adventitia. After entering the abdominal cavity, the short remainder of the tube is covered by serosa, the visceral peritoneum.

Mucosal and submucosal glands of the esophagus secrete mucus to lubricate and protect the luminal wall.

Glands are present in the wall of the esophagus and are of two types. Both secrete mucus, but their locations differ.

- **Esophageal glands proper** lie in the submucosa. These glands are scattered along the length of the esophagus but are somewhat more concentrated in the upper half. They are small, compound, tubuloalveolar glands (Fig. 17.4). The excretory duct is composed of stratified squamous epithelium and is usually conspicuous when present in a section because of its dilated appearance.

FIGURE 17.4. Photomicrograph of an esophageal submucosal gland. This photomicrograph shows a mucicarmine-stained section of the esophagus. An esophageal gland, deeply stained red by the carmine, and an adjacent excretory duct are seen in the submucosa. These small, compound, tubuloalveolar glands produce mucus that lubricates the epithelial surface of the esophagus. Note the stained mucus within the excretory duct. The remaining submucosa consists of dense irregular connective tissue. The inner layer of the muscularis externa (*bottom*) is composed of circularly arranged smooth muscle. $\times 110$.

- **Esophageal cardiac glands** are named for their similarity to the cardiac glands of the stomach and are found in the lamina propria of the mucosa. They are present in the terminal part of the esophagus and frequently, although not consistently, in the beginning portion of the esophagus.

The mucus produced by the esophageal glands proper is slightly acidic and serves to lubricate the luminal wall. Because the secretion is relatively viscous, transient cysts often occur in the ducts. The esophageal cardiac glands produce neutral mucus. Those glands near the stomach tend to protect the esophagus from regurgitated gastric contents. Under certain conditions, however, they are not fully effective, and excessive reflux results in pyrosis, a condition more commonly known as heartburn. This condition may progress to gastroesophageal reflux disease (GERD).

The muscle of the esophageal wall is innervated by both autonomic and somatic nervous systems.

The striated musculature in the upper part of the esophagus is innervated by somatic motor neurons of the vagus nerve, cranial nerve X (from the nucleus ambiguus). The smooth muscle of the lower part of the esophagus is innervated by visceral motor neurons of the vagus nerve (from the dorsal motor nucleus). These motor neurons synapse with postsynaptic neurons whose cell bodies are located in the wall of the esophagus.

■ STOMACH

The stomach is an expanded part of the digestive tube that lies beneath the diaphragm. It receives the bolus of macerated food from the esophagus. Mixing and partial digestion of the food in the stomach by its gastric secretions produce a pulpy fluid mix called chyme. The chyme then passes into the duodenum, a critical step for further digestion and absorption in the small intestine. Regulation of the rate of gastric emptying is provided by feedback from the intestines via a variety of gastrointestinal hormones.

The stomach is divided histologically into three regions based on the type of gland that each contains.

Gross anatomists subdivide the stomach into four regions. The cardia surrounds the esophageal orifice; the fundus lies above the level of a horizontal line drawn through the esophageal (cardiac) orifice; the body lies below this line; and the pyloric antrum is the funnel-shaped region that leads into the pylorus, the distal, narrow sphincteric region between the stomach and duodenum. Histologists also subdivide the stomach but only into three regions (Fig. 17.5). These subdivisions are based not on location but on the types of

glands that occur in the gastric mucosa. The histologic regions are as follows:

FIGURE 17.5. Photograph of a hemisected human stomach with its histologic divisions. This photograph shows the mucosal surface of the posterior wall of the stomach. Numerous longitudinal gastric folds are evident. These folds or rugae allow the stomach to distend as it fills. The histologic divisions of the stomach differ from the anatomic division. The former is based on the types of glands found in the mucosa. Histologically, the portion of the stomach adjacent to the entrance of the esophagus is the

cardiac region in which cardiac glands are located. A *dashed line* approximates its boundary. A slightly larger region leading toward the pyloric sphincter, the *pyloric region*, contains the pyloric glands. Another *dashed line* approximates boundary of the pyloric sphincter. The remainder of the stomach, the *fundic region*, is located between the cardiac and pyloric regions and contains the fundic (gastric) glands.

- **Cardiac region**, the part near the esophageal orifice, which contains the cardiac glands (Fig. 17.6 and Plate 17.2, page 672)

FIGURE 17.6. Photomicrograph of the esophagogastric junction. This low-magnification photomicrograph shows the junction between the esophagus and the stomach. At the esophagogastric junction, the stratified squamous epithelium of the esophagus ends abruptly, and the simple columnar epithelium of the stomach mucosa begins. The surface of the stomach contains numerous and relatively deep depressions called *gastric pits* that are formed by the surface epithelium. The glands in the vicinity of the esophagus, the cardiac glands, extend from the bottom of these pits. The fundic (gastric) glands similarly arise at the base of the gastric pits and are evident in the remaining part of the mucosa. Note the relatively thick muscularis externa. $\times 40$.

- **Pyloric region**, the part proximal to the pyloric sphincter, which contains the pyloric glands
- **Fundic region**, the largest part of the stomach, which is situated between the cardia and pylorus and contains the fundic or **gastric glands** (see Fig. 17.6)

Gastric Mucosa

Longitudinal submucosal folds, rugae, allow the stomach to distend when filled.

The **stomach** has the same general structural plan throughout, consisting of mucosa, submucosa, muscularis externa, and serosa. Examination of the **inner surface** of the empty stomach reveals a number of longitudinal folds or ridges called **rugae**. They are prominent in the narrower regions of the stomach but poorly developed in the upper portion (see Fig. 17.5). When the stomach is fully distended, the rugae, composed of the mucosa and underlying submucosa, virtually disappear. The rugae do not alter total surface area; rather, they serve to accommodate the expansion and filling of the stomach.

A view of the stomach's surface with a hand lens shows that smaller regions of the mucosa are formed by grooves or shallow trenches that divide the stomach surface into bulging irregular areas called **mamillated areas**. These grooves provide a slightly increased surface area for secretion.

At higher magnification, numerous openings can be observed in the mucosal surface. These are the **gastric pits** or **foveolae**. They can be readily demonstrated with the scanning electron microscope (Fig. 17.7). The gastric glands open into the bottom of the gastric pits.

FIGURE 17.7. Mucosal surface of the stomach. **a.** Scanning electron micrograph showing the mucosal surface of the stomach. The gastric pits contain secretory material, mostly mucus (*arrows*). The surface mucus has been washed away to reveal the surface mucous cells. $\times 1,000$. **b.** Higher magnification showing the apical surface of the surface mucous cells that line the stomach and gastric pits. Note the elongated polygonal shape of the cells. $\times 3,000$.

Surface mucous cells line the inner surface of the stomach and the gastric pits.

The epithelium that lines the surface and gastric pits of the stomach is simple columnar. The columnar cells are designated **surface mucous cells**. Each cell possesses a large, apical cup of **mucinogen granules**, creating a glandular sheet of cells (Fig. 17.8). The mucous cup occupies most of the volume of the cell. It typically appears empty in routine hematoxylin and eosin (H&E) sections because the mucinogen is lost in fixation and dehydration. When the mucinogen is preserved by appropriate fixation, however, the granules stain intensely with toluidine blue and with the periodic acid-Schiff (PAS) procedure. The toluidine blue staining reflects the presence of many strongly anionic groups in the glycoprotein of the mucin, among which is bicarbonate.

FIGURE 17.8. Gastric glands. **a.** This photomicrograph shows the fundic mucosa from an Alcian blue/periodic acid-Schiff (PAS) preparation to visualize mucus. Note that the surface epithelium invaginates to form gastric pits. The surface mucous cells and the cells lining the gastric pits are readily identified in this preparation because the neutral mucus within these cells is stained intensely. One of the gastric pits and its associated fundic gland are depicted by the *dashed lines*. This gland represents a simple branched tubular gland (*arrows* indicate the branching pattern). It extends from the bottom of the gastric pit to the muscularis mucosae. Note the segments of the gland: the short isthmus, the site of cell divisions; the relatively long neck; and a shorter and wider fundus. The mucous secretion of mucous neck cells is different from that produced by the surface mucous cells as evidenced by the *lighter magenta* staining in this region of the gland. $\times 320$. **b.** Schematic diagram of a gastric gland illustrating the relationship

of the gland to the gastric pit. Note that the isthmus region contains dividing cells and undifferentiated cells; the neck region contains mucous neck cells, parietal cells, and enteroendocrine cells, including amine precursor uptake and decarboxylation (APUD) cells. Parietal cells are large, pear-shaped acidophilic cells found throughout the gland. The fundus of the gland contains mainly chief cells, some parietal cells, and several types of enteroendocrine cells.

The nucleus and Golgi apparatus of the surface mucous cells are located below the mucous cup. The basal part of the cell contains small amounts of rough endoplasmic reticulum (rER) that may impart a light basophilia to the cytoplasm when observed in well-preserved specimens.

Several mechanisms help protect the gastric mucosa from exogenous injury and contribute to recovery of its functional integrity after damage.

The first line of protection from injury of gastric mucosa is the mucous secretion from the surface mucous cells. It is described as **visible mucus** because of its cloudy appearance and forms a thick, viscous, gel-like coat that adheres to the epithelial surface. It protects against abrasion from rougher components of the chyme. In addition, its **high bicarbonate and potassium concentration** protects the epithelium from the acidic content of the gastric juice. The bicarbonate that makes the mucus alkaline is secreted by the surface cells but is prevented from mixing rapidly with the contents of the gastric lumen by its containment within the mucous coat.

The second line of protection is related to the regulation of the submucosal blood by a number of mediators, including prostaglandins (PGE_2), nitric oxide (NO), and sensory neuropeptides. **Prostaglandins (PGE_2)** and **nitric oxide (NO)** appear to play an important role in protecting the gastric mucosa. PGE_2 stimulate secretion of bicarbonates and increase the thickness of the mucous layer with accompanied vasodilatation in the lamina propria. NO released from vascular endothelium, sensory afferent nerves, and gastric epithelium **increases gastric mucosal blood flow**, thus improving the supply of nutrients to damaged areas of the gastric mucosa. This ability of the gastric mucosa to optimize conditions for tissue repair after injury (independently of the inhibition of acid secretion) is referred to as **gastric cytoprotection**.

The lining of the stomach does not function in an absorptive capacity. However, some water, salts, and lipid-soluble drugs may be absorbed. For instance, alcohol and certain drugs such as aspirin or

nonsteroidal anti-inflammatory drugs (NSAIDs) enter the lamina propria by damaging the surface epithelium. Even small doses of aspirin suppress the production of protective prostaglandins by the gastric mucosa. In addition, aspirin's direct contact with the wall of the stomach interferes with the hydrophobic properties of the gastric mucosa.

Fundic glands of the gastric mucosa

The fundic glands produce the gastric juice of the stomach.

The **fundic glands**, also called **gastric glands**, are present throughout the entire gastric mucosa, except for the relatively small regions occupied by cardiac and pyloric glands. The fundic glands are simple, branched, tubular glands that extend from the bottom of the gastric pits to the muscularis mucosae (see Fig. 17.8). Located between the **gastric pit** and the gland below is a short segment known as the **isthmus**.

Typically, several glands open into a single gastric pit. Each gland has a narrow, relatively long **neck segment** and a shorter and wider base or **fundic segment**. The base of the gland usually divides into two and sometimes three branches that become slightly coiled near the muscularis mucosae. The cells of the gastric glands produce gastric juice (about 2 L/d), which contains a variety of substances. In addition to water and electrolytes, gastric juice contains four major components:

- **Hydrochloric acid (HCl)** in a concentration ranging from 150 to 160 mmol/L, which gives the gastric juice a low pH (<1.0–2.0). It is produced by **parietal cells** and initiates the digestion of dietary protein (it promotes acid hydrolysis of substrates). It also converts inactive pepsinogen into the active enzyme pepsin. Because HCl is bacteriostatic, most of the bacteria entering the stomach with ingested food are destroyed. However, some bacteria can adapt to the low pH of the gastric contents. *Helicobacter pylori* contains large amounts of urease, the enzyme that hydrolyzes urea, in its cytoplasm and on its plasma membrane. This highly active enzyme creates a protective basic “ammonia cloud” around the bacterium, allowing it to survive in the acidic environment of the stomach (Folder 17.1).

FOLDER 17.1

CLINICAL CORRELATION: PERNICIOUS ANEMIA AND PEPTIC ULCER DISEASE

Achlorhydria is a chronic autoimmune disease characterized by the destruction of the gastric mucosa. Consequently, in the absence of parietal cells, the intrinsic factor is not secreted, thereby leading to **pernicious anemia**. Lack of **intrinsic factor** is the most common cause of **vitamin B₁₂ deficiency**. However, other factors such as Gram-negative anaerobic bacterial overgrowth in the small intestine are associated with vitamin B₁₂ deficiency. These bacteria bind to the vitamin B₁₂-intrinsic factor complex, preventing its absorption. Parasitic tapeworm infections also produce clinical symptoms of pernicious anemia. Because the liver has extensive reserve stores of vitamin B₁₂, the disease is often not recognized until long after significant changes in the gastric mucosa have taken place.

Another cause of reduced secretion of intrinsic factor and subsequent pernicious anemia is the loss of gastric epithelium in partial or total gastrectomy. Loss of functional gastric epithelium also occurs in chronic or recurrent **peptic ulcer disease (PUD)**. Often, even healed ulcerated regions produce insufficient intrinsic factor. Repeated loss of epithelium and consequent scarring of the gastric mucosa can significantly reduce the amount of functional mucosa.

Histamine H₂ receptor-antagonist drugs such as ranitidine (Zantac) and cimetidine (Tagamet), which block the attachment of histamine to its receptors in the gastric mucosa, suppress both acid and intrinsic factor production and have been used extensively in the treatment of peptic ulcers and gastroesophageal reflux disease (GERD). These drugs prevent further mucosal erosion and promote healing of the previously eroded surface. However, long-term use can cause vitamin B₁₂ deficiency. Recently, new proton-pump inhibitors (e.g., omeprazole and lansoprazole) have been designed that inhibit H⁺/K⁺-ATPase. They suppress acid production in the parietal cells and do not affect intrinsic factor secretion.

Although it was generally thought that the parietal cells are the direct target of the H₂ receptor-antagonist drugs, evidence from a combination of in situ hybridization histochemistry and antibody staining has unexpectedly revealed that the immunoglobulin A (IgA)-secreting plasma cells and some of the macrophages in the lamina propria display a positive reaction for gastrin receptor messenger RNA (mRNA), not the parietal cells. These findings indicate that the agents used to treat peptic ulcers may act directly on plasma cells or macrophages and that these cells then transmit their effects to the parietal cells to inhibit HCl secretion. The factor that mediates the interaction between the connective tissue cells and the epithelial cells has not been elucidated.

It is now recognized that most peptic ulcers (95%) are actually caused by a chronic infection of the gastric mucosa by the bacterium *Helicobacter pylori*. Lipopolysaccharide antigens are expressed on its surface that mimics those on human gastric epithelial cells. The mimicry appears to cause an initial immunologic tolerance to the pathogen by the host immune system, thus helping to enhance the infection and ultimately causing the production of antibodies. These antibodies against *H. pylori* bind to the gastric mucosa and cause damage to the mucosal cells. Treatment includes antibiotic eradication

of the bacteria. These treatments for ulcerative disease have made the common surgical interventions of the past infrequent.

- **Pepsin**, a potent proteolytic enzyme. It is formed from the conversion by HCl of **pepsinogen**, which is produced by the **chief cells**, when the pH is lower than 5. Pepsin hydrolyzes proteins into small peptides by splitting interior peptide bonds. Peptides are further digested into amino acids by enzymes in the small intestine.
- **Mucus**, an acid-protective coating for the stomach secreted by several types of mucus-producing cells. The mucus and bicarbonates trapped within the mucous layer maintain a neutral pH and contribute to the so-called **physiologic gastric mucosa barrier**. In addition, mucus serves as a physical barrier between the cells of the gastric mucosa and the ingested material in the lumen of the stomach.
- **Intrinsic factor**, a glycoprotein secreted by **parietal cells** that binds to vitamin B₁₂. It is essential for its absorption, which occurs in the distal part of the ileum. **Lack of intrinsic factor leads to pernicious anemia and vitamin B₁₂ deficiency (see Folder 17.1).**

In addition, **gastrin** and other hormones and hormone-like secretions are produced by **enteroendocrine cells** in the fundic glands and secreted into the lamina propria, where they enter the circulation or act locally on other gastric epithelial cells.

Fundic glands are composed of four functionally different cell types.

The cells that constitute the fundic glands are of four functional types. Each has a distinctive appearance. In addition, undifferentiated cells that give rise to these cells are also present. The following are the various cells that constitute the gland:

- **Mucous neck cells**
- **Chief cells**
- **Parietal cells**, also called *oxyntic cells*
- **Enteroendocrine cells**
- **Stem cells**

Mucous neck cells are localized in the neck region of the gland and are interspersed with parietal cells.

As the name implies, the **mucous neck cells** are located in the neck region of the fundic gland. Parietal cells are usually interspersed between groups of these cells. The mucous neck cell is much shorter than the surface mucous cell and contains considerably less mucinogen in the apical cytoplasm. Consequently, these cells do not exhibit a prominent mucous cup. Also, the nucleus tends to be spherical compared with the more prominent, elongated nucleus of the surface mucous cell.

The mucous neck cells secrete less alkaline **soluble mucus** compared with the high-alkaline **insoluble** or **cloudy mucus** produced by the surface mucous cell. Vagal stimulation induces the release of mucinogen granules; thus, secretion from these cells does not occur in the resting stomach. These mucous neck cells differentiate from stem cells, which reside in the neck region or the base of the fundic gland. Mucous neck cells are considered immature precursors of surface mucous cells.

Chief cells are located in the deeper part of the fundic glands.

Chief cells are typical protein-secreting cells (Fig. 17.9 and Plate 17.4, page 676). The abundant rER in the basal cytoplasm gives this part of the cell a basophilic appearance, whereas the apical cytoplasm is eosinophilic owing to the presence of the secretory vesicles, also called *zymogen granules* because they contain enzyme precursors. The basophilia, in particular, allows easy identification of these cells in H&E sections. The eosinophilia may be faint or absent when the secretory vesicles are not adequately preserved. Chief cells secrete **pepsinogen** and a weak lipase. On contact with the acid gastric juice, pepsinogen is converted to pepsin, a proteolytic enzyme.

CHIEF CELL

FIGURE 17.9. Diagram of a chief cell. The large amount of rough endoplasmic reticulum (*rER*) in the basal portion of the cell accounts for the intense basophilic staining seen in this region. Secretory vesicles (zymogen granules) containing pepsinogen and a weak lipase are not always adequately preserved, and thus, the staining in the apical region of the cell is somewhat variable. This cell produces and secretes the precursor enzyme of the gastric secretion.

Parietal cells secrete HCl and intrinsic factor.

Parietal (oxyntic) cells are found in the neck of the fundic glands, among the mucous neck cells, and in the deeper part of the gland. They tend to be most numerous in the upper and middle portions of the neck. They are large cells, sometimes binucleate, and appear somewhat triangular in sections, with the apex directed toward the lumen of the gland and the base resting on the basal lamina. The nucleus is spherical, and the cytoplasm stains with eosin and other acidic dyes.

Their size and distinctive staining characteristics allow them to be easily distinguished from other cells in the fundic glands.

When examined with the transmission electron microscope (TEM), parietal cells (Fig. 17.10) are seen to have an extensive **intracellular canalicular system** that communicates with the lumen of the gland. Numerous microvilli project from the surface of the canaliculi, and an elaborate **tubulovesicular membrane system** is present in the cytoplasm adjacent to the canaliculi. In an actively secreting cell, the number of microvilli in the canaliculi increases, and the tubulovesicular system is reduced significantly or disappears. The membranes of the tubulovesicular system serve as a reservoir of plasma membrane containing active **proton pumps**. This membrane material can be inserted into the plasma membrane of the canaliculi to increase their surface area and the number of proton pumps available for acid production. Numerous mitochondria with complex cristae and many matrix granules supply the high levels of energy necessary for acid secretion.

PARIETAL CELL

FIGURE 17.10. Diagram of a parietal cell. The cytoplasm of the parietal cell stains with eosin largely because of the extensive amount of membrane comprising the intracellular canaliculus, tubulovesicular system, mitochondria, and the relatively small number of ribosomes. This cell produces hydrochloric acid (HCl) and intrinsic factor.

HCl is produced in the lumen of the intracellular canaliculi.

Parietal cells have three different types of membrane receptors for substances that activate HCl secretion: **gastrin receptors**, **histamine H_2 receptors**, and **acetylcholine M_3 receptors**. Activation of gastrin receptors by **gastrin**, a gastrointestinal peptide hormone, is the major path for parietal cell stimulation (Folder 17.2). After

stimulation, several steps occur in the production of HCl (Fig. 17.11):

FIGURE 17.11. Diagram of parietal cell hydrochloric acid (HCl) synthesis. After parietal cell stimulation, several steps occur leading to the production of HCl. Carbon dioxide (CO_2) from the blood diffuses across the basement membrane into the cell to form H_2CO_3 . The H_2CO_3 dissociates into H^+ and HCO_3^- . The reaction is catalyzed by carbonic anhydrase, which leads to the production of H^+ ions in the cytoplasm, which are then transported across the membrane to the lumen of the intracellular canaliculus by an H^+/K^+ -ATPase proton pump. Simultaneously, K^+ within the canaliculus is transported into the cell in exchange for the H^+ ions. Cl^- ions are also transported from the cytoplasm of the parietal cell into the lumen of the canaliculus by Cl^- channels in the membrane. HCl is then formed from H^+ and Cl^- . The $\text{HCO}_3^-/\text{Cl}^-$ anion channels maintain the normal concentration of both ions in the cell and Na^+/K^+ -ATPase on the basolateral cell membrane.

CLINICAL CORRELATION: ZOLLINGER - ELLISON SYNDROME

Excessive secretion of **gastrin** is usually caused by a tumor of the gastrin-producing enteroendocrine cells located in the duodenum or the pancreatic islet. This condition, known as the **Zollinger - Ellison syndrome** or **gastrinomas**, is characterized by excessive secretion of hydrochloric acid (HCl) by continuously stimulated parietal cells. The excess acid cannot be adequately neutralized in the duodenum, thereby leading to gastric and duodenal ulcers. Gastric ulcers are present in 95% of patients with this syndrome and are 6 times more prevalent than duodenal ulcers. Patients with Zollinger - Ellison syndrome may experience intermittent abdominal pain, diarrhea, and steatorrhea (excretion of stool containing a large amount of fat). Patients without symptoms who have severe ulceration of the stomach and small intestine, especially if they fail to respond to conventional treatment, should be also suspected of having a tumor that is producing excess gastrin. Treatment of Zollinger - Ellison syndrome in the past involved blockage of the parietal cell membrane receptors that stimulate HCl production. Recently, proton-pump inhibitors have become the treatment of choice in managing HCl hypersecretion. In addition, surgical excision of the tumor, when possible, removes the source of gastrin production and alleviates symptoms.

- **Production of H^+ ions** in the parietal cell cytoplasm by the enzyme carbonic anhydrase. This enzyme catalyzes the combination of H_2O and CO_2 to form carbonic acid (H_2CO_3), which then rapidly dissociates into H^+ and HCO_3^- . Carbon dioxide (CO_2), necessary for synthesis of carbonic acid, diffuses across the basement membrane into the cell from the blood capillaries in the lamina propria.
- **Transport of H^+ ions** from the cytoplasm across the membrane to the lumen of the canaliculus by the H^+/K^+ -ATPase proton pump. Simultaneously, K^+ from the canaliculus is transported into the cell cytoplasm in exchange for the H^+ ions.
- **Transport of K^+ and Cl^- ions** from the parietal cell cytoplasm into the lumen of the canaliculus through activation of K^+ and Cl^- channels (uniporters) in the plasma membrane
- **Formation of HCl** from the H^+ and Cl^- that were transported into the lumen of the canaliculus

In humans, **intrinsic factor** is secreted by the parietal cells (chief cells do so in some other species). Its secretion is stimulated by the same receptors that stimulate gastric acid secretion. **Intrinsic factor** is a 44-kDa glycoprotein that complexes with vitamin B_{12} in the stomach and duodenum, a step necessary for

subsequent absorption of the vitamin in the ileum. Autoantibodies directed against intrinsic factor or parietal cells themselves lead to an intrinsic factor deficiency, resulting in malabsorption of vitamin B₁₂ and pernicious anemia (see Folder 17.1).

Enteroendocrine cells secrete their products into either the lamina propria or the underlying blood vessels.

Enteroendocrine cells are found at every level of the fundic gland, although they tend to be somewhat more prevalent in the base (Folder 17.3). In general, **two types of enteroendocrine cells** can be distinguished throughout the gastrointestinal tract. Most represent small cells that rest on the basal lamina and do not always reach the lumen; they are known as **enteroendocrine “closed” cells** (Fig. 17.12a and b and Plate 17.4, page 676). Some cells, however, have a thin cytoplasmic extension bearing microvilli that are exposed to the gland lumen (Fig. 17.12c); these are referred to as **enteroendocrine “open” cells**. Open cells serve as **primary chemoreceptors** that sample the contents of the gland lumen and release hormones based on the information obtained from those samples. Taste receptors, similar to those found in taste buds of the specialized oral mucosa (pages 592–596), detect sweet, bitter, and umami sensations and are present on the free surface of open enteroendocrine cells. They belong to the T1R and T2R families of G-protein-coupled receptors described in Chapter 16, Digestive System I: Oral Cavity and Associated Structures (pages 594–595). Secretion from closed cells, however, is regulated by the luminal contents indirectly through neural and paracrine mechanisms.

FIGURE 17.12. Electron micrograph and diagrams of enteroendocrine cells. **a.** This electron micrograph shows an example of a “closed” enteroendocrine cell. *Arrowheads* mark the boundary between the enteroendocrine cell and the adjacent epithelial cells. At its base, the enteroendocrine cell rests on the basal lamina (*BL*). This cell does not extend to the epithelial or luminal surface. Numerous secretory vesicles (*G*) in the base of the cell are secreted in the direction of the *arrows* across the *BL* and into the connective tissue (*CT*). **b.** This diagram of an enteroendocrine “closed” cell is drawn to show that it does not reach the epithelial surface. The secretory vesicles are regularly lost during routine preparation. Because of the absence of other distinctive organelles, the nucleus appears to be surrounded by a small amount of clear cytoplasm in hematoxylin and eosin (H&E)-stained sections. **c.** The enteroendocrine “open” cell extends to the epithelial surface. Microvilli on the apical surface of these cells possess taste receptors and are able to detect sweet, bitter, and umami sensations. These cells serve as chemoreceptor cells, which monitor the environment on the surface of the epithelium. They are involved in the regulation of gastrointestinal hormone secretion. *En*, endothelium of capillary; *M*, mitochondria; *rER*, rough endoplasmic reticulum; *sER*, smooth endoplasmic reticulum.

FOLDER 17.3

FUNCTIONAL CONSIDERATIONS: THE GASTROINTESTINAL ENDOCRINE SYSTEM

Enteroendocrine cells are specialized cells present in the mucosa of the digestive tract. They account for <1% of all epithelial cells in the gastrointestinal tract, but as a whole, they collectively constitute the largest endocrine “organ” in the body. Enteroendocrine cells are also found in the ducts of the pancreas, the liver, and the respiratory system, another endodermal derivative that originates by invagination of the epithelium of the embryonic foregut. Because enteroendocrine cells closely resemble neurosecretory cells of the central nervous system (CNS) that secrete many of the same hormones, signaling molecules, and regulatory agents, they are also called **neuroendocrine cells**. Most of these cells are not grouped as clusters in any specific part of the gastrointestinal tract. Rather, enteroendocrine cells are distributed singly throughout the gastrointestinal epithelium. For that reason, they are described as constituting part of a **diffuse neuroendocrine system (DNES)**. Figure 17.13 shows the parts of the gastrointestinal tract in which the gastrointestinal peptides are produced. One notable exception to this distribution pattern is found in the pancreas. Here, enteroendocrine cells, derived from pancreatic buds that also arise from the embryonic foregut, form specialized accumulations called **endocrine islets of Langerhans** (see pages 715–719).

FIGURE 17.13. Gastrointestinal hormones. This schematic diagram shows the distribution of gastrointestinal peptide hormones produced by enteroendocrine cells in the alimentary canal. *CCK*, cholecystokinin; *GIP*, gastric inhibitory peptide; *VIP*, vasoactive intestinal peptide.

In the current view, the DNES includes both neurons and endocrine cells that share common characteristics, including the expression of specific markers (e.g., neuropeptides, chromogranins, and neuropeptide-processing enzymes) and the presence of dense-core secretory granules. Secretory products of enteroendocrine cells derive from a variety of genes; they are expressed in different forms because of alternative splicing and differential processing. Secretion of enteroendocrine cells is regulated by G-protein-coupled receptors and tyrosine kinase activity. There is evidence that chromogranin A regulates biosynthesis of dense-core secretory granules, whereas chromogranin B controls sorting and packaging of produced peptides into secretory vesicles. Table 17.1 lists important

gastrointestinal hormones, their sites of origin, and their major functions.

TABLE 17.1

Physiologic Actions of Gastrointestinal Hormones

Hormone	Site of Synthesis	Major Action	
		Stimulates	Inhibits
Gastrin	G cells in stomach	Gastric acid secretion	
Ghrelin	Gr cells in stomach	GH secretion Appetite and perception of hunger	Lipid metabolism Fat utilization in adipose tissue
Cholecystokinin (CCK)	I cells in duodenum and jejunum	Gallbladder contraction Pancreatic enzyme secretion Pancreatic bicarbonate ion secretion Pancreatic growth	Gastric emptying
Secretin	S cells in duodenum	Pancreatic enzyme secretion Pancreatic bicarbonate ion secretion Pancreatic growth	Gastric acid secretion
Gastric inhibitory peptide (GIP)	K cells in duodenum and jejunum	Insulin release	Gastric acid secretion
Motilin	Mo cells in duodenum and jejunum	Gastric motility Intestinal motility	

GH, growth hormone.

Modified from Johnson LR, ed. *Essential Medical Physiology*. Lippincott-Raven; 1998.

Neoplastic transformations of DNES cells are responsible for the development of **gastroenteropancreatic (GEP) neuroendocrine tumors**. These tumors represent rare neoplasms of the gastrointestinal tract and pancreas that often secrete hormonally active agents, causing distinct clinical syndromes. The appendix is the most common gastrointestinal site of origin for neuroendocrine tumors. The classic example is the **carcinoid syndrome** caused by the release of a variety of hormonally active substances by tumor cells. Symptoms include diarrhea (case by

serotonin), episodic flushing, bronchoconstriction, and right-sided cardiac valve disease.

Some enteroendocrine cells may be classifiable functionally as **amine precursor uptake and decarboxylation (APUD) cells**. They should not, however, be confused with the APUD cells that are derived from the embryonic neural crest and migrate to other sites in the body. APUD cells secrete a variety of regulator substances in tissues and organs, including the respiratory epithelium, adrenal medulla, islets of Langerhans, thyroid gland (parafollicular cells), and pituitary gland. The enteroendocrine cells differentiate from the progeny of the same stem cells as all of the other epithelial cells of the digestive tract. The fact that two different cells may produce similar products should not imply that they have the same origin.

Enteroendocrine cells produce not only gastrointestinal hormones such as gastrin, ghrelin, secretin, cholecystokinin (CCK), gastric inhibitory peptide (GIP), and motilin but also **paracrine hormones**. A paracrine hormone differs from an endocrine hormone in that it diffuses locally to its target cell instead of being carried by the bloodstream to a target cell. A well-known substance that appears to act as a paracrine hormone within the gastrointestinal tract and pancreas is somatostatin, which inhibits other gastrointestinal and pancreatic islet endocrine cells.

In addition to the established gastrointestinal hormones, several gastrointestinal peptides have not been definitely classified as hormones or paracrine hormones. These peptides are designated **candidate or putative hormones**.

Other locally active agents isolated from the gastrointestinal mucosa are **neurotransmitters**. These agents are released from nerve endings close to the target cell, usually the smooth muscle of the muscularis mucosae, the muscularis externa, or the tunica media of a blood vessel. Enteroendocrine cells can also secrete neurotransmitters that activate afferent neurons, sending signals to the central nervous system (CNS) and enteric division of the autonomic nervous system. In addition to acetylcholine (not a peptide), peptides found in nerve fibers of the gastrointestinal tract are vasoactive intestinal peptide (VIP), bombesin, and enkephalins. Thus, a particular peptide may be produced by endocrine and paracrine cells and also be localized in nerve fibers.

Electron micrographs (EMs) reveal small membrane-bound secretory vesicles throughout the cytoplasm; however, these vesicles are typically lost in H&E preparations, and the cytoplasm appears clear because of the lack of sufficient stainable material. Although enteroendocrine cells are often difficult to identify because of their small size and lack of distinctive staining, their clear cytoplasm sometimes stands out in contrast to the adjacent chief or parietal cells, thus allowing their easy recognition.

The names given to the enteroendocrine cells in the older literature were based on their staining with salts of silver and chromium (i.e., enterochromaffin cells, argentaffin cells, and argyrophil cells). Such cells are currently identified and

characterized by immunochemical staining for the more than 20 peptide and polypeptide hormones and hormone-like regulating agents that they secrete (a list of many of these agents and their actions is given in Fig. 17.13 and Tables 17.1 and 17.2). With the aid of the TEM, at least 17 different types of enteroendocrine cells have been described on the basis of size, shape, and density of their secretory vesicles.

Major Action			
Hormone	Site of Synthesis	Stimulates	Inhibits
Candidate hormones			
Pancreatic polypeptide	PP cells in pancreas	Gastric emptying and gut motility	Pancreatic enzyme secretion Pancreatic bicarbonate secretion
Peptide YY	L cells in ileum and colon	Electrolyte and water absorption in the colon	Gastric acid secretion Gastric emptying Food intake
Glucagon-like peptide-1 (GLP-1)	L cells in ileum and colon	Insulin release	Gastric acid secretion Gastric emptying
Paracrine hormones			
Somatostatin	D cells in mucosa throughout GI tract		Gastrin release Gastric acid secretion Release of other GI hormones
Histamine	Mucosa throughout GI tract	Gastric acid secretion	
Neurocrine hormones			
Bombesin	Stomach	Gastrin release	
Enkephalins	Mucosa and smooth muscle throughout GI tract	Smooth muscle contraction	Intestinal secretion

Vasoactive intestinal peptide (VIP)	Mucosa and smooth muscle throughout GI tract	Pancreatic enzyme secretion Intestinal secretion	Smooth muscle contraction Sphincter contraction

Cardiac glands of the gastric mucosa

Cardiac glands are composed of mucus-secreting cells.

Cardiac glands are limited to a narrow region of the stomach (the cardia) that surrounds the esophageal orifice. Their secretion, in combination with that of the esophageal cardiac glands, contributes to the gastric juice and helps protect the esophageal epithelium against gastric reflux. The glands are tubular, somewhat tortuous, and occasionally branched (Fig. 17.14 and Plate 17.3, page 674). They are composed mainly of mucus-secreting cells, with occasional interspersed enteroendocrine cells. The mucus-secreting cells are similar in appearance to the cells of the esophageal cardiac glands. They have a flattened basal nucleus, and the apical cytoplasm is typically filled with mucin granules. A short duct segment containing columnar cells with elongated nuclei is interposed between the secretory portion of the gland and the shallow pits into which the glands secrete. The duct segment is the site at which the surface mucous cells and the gland cells are produced.

FIGURE 17.14. Photomicrograph of cardiac glands. This photomicrograph shows the esophagogastric junction. Note the presence of the stratified squamous epithelium of the esophagus in the *upper right corner* of the micrograph. The cardiac glands are tubular, somewhat tortuous, and occasionally branched. They are composed mainly of mucus-secreting cells similar in appearance to the cells of the esophageal glands. Mucous secretion reaches the lumen of the gastric pit via a short duct segment containing columnar cells. $\times 240$.

Pyloric glands of the gastric mucosa

Pyloric gland cells are similar to surface mucous cells and help protect the pyloric mucosa.

Pyloric glands are located in the pyloric antrum (the part of the stomach between the fundus and the pylorus). They are branched, coiled, tubular glands (Plate 17.5, page 678). The lumen is relatively wide, and the secretory cells are similar in appearance to the surface mucous cells, suggesting a relatively viscous secretion. Enteroendocrine cells are found interspersed within the gland epithelium along with occasional parietal cells. The glands empty into deep gastric pits that occupy about half the thickness of the mucosa (Fig. 17.15).

FIGURE 17.15. Photomicrograph of pyloric glands. This photomicrograph shows a section of the wall of the pylorus. The pyloric glands are relatively straight for most of their length but are slightly coiled near the muscularis mucosae. The lumen is relatively wide, and the secretory cells are similar in appearance to the surface mucous cells, suggesting a relatively viscous secretion. They are restricted to the mucosa and empty into the gastric pits. The boundary between the pits and glands is, however, hard to ascertain in routine hematoxylin and eosin (H&E) preparations. $\times 120$.

Epithelial Cell Renewal in the Stomach

Gastric glands contain stem cell niches that are responsible for epithelial cell renewal.

Previous studies using nucleotide incorporation assays and EM showed that the **isthmus of the fundic gland** is a site of **stem cell location (stem cell niche)** in which stem cells replicate and differentiate. Cells destined to become mucous surface cells migrate upward in the gastric pits to the stomach surface. Other cells migrate downward, maintaining the population of the fundic gland epithelium. However, the differentiation of these stem cells and their migration routes has remained elusive.

Experimental studies using retrovirus-infected stem cells containing labeled transgenes (genes altered by genetic engineering) and in situ hybridization techniques (to trace the stem cells' progeny) show the location of these stem cells in two different regions of the gastric gland. These studies confirm the presence of an isthmus cell niche and identify a second stem cell location at the **base of the gastric glands**. These cells were also capable of self-renewing and differentiating into surface mucous cells, mucous neck cells, chief cells, parietal cells, and enteroendocrine cells. A similar distribution of stem cells is found in all regions of the stomach; however, in each region, stem cells express different molecular markers and play different roles in cell renewal. For instance, stem cells located in the base of pyloric glands maintain epithelial cell renewal under normal homeostatic conditions, whereas in the fundic region, these cells remain quiescent under normal homeostatic conditions.

Surface mucous cells are renewed approximately every 3 - 5 days.

The relatively short life span of the **surface mucous cells**, 3 - 5 days, is accommodated by mitotic activity in the isthmus, the narrow segment that lies between the gastric pit and the fundic gland (Fig. 17.16). The isthmus of the fundic gland contains a reservoir of tissue stem cells that undergo mitotic activity, providing for continuous cell renewal. Most of the newly produced cells at this site become surface mucous cells. They migrate upward along the wall of the pit to the luminal surface of the stomach and are ultimately shed into the stomach lumen.

FIGURE 17.16. Photomicrograph of a dividing cell in the isthmus of a pyloric gland. The gastric pits in this photomicrograph were sectioned in a plane that is oblique to the axis of the pit. Note that in this section, gastric pits (*arrows*) can be recognized as invaginations of surface epithelium that are surrounded by lamina propria. The lamina propria is highly cellular because of the presence of large numbers of lymphocytes. $\times 240$. Inset. This high magnification of the area indicated by the *square* shows a dividing cell in the isthmus. $\times 580$.

The cells of the fundic glands have a relatively long life span.

Other cells from the isthmus migrate down into the gastric glands to give rise to the parietal cells, chief cells, mucous gland cells, and enteroendocrine cells that constitute the gland epithelium. As mentioned previously, these cells also can differentiate from stem cells located at the base of the gland. These cells have a relatively long life span. **Parietal cells** have the longest life span, approximately 150–200 days. Although parietal cells develop from the same undifferentiated stem cells, their life span is distinctly different. It has been hypothesized that parietal cells may have originated from a fungus called *Neurospora crassa* that previously existed in a symbiotic relationship with the cells of the human stomach. The basis for this hypothesis is that the human proton pump ($H^+/K^+-ATPase$) found in parietal cells bears a strong genetic resemblance to proton pumps found in this organism. The fungal DNA is thought to have been translocated and subsequently incorporated into the nucleus of the stem cells, probably with the help of a virus.

Chief and **enteroendocrine cells** are estimated to live for about 60–90 days before they are replaced by new cells migrating downward from the isthmus. **Mucous neck cells**, in contrast, have a much shorter life span, approximately 6 days.

Lamina Propria and Muscularis Mucosae

The **lamina propria** of the stomach is relatively scant and restricted to the limited spaces surrounding the gastric pits and glands. The stroma is composed largely of reticular fibers with associated fibroblasts and smooth muscle cells. Other components include cells of the immune system, namely, lymphocytes, plasma cells, macrophages, and some eosinophils. When inflammation occurs, as is often the case, neutrophils may also be prominent. Occasional lymphatic nodules are also present, usually intruding partially into the muscularis mucosae.

The **muscularis mucosae** is composed of two relatively thin layers, usually arranged as an inner circular and outer longitudinal layer. In some regions, a third layer may be present; its orientation tends to be in a circular pattern. Thin strands of smooth muscle cells extend toward the surface of the lamina propria from the inner layer of the muscularis mucosae. These smooth muscle cells in the lamina propria are thought to help outflow of the gastric gland secretions.

Gastric Submucosa

The **submucosa** is composed of a dense connective tissue containing variable amounts of adipose tissue and blood vessels as well as the nerve fibers and ganglion cells that compose the **submucosal (Meissner) plexus**. The latter innervates the vessels of the submucosa and the smooth muscle of the muscularis mucosae.

Gastric Muscularis Externa

The **muscularis externa** of the stomach is traditionally described as consisting of an outer longitudinal layer, a middle circular layer, and an inner oblique layer. This description is somewhat misleading, as distinct layers may be difficult to discern. As with other hollow, spheroidal organs (e.g., gallbladder, urinary bladder, and uterus), the smooth muscle of the muscularis externa of the stomach is somewhat more randomly oriented than the term *layer* implies. Moreover, the longitudinal layer is absent from much of the anterior and posterior stomach surfaces, and the circular layer is poorly developed in the periesophageal region. The arrangement of the muscle layers is functionally important, as it relates to its role in mixing chyme during the digestive process as well as to its ability to force the partially digested contents into the small intestine. Groups of ganglion cells and bundles of unmyelinated nerve fibers are present between the muscle layers. Collectively, they represent the **myenteric (Auerbach) plexus**, which provides innervation of the muscle layers.

Gastric Serosa

The **serosa** of the stomach is, as described earlier, for the alimentary canal in general. It is continuous with the parietal peritoneum of the abdominal cavity via the greater omentum and with visceral peritoneum of the liver at the lesser omentum. Otherwise, it exhibits no special features.

■ SMALL INTESTINE

The small intestine is the longest component of the digestive tract, measuring over 6 m, and is divided into three anatomic portions:

- **Duodenum** (~25 cm long) is the first, shortest, and widest part of the small intestine. It begins at the pylorus of the stomach and ends at the duodenojejunal junction (Plate 17.6, page 680).

- **Jejunum** (~2.5 m long) begins at the **duodenojejunal junction** and constitutes the upper two-fifths of the small intestine. It gradually changes its morphologic characteristics to become the ileum (Plate 17.7, page 682).
- **Ileum** (~3.5 m long) is a continuation of the jejunum and constitutes the lower three-fifths of the small intestine. It ends at the **ileocecal junction**, the union of the distal ileum and cecum (Plate 17.8, page 684).

Mucosa

The small intestine is the principal site for the digestion of food and absorption of the products of digestion.

Chyme from the stomach enters the duodenum, where enzymes from the pancreas and bile from the liver are also delivered to continue the solubilization and digestion process. Enzymes, particularly disaccharidases and dipeptidases, are also located in the glycocalyx of the microvilli of the **enterocytes**, the **intestinal absorptive cells**. These enzymes contribute to the digestive process by completing the breakdown of most sugars and proteins to monosaccharides and amino acids, which are then absorbed (Folder 17.4). Water and electrolytes that reach the small intestine with the chyme and pancreatic and hepatic secretions are also reabsorbed in the small intestine, particularly in the distal portion.

FOLDER 17.4

FUNCTIONAL CONSIDERATIONS: DIGESTIVE AND ABSORPTIVE FUNCTIONS OF ENTEROCYTES

The plasma membrane of the microvilli of the enterocyte plays a role in digestion as well as absorption. Digestive enzymes are anchored in the plasma membrane, and their functional groups extend outward to become part of the glycocalyx. This arrangement brings the end products of digestion close to their site of absorption. Included among the enzymes are peptidases and disaccharidases. The plasma membrane of the apical microvilli also contains the enzyme **enteropeptidase (enterokinase)**, which is particularly important in the duodenum, where it converts trypsinogen into trypsin. Trypsin can then continue to convert additional trypsinogen into trypsin, and trypsin converts several other pancreatic zymogens into active enzymes (Fig. F17.4.1). A summary of digestion and absorption of the three major nutrients is outlined in the following paragraphs.

FIGURE F17.4.1. Diagram showing events in the activation of the proteolytic enzymes of the pancreas. The majority of pancreatic enzymes (proteases) are secreted as inactive proenzymes. Their activation is triggered by the arrival of chyme into the duodenum. This stimulates the mucosal cells to release and activate the enterokinase (*blue box*) within the glycocalyx. The enterokinase activates trypsinogen, converting it into its active form, trypsin (*green box*). In turn, trypsin activates other pancreatic proenzymes (*red box*) into their active forms (*purple box*). The active proteases hydrolyze peptide bonds of proteins or polypeptides and reduce them to small peptides and amino acids.

Carbohydrate final digestion is brought about by enzymes bound to the microvilli of the enterocytes (Fig. F17.4.2). Galactose, glucose, and fructose are absorbed directly into venous capillaries and conveyed to the liver by the vessels of the hepatic portal system. Some infants and a larger percentage of adults cannot tolerate milk and unfermented milk

products because of the absence of lactase, the disaccharidase that splits lactose into galactose and glucose. These individuals are unable to break down milk or milk products, which leads to bloating caused by the buildup of gas from the bacterial digestion of the unprocessed lactose and diarrhea. The condition is completely alleviated if lactose (milk sugar) is eliminated from the diet. For some individuals, milk intolerance may be also partially or completely alleviated by using lactose-reduced milk products or tablets of lactase (enzyme that digests lactose), which are available as over-the-counter drugs.

FIGURE F17.4.2. Diagram showing the digestion and absorption of carbohydrates by an enterocyte. Carbohydrates are delivered to the alimentary canal as monosaccharides (e.g., glucose, fructose, and galactose), disaccharides (e.g., sucrose, lactose, and maltose), and polysaccharides (e.g., glycogen and starch). Enzymes involved in the digestion of carbohydrates are classified as salivary and pancreatic amylases. Further digestion is performed at the striated border of the enterocytes by enzymes, breaking down oligosaccharides and polysaccharides

into three basic monosaccharides (glucose, galactose, and fructose). Glucose and galactose are absorbed by the enterocyte via active transport using Na^+ -dependent glucose transporters (SGLT1). These transporters are localized at the apical cell membrane (*circles with G and Na^+ labels*). Fructose enters the cell via facilitated Na^+ -independent transport using GLUT5 (*gray circle with F label*) and GLUT2 glucose transporters (*orange octagons with G_2 label*). The three absorbed monosaccharides then pass through the basal membrane of the enterocyte, using GLUT2 glucose transporters, into the underlying capillaries of the portal circulation to reach their final destination in the liver.

Triglycerides are broken down into glycerol, monoglycerides, and long-, medium-, and short-chain fatty acids. These substances are emulsified by bile salts and pass into the apical portion of the enterocyte. Here, the glycerol and long-chain fatty acids are resynthesized into triglycerides. The resynthesized triglycerides appear first in apical vesicles of the smooth endoplasmic reticulum (sER) (see Fig. 17.21), then in the Golgi (where they are converted into **chylomicrons**, small droplets of neutral fat), and finally in vesicles that discharge the chylomicrons into the intercellular space. Instead of being absorbed directly into venous capillaries, chylomicrons are conveyed away from the intestine via lymphatic vessels (lacteals) that penetrate into each villus. Chylomicron-rich lymph then drains into the thoracic duct, which flows into the venous blood system. When in the blood circulation, chylomicrons are rapidly disassembled, and their constituent lipids are utilized throughout the body. Short- and medium-chain fatty acids and glycerol cross the apical cell membrane and enter and leave the enterocyte exclusively via capillaries that lead to the portal vein and the liver.

Protein digestion and absorption are shown in Figure F17.4.3. The major end products of protein digestion are amino acids (about 30%) and oligopeptides (about 70%), which are absorbed by enterocytes. The mechanism of amino acid absorption is conceptually identical to that of carbohydrates. The apical plasma membrane of the enterocytes bears at least four Na^+ -amino acid cotransporters. The dipeptides and tripeptides are transported across the apical membrane into the cell cytoplasm by the H^+ -oligopeptide cotransporter (PepT1). Most of the dipeptides and tripeptides are then digested by cytoplasmic peptidases into free amino acids, which are subsequently transported through the basal membrane (without a need for cotransporter) into the underlying capillaries of the portal circulation. In one disorder of amino acid absorption (Hartnup disease), free amino acids appear in the blood when dipeptides are fed to patients, but not when free amino acids are fed. This supports the conclusion that dipeptides of certain amino acids are absorbed via the PepT1 cotransporter, which is involved in different pathways from those involved in absorption of free amino acids.

FIGURE F17.4.3. Diagram showing the digestion and absorption of protein by an enterocyte. Proteins entering the alimentary canal are completely digested into free amino acids (*aa*) and small dipeptide or tripeptide fragments. Protein digestion starts in the stomach with pepsin, which hydrolyzes proteins to large polypeptides. The next step occurs in the small intestine by the action of pancreatic proteolytic enzymes. The

activation process is shown in Figure F17.4.1. Free amino acids are transported by four different amino acid Na^+ cotransporters. The dipeptides and tripeptides are transported across the apical membrane into the cell by H^+ oligopeptide cotransporters (PepT1). Most of the dipeptides and tripeptides are then broken down by cytoplasmic peptidases, and free amino acids are transported through the basal membrane into the underlying capillaries of the portal circulation.

Plicae circulares, villi, and microvilli increase the absorptive surface area of the small intestine.

The absorptive surface area of the small intestine is amplified by tissue and cell specializations of the submucosa and mucosa.

- **Plicae circulares (circular folds)**, also known as the *valves of Kerckring*, are permanent transverse folds that contain a core of submucosa. Each circular fold is circularly arranged and extends about one-half to two-thirds of the way around the circumference of the lumen (Fig. 17.17). The folds begin to appear about 5–6 cm beyond the pylorus. They are most numerous in the distal part of the duodenum and the beginning of the jejunum and become reduced in size and frequency in the middle of the ileum.

FIGURE 17.17. Photograph of the mucosal surface of the small intestine. This photograph of a segment of a human jejunum shows the mucosal surface. The circular folds (plicae circulares) appear as a series of transversely oriented ridges that extend partially around the lumen. Consequently, some of the circular folds appear to end (or begin) at

various sites along the luminal surface (*arrows*). The entire mucosa has a velvety appearance because of the presence of villi.

- **Villi** are unique, finger-like and leaf-like projections of the mucosa that extend from the theoretical mucosal surface for 0.5–1.5 mm into the lumen (Fig. 17.18). They completely cover the surface of the small intestine, giving it a velvety appearance when viewed with the unaided eye.

FIGURE 17.18. Intestinal villi in the small intestine. **a.** Scanning electron micrograph of the intestinal mucosa showing its villi. Note the openings (*arrows*) located between the bases of the villi that lead into the intestinal glands (crypts of Lieberkühn). $\times 800$. **b.** This three-dimensional diagram of the intestinal villi shows the continuity of the epithelium covering the villi with the epithelium lining the intestinal glands. Note blood vessels and the blind-ending lymphatic capillary, called a *lacteal*, in the core of the villus. Between the bases of the villi, the openings of the intestinal glands can be seen (*arrows*). Also, the small openings on the surface of the villi indicate the location of discharged goblet cells.

- **Microvilli** of the enterocytes provide the major amplification of the luminal surface. Each cell possesses several thousand closely packed microvilli. They are visible in the light microscope (LM) and give the apical region of the cell a striated appearance, the so-called **striated border**. Enterocytes and their microvilli are described later in this chapter (see pages 653–655).

The villi and intestinal glands, along with the lamina propria, associated GALT, and muscularis mucosae, constitute the essential

features of the small intestinal mucosa.

Villi, as noted, are projections of the mucosa. They consist of a core of loose connective tissue covered by a simple columnar epithelium. The core of the villus is an extension of the lamina propria, which contains numerous fibroblasts, smooth muscle cells, lymphocytes, plasma cells, eosinophils, macrophages, and a network of fenestrated blood capillaries located just beneath the epithelial basal lamina. In addition, the lamina propria of the villus contains a central, blind-ending lymphatic capillary, the **lacteal** (Fig. 17.19 and Plate 17.7, page 682). Smooth muscle cells derived from the muscularis mucosae extend into the villus and accompany the lacteal. These smooth muscle cells may account for the observation that villi contract and shorten intermittently, an action that may force lymph from the lacteal into the lymphatic vessel network surrounding the muscularis mucosae.

FIGURE 17.19. Photomicrograph of an intestinal villus. The surface of the villus consists of columnar epithelial cells, chiefly enterocytes with a striated border. Also evident are goblet cells that can be readily identified by the presence of the apical mucous cup. Located beneath the epithelium is the highly cellular loose connective tissue, the lamina propria. The lamina propria contains large numbers of round cells, mostly lymphocytes. In addition, smooth muscle cells can be identified. A lymphatic capillary called a *lacteal* occupies the center of the villus. When the lacteal is dilated, as it is in this specimen, it is easily identified. $\times 160$.

The **intestinal glands**, or **crypts of Lieberkühn**, are simple tubular structures that extend from the muscularis mucosae through the thickness of the lamina propria, where they open onto the luminal surface of the intestine at the base of the villi (see Fig. 17.18). The glands are composed of a simple columnar epithelium that is continuous with the epithelium of the villi.

As in the stomach, the lamina propria surrounds the intestinal glands and contains numerous cells of the immune system (lymphocytes, plasma cells, mast cells, macrophages, and eosinophils), particularly in the villi. The **lamina propria** also contains numerous **nodules of lymphatic tissue** that represent a major component of the GALT. The nodules are particularly large and numerous in the ileum, where they are preferentially located on the side of the intestine opposite the mesenteric attachment (Fig. 17.20). These nodular aggregations are known as **aggregated nodules** or **Peyer patches**. In gross specimens, they appear as aggregates of white specks.

The **muscularis mucosae** consists of two thin layers of smooth muscle cells, an inner circular and an outer longitudinal layer. As noted earlier, strands of smooth muscle cells extend from the muscularis mucosae into the lamina propria of the villi.

At least five types of cells are found in the intestinal mucosal epithelium.

The mature cells of the intestinal epithelium are found both in the intestinal glands and on the surface of the villi. They include the following:

- **Enterocytes**, whose primary function is absorption
- **Goblet cells**, unicellular mucin-secreting glands
- **Paneth cells**, whose primary function is to maintain mucosal innate immunity by secreting antimicrobial substances
- **Enteroendocrine cells**, which produce various paracrine and endocrine hormones
- **M cells (microfold cells)**, specialized cells located in the epithelium that covers lymphatic nodules in the lamina propria

Enterocytes are absorptive cells specialized for the transport of substances from the lumen of the intestine to the circulatory system.

Enterocytes are tall columnar cells with a basally positioned nucleus (see Figs. 17.18 and 17.21). Microvilli increase the apical surface

area as much as 600 times; they are recognized in the LM as forming a **striated border** on the luminal surface.

FIGURE 17.20. Photomicrograph of Peyer patches. This photomicrograph shows a longitudinal section through the wall of a human ileum. Note the

extensive lymphatic nodules located in the mucosa and the section of a circular fold projecting into the lumen of the ileum. Lymphatic nodules within the Peyer patch are primarily located within the lamina propria, although many extend into the submucosa. They are covered by the intestinal epithelium, which contains enterocytes, occasional goblet cells, and specialized antigen-transporting M cells. $\times 40$.

ABSORPTIVE CELLS

FIGURE 17.21. Diagrams of an enterocyte in different phases of absorption. a. This cell has a striated border on its apical surface and junctional complexes that seal the lumen of the intestine from the lateral intercellular space. The characteristic complement of major organelles is depicted in the diagram. b. This cell shows the distribution of lipid during fat absorption as seen with transmission electron microscopy (TEM). Initially, lipids are seen in association with the microvilli of the striated border. Lipids are internalized and seen in vesicles of the smooth endoplasmic reticulum (*sER*) in the apical portion of the cell. The membrane-bound lipid can be traced to the center of the cell, where many of the lipid-containing vesicles fuse. The lipid is then discharged into the intercellular

space. The extracellular lipids, recognized as chylomicrons, pass beyond the basal lamina for further transport into lymphatic (*green*) and/or blood vessels (*red*). *rER*, rough endoplasmic reticulum.

Each microvillus has a core of vertically oriented actin microfilaments that are anchored to villin located in the tip of the microvillus and that also attach to the microvillus plasma membrane by myosin I molecules. The actin microfilaments extend into the apical cytoplasm and insert into the **terminal web**, a network of horizontally oriented contractile microfilaments that form a layer in the most apical cytoplasm and attach to the intracellular density associated with the zonula adherens. Contraction of the terminal web causes the microvilli to spread apart, thus increasing the space between them to allow more surface area exposure for absorption to take place. In addition, contraction of the terminal web may aid in “closing” the holes left in the epithelial sheet by exfoliation of aging cells. Enterocytes are bound to one another and to goblet, enteroendocrine, and other cells of the epithelium by junctional complexes.

Tight junctions establish a barrier between the intestinal lumen and the epithelial intercellular compartment.

The **tight junctions** between the intestinal lumen and the connective tissue compartment of the body allow selective retention of substances absorbed by the enterocytes. As noted in Chapter 5, Epithelial Tissue (pages 141–145), the “tightness” of these junctions can vary.

In relatively impermeable tight junctions, as in the ileum and colon, active transport is required to move solutes across the barrier. In simplest terms, active transport systems, for example, sodium pumps ($\text{Na}^+/\text{K}^+\text{-ATPase}$), located in the lateral plasma membrane, transiently reduce the cytoplasmic concentration of Na^+ by transporting sodium ions across the lateral plasma membrane into the extracellular space below the tight junction. This transport of Na^+ creates a high intercellular Na^+ concentration, causing water from the cell to enter the intercellular space, reducing both the water and Na^+ concentrations in the cell. Consequently, water and Na^+ enter the cell at its apical surface, passing through the cell and exiting at the lateral plasma membrane as long as the sodium pump continues to function. Increased osmolarity in the intercellular space draws water into this space, establishing a hydrostatic pressure that drives Na^+ and water across the basal lamina into the connective tissue.

In epithelia with more permeable tight junctions, such as those in the duodenum and jejunum, a sodium pump also creates low intracellular Na^+ concentration. When the contents that pass into the duodenum and jejunum are hypotonic, however, considerable absorption of water, along with additional Na^+ and other small solutes, takes place directly across the tight junctions of the enterocytes into the intercellular spaces. This mechanism of absorption is referred to as **solvent drag**.

Other transport mechanisms also increase the concentrations of specific substances, such as sugars, amino acids, and other solutes in the intercellular space. These substances then diffuse or flow down their concentration gradients within the intercellular space to cross the epithelial basal lamina and enter the fenestrated capillaries in the lamina propria located immediately beneath the epithelium. Substances that are too large to enter the blood vessels, such as lipoprotein particles, enter the lymphatic lacteal.

The lateral cell surface of the enterocytes exhibits elaborate, flattened cytoplasmic processes (plicae) that interdigitate with those of adjacent cells (see Fig. 5.24). These folds increase the lateral surface area of the cell, thus increasing the amount of plasma membrane containing transport enzymes. During active absorption, especially of solutes, water, and lipids, these **lateral plications** separate, enlarging the intercellular compartment. The increased hydrostatic pressure from the accumulated solutes and solvents causes a directional flow through the basal lamina into the lamina propria (see Fig. 5.1).

In addition to the membrane specializations associated with absorption and transport, the enterocyte cytoplasm is also specialized for these functions. Elongated mitochondria that provide energy for transport are concentrated in the apical cytoplasm between the terminal web and the nucleus. Tubules and cisternae of the smooth endoplasmic reticulum (sER), which are involved in the absorption of fatty acids and glycerol and in the resynthesis of neutral fat, are found in the apical cytoplasm beneath the terminal web.

Enterocytes are also secretory cells, producing enzymes needed for terminal digestion and absorption as well as secretion of water and electrolytes.

The secretory function of **enterocytes**, primarily the synthesis of glycoprotein enzymes that will be inserted into the apical plasma membrane, is represented morphologically by aligned stacks of Golgi cisternae in the immediate supranuclear region and by the presence of

free ribosomes and rER lateral to the Golgi apparatus (see Fig. 17.21). Small secretory vesicles containing glycoproteins destined for the cell surface are located in the apical cytoplasm, just below the terminal web, and along the lateral plasma membrane. Histochemical or autoradiographic methods are needed, however, to distinguish these secretory vesicles from endocytotic vesicles or small lysosomes.

The small intestine also secretes water and electrolytes. This activity occurs mainly in the cells within the intestinal glands. The secretion that occurs in these glands is thought to assist the process of digestion and absorption by maintaining an appropriate liquid state of the intestinal chyme. Under normal conditions, the absorption of fluid by the villus enterocyte is balanced by the secretion of fluid by the gland enterocyte.

Goblet cells represent unicellular glands that are interspersed among the other cells of the intestinal epithelium.

As in other epithelia, **goblet cells** produce mucus. In the small intestine, goblet cells increase in number from the duodenum to the terminal part of the ileum. Also, as in other epithelia, because water-soluble mucinogen is lost during preparation of routine H&E sections, the part of the cell that normally contains mucinogen granules appears empty. Examination with the TEM reveals a large accumulation of mucinogen granules in the apical cytoplasm that distends the apex of the cell and distorts the shape of neighboring cells (Fig. 17.22). With the apex of the cell containing a large accumulation of mucinogen granules, the basal portion of the cell resembles a narrow stem. This basal portion is intensely basophilic in histologic preparations because it is occupied by a heterochromatic nucleus, extensive rER, and free ribosomes. Mitochondria are also concentrated in the basal cytoplasm. The characteristic shape, with the apical accumulation of granules and the narrow basal stem, is responsible for the name of the cell, as in a glass "goblet." An extensive array of flattened Golgi cisternae forms a wide cup around the newly formed mucinogen granules adjacent to the basal part of the cell (see Fig. 17.22a). The microvilli of goblet cells are restricted to a thin rim of cytoplasm (the theca) that surrounds the apical-lateral portion of the mucinogen granules. Microvilli are more obvious on the immature goblet cells in the deep one-half of the intestinal gland.

FIGURE 17.22. Electron micrograph and diagram of a goblet cell. **a.** This electron micrograph shows the basal portion of a goblet cell depicted on the adjacent diagram. The cell rests on the basal lamina. The basal portion of the cell contains the nucleus, rough endoplasmic reticulum, and mitochondria. Just apical to the nucleus are extensive profiles of the Golgi apparatus. As the mucous product accumulates in the Golgi cisternae, they become enlarged (*asterisks*). The large mucinogen granules fill most of the apical portion of the cell and collectively constitute the “mucous cup” seen in the light microscope. $\times 15,000$. **b.** This diagram shows the entire goblet cell. The *boxed region* on this diagram represents an area from which the adjacent electron micrograph was most likely obtained. The nucleus is located at the basal portion of the cell. The major portion of the cell is filled with mucinogen granules forming the mucous cup that is evident in the light microscope. At the base and lower sides of the mucous cup are flattened saccules of the large Golgi apparatus. Other organelles are distributed throughout the remaining cytoplasm, especially in the perinuclear cytoplasm at the base of the cell.

Paneth cells play a role in the regulation of normal bacterial flora of the small intestine.

Paneth cells are found in the bases of the intestinal glands. (They are also occasionally found in the normal colon in small numbers; their number may increase in certain pathologic conditions.) They have a basophilic basal cytoplasm, a supranuclear Golgi apparatus, and large, intensely acidophilic, refractile apical secretory vesicles. These vesicles allow their easy identification in routine histologic sections (Fig. 17.23). **The secretory vesicles contain the**

antibacterial enzyme lysozyme, α -defensins, other glycoproteins, an arginine-rich protein (probably responsible for the intense acidophilia), and zinc. Lysozyme digests the cell walls of certain groups of bacteria. α -Defensins are homologs of peptides that function as mediators in cytotoxic CD8⁺ T lymphocytes. Their antibacterial action and ability to phagocytose certain bacteria and protozoa suggest that Paneth cells play a role in regulating the normal bacterial flora of the small intestine.

FIGURE 17.23. Photomicrograph of intestinal glands showing Paneth cells. This photomicrograph shows the base of intestinal (jejunal) glands in a hematoxylin and eosin (H&E) preparation. The gland on the *right* is sectioned longitudinally; the circular cross-sectional profile of another gland is seen on the *left*. Paneth cells are typically located in the base of the intestinal glands and are readily seen in the light microscope because of the intensive eosin staining of their vesicles. The lamina propria contains an abundance of plasma cells, lymphocytes, and other connective tissue cells. Note several lymphocytes in the epithelium of the gland (*arrows*). $\times 240$. *Inset*. This high magnification of the area indicated by the *rectangle* shows the characteristic basophilic cytoplasm in the basal portion of the cell and

large accumulations of intensely staining, eosinophilic, refractile secretory vesicles in the apical portion of the cell. An arginine-rich protein found in the vesicles is probably responsible for the intense eosinophilic reaction. $\times 680$.

Enteroendocrine cells in the small intestine produce nearly all of the same peptide hormones as they do in the stomach.

Enteroendocrine cells in the small intestine resemble those that reside in the stomach (see Fig. 17.12). The “closed cells” are concentrated in the lower portion of the intestinal gland, whereas the “open cells” can be found at all levels of each villus. Activation of taste receptors found on the apical cell membrane of “open cells” activates the **G-protein signaling cascade**, resulting in the release of peptides that regulate a variety of gastrointestinal functions. These include pancreatic secretion, inducing digestion and absorption, and energy homeostasis by acting on neural pathways of the **brain-gut-adipose axis**. Nearly all of the same peptide hormones identified in this cell type in the stomach can be demonstrated in the enteroendocrine cells of the intestine (see Table 17.1). **Cholecystokinin (CCK)**, **secretin**, **gastric inhibitory polypeptide (GIP)**, and **motilin** are the most active regulators of gastrointestinal physiology that are released in this portion of the gut (see Fig. 17.13). CCK and secretin increase pancreatic and gallbladder activity and inhibit gastric secretory function and motility. GIP stimulates insulin release in the pancreas, and motilin initiates gastric and intestinal motility. Although other peptides produced by enteroendocrine cells have been isolated, they are not considered hormones and are, therefore, called **candidate hormones** (see Folder 17.3, page 644). Enteroendocrine cells also produce at least two hormones, somatostatin and histamine, which act as **paracrine hormones** (see Folder 17.3, page 644) (i.e., hormones that have a local effect and do not circulate in the bloodstream). In addition, several peptides are secreted by the nerve cells located in the submucosa and muscularis externa. These peptides, called **neurocrine hormones**, are represented by vasoactive intestinal peptide (VIP), bombesin, and enkephalins. The functions of these peptides are listed in Table 17.2 (page 647).

M cells convey microorganisms and other macromolecules from the intestinal lumen to Peyer patches.

M cells are epithelial cells that overlie **Peyer patches** and other large lymphatic nodules; they differ significantly from the

surrounding intestinal epithelial cells (Folder 17.5). M cells have a characteristic shape because each cell develops a deep pocket-like recess connected to the extracellular space. Dendritic cells, macrophages, and T and B lymphocytes reside in this space. Owing to this unique shape, the basolateral cell surface of the M cell resides within a few microns of its apical surface, greatly reducing the distance that endocytic vesicles must travel to cross the epithelial barrier. On their apical surface, M cells have **microfolds** rather than microvilli and a thin layer of glycocalyx. The apical surface expresses an abundance of glycoprotein 2 (GP2) receptors that bind specific macromolecules and Gram-negative bacteria (e.g., *Escherichia coli*). The substances bound to GP2 receptors are internalized in endocytic vesicles and transported to the basolateral cell surface of the pocket-like recess. Within the recess, the released contents are immediately transferred to immune cells residing in this space. Thus, M cells function as highly specialized **antigen-transporting cells** that relocate intact antigens from the intestinal lumen across the epithelial barrier. Antigens that reach the immune cells in this manner stimulate a response in the GALT that is described later in this chapter.

FOLDER 17.5

FUNCTIONAL CONSIDERATIONS: IMMUNE FUNCTIONS OF THE ALIMENTARY CANAL

Immunologists have shown that the gut-associated lymphatic tissue (GALT) not only responds to antigenic stimuli but also functions in a monitoring capacity. This function has been partially clarified for the lymphatic nodules of the intestinal tract. The **M cells** that are part of the epithelium that cover Peyer patches and lymphatic nodules have a distinctive surface that might be misinterpreted in sections as thick microvilli. The cells are readily identified with the scanning electron microscope because microfolds contrast sharply with the microvilli that constitute the striated border of the adjacent enterocytes.

It has been shown with **glycoprotein GP2** (molecular marker for M cells) that the M cells endocytose proteins and bacteria from the intestinal lumen, transport them in the vesicles through the cell, and discharge the contents by exocytosis into deep recesses that are continuous with the extracellular space (Fig. F17.5.1). Dendritic cells and lymphocytes within the deeply recessed extracellular space sample the luminal protein, including antigens, and thus have the opportunity to stimulate the development of specific antibodies against the antigens. The destination of these exposed lymphocytes has not yet been fully determined. Some remain within the local lymphatic tissue, but others may be destined for other sites in the body, such as the salivary and mammary glands. Recall that in the salivary glands, cells of the immune system (plasma cells) secrete immunoglobulin A (IgA), which the glandular

epithelium then converts into secretory IgA (sIgA). Some experimental observations suggest that antigen contact necessary for the production of IgA by plasma cells occurs in the lymphatic nodules of the intestines. Recent findings using glycoprotein 2 (GP2)-deficient mice show that the interaction of GP2 with bacteria plays an important role in antigen-specific immune responses in Peyer patches. This discovery may lead to the development not only of new oral vaccines for infectious diseases but also of the innovative treatment of tumors and inflammatory bowel diseases.

FIGURE F17.5.1. Diagram of M cells covering the lymphatic nodule of the intestine. **a.** This diagram shows the relationship of the M cells (microfold cells) and absorptive cells in the epithelium covering a lymphatic nodule. The M cell is an epithelial cell that displays microfolds rather than microvilli on its apical surface. It has deep recesses within which lymphocytes, macrophages, and processes of dendritic cells come close to the lumen of the small intestine. An intact antigen from the intestinal lumen is transferred across the thin layer of the M cell apical cytoplasm to lymphocytes and other antigen-presenting cells residing within the recesses. **b.** Scanning electron micrograph of a Peyer patch lymphatic nodule bulging into the lumen of the ileum. Note that the area of the follicle covered by M cells is surrounded by the finger-like projections of the intestinal villi. The surface of the M cells has a smooth appearance. The absence of absorptive cells and mucus-producing goblet cells in the area covered by M cells facilitates immunoreactions to antigens. $\times 80$. (Reprinted with permission from Owen RL, Johns AL. Epithelial cell specialization within human Peyer's patches: an ultrastructural study of intestinal lymphoid follicles. *Gastroenterology*. 1974;66:189 - 203.)

Intermediate cells constitute the amplifying compartment of the intestinal stem cell niche.

Intermediate cells constitute most of the cells found within the intestinal stem cell niche that is located in the lower half of the intestinal gland. These cells constitute the amplifying compartment

of the cells that are still capable of cell division and usually undergo one or two divisions before they become committed to differentiation into either absorptive or goblet cells. These cells have short, irregular microvilli with long core filaments extending deep into the apical cytoplasm and numerous macular (desmosomal) junctions with adjacent cells. Small mucin-like secretory granules form a column in the center of the supranuclear cytoplasm. Intermediate cells that are committed to becoming goblet cells develop a small, rounded collection of secretory granules just beneath the apical plasma membrane; those that are committed to becoming absorptive cells lose the secretory granules and begin to show concentrations of mitochondria, rER, and ribosomes in the apical cytoplasm.

GALT is prominent in the lamina propria of the small intestine.

As noted earlier, the **lamina propria** of the digestive tract is heavily populated with elements of the immune system; approximately one-fourth of the mucosa consists of a loosely organized layer of lymphatic nodules, lymphocytes, macrophages, plasma cells, and eosinophils in the lamina propria (Plate 17.2, page 672). Lymphocytes are also located between epithelial cells. The **GALT** serves as an immunologic barrier throughout the length of the gastrointestinal tract. In cooperation with the overlying epithelial cells, particularly M cells, the lymphatic tissue samples the antigens in the epithelial intercellular spaces. Lymphocytes, macrophages, and other antigen-presenting cells process the antigens and migrate to lymphatic nodules in the lamina propria where they undergo activation (see page 494), leading to antibody secretion by newly differentiated plasma cells.

The mucosal surface is protected by immunoglobulin-mediated responses.

The **mucosal surface** of the gut tube is constantly challenged by the presence of ingested microorganisms (i.e., viruses, bacteria, parasites) and toxins, which, after compromising the epithelial barrier, may cause infections or diseases. An example of a specific defense mechanism is the immunoglobulin-mediated response using immunoglobulin A (IgA), IgM, and IgE antibodies. Most of the plasma cells in the lamina propria of the intestine secrete **dimeric dIgA antibodies** rather than the more common IgG; other plasma cells produce **pentameric IgM** and IgE (see page 490). Diameric dIgA is composed of two monomeric IgA subunits and a polypeptide J chain (see

Fig. 16.28). Secreted dIgA molecules bind to the **polymeric immunoglobulin receptor (pIgR)** located at the basal domain of the epithelial cells (Fig. 17.24). The pIgR is a transmembrane glycoprotein (75 kDa) synthesized by enterocytes and expressed on the basal plasma membrane. The pIgR-dIgA complex is then endocytosed and transported across the epithelium to the apical surface of the enterocyte (this type of transport refers to as *transcytosis*). After the pIgR-dIgA complex reaches the apical surface, pIgR is proteolytically cleaved and the extracellular part of the receptor that is bound to dIgA is released into the gut lumen (see Fig. 17.24). This cleaved extracellular binding domain of the receptor is known as the **secretory component (SC)**; secreted dIgA in association with the SC is known as **secretory IgA (sIgA)**. The release of sIgA immunoglobulins is critical for proper immunologic surveillance by the mucosal immune system. In the lumen, sIgA binds to antigens, toxins, and microorganisms. Secretory IgA prevents the attachment and invasion of viruses and bacteria into the mucosa by either inhibiting their motility, causing microbial aggregation, or masking pathogen adhesion sites on the epithelial surface. For example, sIgA binds to a glycoprotein on the viral envelope of HIV, preventing its attachment, internalization, and subsequent replication in the cell.

FIGURE 17.24. Diagram of immunoglobulin A (IgA) secretion and transport. A monomeric form of immunoglobulin A (*IgA*) is synthesized by the plasma cell. *IgAs* are secreted into the lamina propria in a dimeric form as *dIgA*. Dimeric *dIgA* is composed of two monomeric *IgA* subunits and a polypeptide J chain also produced by the plasma cell. In the lamina propria, *dIgA* binds to the polymeric immunoglobulin receptor (*pIgR*) on the basal cell

membrane of the enterocyte. The *pIgR-IgA* complex enters the cell by endocytosis and is carried out within the endocytotic vesicles to the early endosomal compartment and then to the apical surface (a process called *transcytosis*). Endocytic vesicles fuse with the apical plasma membrane, the *pIgR* is proteolytically cleaved, and *dIgA* is released with the extracellular portion of the *pIgR*. This portion of the *pIgR* remains with the *IgA* dimer and becomes the secretory component (*SC*) of the secretory IgA (*sIgA*).

Secretory IgA is the principal molecule of mucosal immunity. However, IgM molecules utilize similar pathways of receptor-mediated transcytosis to reach the mucosal surface. Some of the IgE binds to the plasma membranes of mast cells in the lamina propria (see pages 200–204), selectively sensitizing them to specific antigens derived from the lumen.

Epithelial Cell Renewal in the Small Intestine

Mature cells of the intestinal epithelium are derived from a single stem cell population.

Stem cells are located in the base of the intestinal gland. This **intestinal stem cell niche** (zone of cell replication) is restricted to the lower one-half of the gland and contains highly proliferative intermediate cells (as previously explained) and cells in various stages of differentiation. A cell destined to become a goblet cell or absorptive cell usually undergoes several additional divisions after it leaves the pool of stem cells. The epithelial cells migrate upward in the intestinal gland onto the villus where they undergo apoptosis and slough off into the lumen. Autoradiographic studies have shown that the renewal time for absorptive and **goblet cells** in the human small intestine is 4–6 days.

Enteroendocrine cells and Paneth cells are also derived from the stem cells at the base of the intestinal gland. Enteroendocrine cells appear to divide only once before differentiating. They migrate with the absorptive and goblet cells but at a slower rate. **Paneth cells** migrate downward and reside at the bottom of the intestinal gland. They live for approximately 4 weeks and are then replaced by differentiation of a nearby “committed” cell in the intestinal gland. Cells that are recognizable as Paneth cells no longer divide. As mentioned in Chapter 5, Epithelial Tissue (page 166), expression of **transcription factor Math1** appears to determine the fate of differentiating cells in the intestinal stem cell niche. The cells committed to the secretory lineage (i.e., they will differentiate into goblet, enteroendocrine, and Paneth cells) have increased

expression of Math1. Inhibition of Math1 expression characterizes the default developmental pathway into absorptive intestinal cells (enterocytes).

Submucosa

A distinguishing characteristic of the duodenum is the presence of submucosal glands.

The **submucosa** consists of dense connective tissue and localized sites that contain aggregates of adipose cells. A conspicuous feature in the duodenum is the presence of **submucosal glands**, also called **Brunner glands**.

The branched, tubular submucosal glands of the duodenum have secretory cells with characteristics of both zymogen-secreting and mucus-secreting cells (Fig. 17.25).

FIGURE 17.25. Photomicrograph of Brunner glands in the duodenum. This photomicrograph shows part of the duodenal wall in a hematoxylin and eosin (H&E) preparation. A distinctive feature of the duodenum is the presence of Brunner glands. The *dashed line* marks the boundary between the villi and the typical intestinal glands (crypts of Lieberkühn). The latter extend to the muscularis mucosae. Beneath the mucosa is the submucosa, which contains Brunner glands. These are branched tubular glands whose secretory component

consists of columnar cells. The duct of Brunner gland opens into the lumen of the intestinal gland (*arrow*). $\times 120$.

The secretion of these glands has a pH of 8.1–9.3 and contains neutral and alkaline glycoproteins and bicarbonate ions. This highly alkaline secretion probably serves to protect the proximal small intestine by neutralizing the acid-containing chyme delivered to it. It also brings the intestinal contents close to the optimal pH for activation of pancreatic enzymes that are also delivered to the duodenum.

Muscularis Externa

The **muscularis externa** consists of an inner layer of circularly arranged smooth muscle cells and an outer layer of longitudinally arranged smooth muscle cells (Fig. 17.26). The main components of the **myenteric plexus (Auerbach plexus)** are located between these two muscle layers (see Fig. 17.26 for an LM image and 17.27 for an EM image). Two kinds of muscular contraction occur in the small intestine. Local contractions displace intestinal contents both proximally and distally; this type of contraction is called **segmentation**. These contractions primarily involve the circular muscle layer. They serve to circulate the chyme locally, mixing it with digestive juices and moving it into contact with the mucosa for absorption. **Peristalsis**, the second type of contraction, involves the coordinated action of both circular and longitudinal muscle layers and moves the intestinal contents distally.

FIGURE 17.26. Photomicrograph of muscularis externa in the ileum. This photomicrograph of a hematoxylin and eosin (H&E)-stained specimen shows the cross section of the outer section of the intestinal wall. In this image, the most prominent structure is the muscularis externa, which consists of two layers of smooth muscle. The inner layer appears as circularly arranged smooth muscle cells distinguished in this section by the elongated profiles of their nuclei. In the outer layer, the smooth muscle cells are longitudinally arranged, and in this section, they display cross-sectional profiles with small round nuclei surrounded by cytoplasm. Owing to the plane of the section, many cytoplasmic profiles of smooth muscle cells in the outer layer do not have visible nuclei. The arrangement of smooth muscles in both layers can be seen at higher magnification in the *inset*. Located between these two muscle layers is the myenteric (Auerbach) plexus. In the section, the plexus exhibits lighter stained irregular profiles of tissue containing dispersed darker stained nerve cells. The main components of the myenteric

plexus shown on the *inset* at higher magnification are nerve cell bodies of the postsynaptic parasympathetic neurons, satellite cells (peripheral neuroglia cells), and unmyelinated nerve fibers with nonmyelinating Remak Schwann cells. Nerve cells can be distinguished by their basophilic cytoplasm and prominent nucleus containing darker nucleolus. The free surface of the intestine is covered by the serosa, which consists of simple squamous epithelium (mesothelium) and a small amount of underlying connective tissue (*CT*). Deep into the muscularis externa toward the lumen of the intestine is a dense irregular connective tissue layer known as *submucosa*. Note collagen fibers, adipose cells, and accumulation of lymphocytes (*lower right corner*) in this layer. $\times 180$; inset $\times 450$.

FIGURE 17.27. Electron micrograph of the myenteric (Auerbach) plexus. The plexus is located between the two smooth muscle (*SM*) layers of the muscularis externa. It consists of nerve cell bodies (*CB*) and an extensive network of nerve fibers (*N*). A satellite cell (*SC*), also referred to as an *enteric glial cell*, is seen in proximity to the neuron cell bodies. These cells have structural and chemical features in common with glial cells of the CNS. *BV*, blood vessel. $\times 3,800$.

Serosa

The **serosa** of the parts of the small intestine that are located intraperitoneally in the abdominal cavity corresponds to the general description at the beginning of the chapter. Parts of the duodenum that lie in the retroperitoneal space and have direct contact with structures and organs on the posterior abdominal wall have typical adventitia.

■ LARGE INTESTINE

The **large intestine** comprises the **cecum** with its projecting **vermiform appendix**, the **colon**, the **rectum**, and the **anal canal**. The colon is further subdivided on the basis of its anatomic locations into the ascending colon, transverse colon, descending colon, and sigmoid colon. The four layers characteristic of the alimentary canal are present throughout. However, several distinctive features exist at the gross level (Fig. 17.28):

FIGURE 17.28. Photograph of the large intestine. This photograph shows the outer (serosal) surface (*left*) and internal (mucosal) surface (*right*) of the transverse colon. On the outer surface, note the characteristic features of the large intestine: a distinctive smooth muscle band representing one of the three teniae coli (*TC*); haustra coli (*HC*), the sacculations of the colon located between the teniae; and omental appendices (*OA*), small peritoneal projections filled with fat. The smooth mucosal surface shows semilunar folds (*arrows*) formed in response to contractions of the muscularis externa. Compare the mucosal surface as shown here with that of the small intestine (Fig. 17.17).

- **Teniae coli** represent three narrowed, thickened, equally spaced bands of the outer longitudinal layer of the muscularis externa. They are primarily visible in the cecum and colon and are absent in the rectum, anal canal, and vermiform appendix.
- **Haustra coli** are visible sacculations between the teniae coli on the external surface of the cecum and colon.
- **Omental appendices** are small, fatty projections of the serosa, observed on the outer surface of the colon.

Mucosa

The **mucosa** of the large intestine has a “smooth” surface; neither plicae circulares nor villi are present. It contains numerous straight tubular intestinal glands (crypts of Lieberkühn) that extend through the full thickness of the mucosa (Fig. 17.29a). The glands consist of simple columnar epithelium, as does the intestinal surface from which they invaginate. Examination of the luminal surface of the large intestine at the microscopic level reveals the openings of the glands, which are arranged in an orderly pattern (Fig. 17.29b).

FIGURE 17.29. Mucosa of the large intestine. a. This photomicrograph of a hematoxylin and eosin (H&E) preparation shows the mucosa and part of the submucosa. The surface epithelium is continuous with the straight, unbranched, tubular intestinal glands (crypts of Lieberkühn). The openings of the glands at the intestinal surface are identified (*arrows*). The epithelial cells consist principally of absorptive and goblet cells. As the absorptive cells are followed into the glands, they become fewer in number, whereas the goblet cells increase in number. The highly cellular lamina propria contains numerous lymphocytes and other cells of the immune system. b. Scanning electron micrograph of the human mucosal surface of the large intestine. The

surface is divided into territories by clefts (*arrows*). Each territory contains 25-100 gland openings. $\times 140$. (Reprinted with permission from Fenoglio CM, Richart RM, Kaye GI. Comparative electron-microscopic features of normal, hyperplastic, and adenomatous human colonic epithelium. II. Variations in surface architecture found by scanning electron microscopy. *Gastroenterology*. 1975;69:100-109.)

The principal functions of the large intestine are reabsorption of electrolytes and water and elimination of undigested food and waste.

The primary function of the **columnar absorptive cells** is reabsorption of water and electrolytes. The morphology of the absorptive cells of the large intestine is essentially identical to that of the enterocytes of the small intestine. Reabsorption is accomplished by the same Na^+/K^+ -activated ATPase-driven transport system as described for the small intestine.

Elimination of semisolid to solid waste materials is facilitated by the large amounts of mucus secreted by the numerous **goblet cells** of the intestinal glands. Goblet cells are more numerous in the large intestine than in the small intestine (see Fig. 17.29a and Plate 17.9, page 686). They produce mucin that is secreted continuously to lubricate the bowel, facilitating the passage of increasingly solid contents.

The mucosal epithelium of the large intestine contains the same cell types as the small intestine, except Paneth cells, which are normally absent in humans.

Columnar absorptive cells predominate (4:1) over goblet cells in most of the colon, although this is not always apparent in histologic sections (see Fig. 17.29a). The ratio decreases, however, approaching 1:1, near the rectum, where the number of goblet cells increases. Although the absorptive cells secrete glycocalyx at a rapid rate (turnover time is 16-24 hours in humans), this layer has not been shown to contain digestive enzymes in the colon. As in the small intestine, however, Na^+/K^+ -ATPase is abundant and is localized in the lateral plasma membranes of the absorptive cells. The intercellular space is often dilated, indicating active transport of fluid.

Goblet cells may mature deep into the intestinal gland, even in the replicative zone (Fig. 17.30). They secrete mucus continuously, even to the point where they reach the luminal surface. Here, at the surface, the secretion rate exceeds the synthesis rate, and “exhausted” goblet cells appear in the epithelium. These cells are tall and thin and have a small number of mucinogen granules in the

central apical cytoplasm. An infrequently observed cell type, the caveolated “tuft” cell, has also been described in the colonic epithelium; however, this cell may be a form of exhausted goblet cell.

FIGURE 17.30. Electron micrograph of dividing goblet cells. This electron micrograph demonstrates that certain cells of the intestine continue to divide even after they have differentiated. Here, two goblet cells (*GC*) are shown dividing. Typically, dividing cells move away from the basal lamina toward the lumen. One of the goblet cells demonstrates mucinogen granules (*M*) in its apical cytoplasm. The chromosomes (*C*) of the dividing cells are not surrounded by a nuclear membrane. Compare with the nuclei (*N*) of the nondividing intestinal epithelial cells. The lumen of the gland (*L*) is on the *right*. *CT*, connective tissue; *E*, eosinophil. $\times 5,000$.

Epithelial Cell Renewal in the Large Intestine

All intestinal epithelial cells in the large intestine derive from a single stem cell population.

As in the **small intestine**, all of the mucosal epithelial cells of the large intestine arise from stem cells located at the bottom of the intestinal gland. The lower third of the gland constitutes the intestinal stem cell niche, where newly generated cells undergo two to three more divisions as they begin their migration up to the luminal surface, where they are shed about 5 days later. The intermediate cell types found in the lower third of the intestinal gland are identical to those seen in the small intestine.

The turnover times of the epithelial cells of the large intestine are similar to those of the small intestine (i.e., about 6 days for absorptive cells and goblet cells and up to 4 weeks for enteroendocrine cells). Senile epithelial cells that reach the mucosal surface undergo apoptosis and are shed into the lumen at the midpoint between two adjacent intestinal glands.

Lamina Propria

Although the **lamina propria** of the large intestine contains the same basic components as the rest of the digestive tract, it demonstrates some additional structural features and greater development of some others, including:

- **Collagen table**, which represents a thick layer of collagen and proteoglycans that lies between the basal lamina of the epithelium and that of the fenestrated absorptive venous capillaries. This layer is as much as 5 μm thick in the normal human colon and can be up to 3 times that thickness in human hyperplastic colonic polyps. The collagen table participates in the regulation of water and electrolyte transport from the intercellular compartment of the epithelium to the vascular compartment.

- **Pericryptal fibroblast sheath**, which constitutes a well-developed fibroblast population of regularly replicating cells. They divide immediately beneath the base of the intestinal gland, adjacent to the stem cells found in the epithelium (in both the large and small intestines). The fibroblasts then differentiate and migrate upward in parallel and synchrony with the epithelial cells. Although the ultimate fate of the pericryptal fibroblast is unknown, most of these cells, after they reach the level of the luminal surface, take on the morphologic and histochemical characteristics of macrophages. Some evidence suggests that the macrophages of the core of the lamina propria in the large intestine may arise as a terminal differentiation of the pericryptal fibroblasts.
- **GALT**, which is continuous with that of the terminal ileum. In the large intestine, GALT is more extensively developed; large lymphatic nodules distort the regular spacing of the intestinal glands and extend into the submucosa. The extensive development of the immune system in the colon probably reflects the large number and variety of microorganisms and noxious end products of metabolism normally present in the lumen.
- **Lymphatic vessels**. In general, lymphatic vessels are not present in the core of the lamina propria between the intestinal glands, and there are no vessels that extend toward the luminal surface of the large intestine. However, using a selective marker for lymphatic epithelium, researchers have found occasional small lymphatic vessels at the bases of the intestinal glands. These lymphatic vessels drain into the lymphatic network within the muscularis mucosae. The next step in lymph drainage occurs in the lymphatic plexuses in the submucosa and muscularis externa before lymph leaves the wall of the large intestine and drains into the regional lymph nodes. [To understand the clinical significance of the lymphatic pattern in the large intestine, see Folder 17.6.](#)

FOLDER 17.6

CLINICAL CORRELATION: THE PATTERN OF LYMPH VESSEL DISTRIBUTION AND DISEASES OF THE LARGE INTESTINE

The normal **absence of lymphatic drainage** from the lamina propria of the large intestine was initially discovered using standard techniques of analyzing tissue samples obtained from biopsies with light and electron microscopy. A specific monoclonal antibody called *D2-40* is currently being used to study the distribution of lymphatic vessels within the lamina propria that may be associated with several disease processes. D2-40 reacts with a 40-kDa *O*-linked sialoglycoprotein expressed on the lymphatic endothelium. For instance, in the chronic

superficial inflammation of the colon and rectum known as **ulcerative colitis**, the formation of granulation tissue is associated with proliferation of blood and lymphatic vessels within the lamina propria. Lymphangiogenesis (the growth of lymphatic vessels) in this disease is linked to the expression of vascular endothelial growth factors (VEGFs). The progress of treatment in ulcerative colitis can be monitored by biopsies, which show the disappearance of lymphatic vessels from the lamina propria. Conversely, an increased number of lymphatic vessels in the lamina propria signals the presence of active inflammation.

Discovery of the distribution of lymphatic vessels in the large intestine established the basis for the current management of **adenomas** (adenomatous polyps of the large intestine). These are intraepithelial neoplasms located on the mass of tissue that protrudes into the lumen of the large intestine (Fig. F17.6.1). The absence of lymphatic vessels from the lamina propria was important in understanding the slow rate of metastasis from certain colon cancers. Cancers that develop in large adenomatous colonic polyps may grow extensively within the epithelium and lamina propria before they gain access to the lymphatic vessels at the level of the muscularis mucosae. Because almost 50% of all adenomatous polyps of the large intestine are located in the rectum and sigmoid colon, they can be detected with rectosigmoidoscopy. As long as the lesion is confined to the mucosa, the endoscopic removal of such polyps is regarded as adequate clinical treatment. However, the final therapeutic decision must be confirmed after careful microscopic examination of the resected specimen.

FIGURE F17.6.1. Adenomatous polyp of the large intestine. **a.** This image shows a macroscopic view of a polyp (about 2 cm in diameter) that was surgically removed from the large intestine during endoscopic colonoscopy. It has a characteristic bosselated surface (with rounded swellings) and a stalk by which it attaches to the wall of the colon. **b.** This photomicrograph was obtained from the center of the polyp. At the tip of the polyp, note the repetitive pattern of tubules covered with neoplastic epithelial cells that have migrated and accumulated on the intestinal surface. The stalk in the center is continuous with the submucosa of the colon. Note also the normal simple columnar epithelium of the large intestine at the base of the stalk. (Reproduced from Mitros FA, Rubin E. The gastrointestinal tract. In Rubin R, Strayer DS, eds. *Rubin's Pathology: Clinicopathologic Foundations of Medicine*. 5th ed. Lippincott Williams & Wilkins; 2008.)

Muscularis Externa

As noted, in the cecum and colon (the ascending, transverse, descending, and sigmoid colons), the **outer layer of the muscularis externa** is, in part, condensed into prominent longitudinal bands of muscle, called **teniae coli**, which may be seen at the gross level (see Fig. 17.28). Between these bands, the longitudinal layer forms an extremely thin sheet. In the rectum, anal canal, and vermiform appendix, the outer longitudinal layer of smooth muscle is a uniformly thick layer, as in the small intestine.

Bundles of muscle from the teniae coli penetrate the **inner, circular layer of muscle** at irregular intervals along the length and circumference of the colon. These apparent discontinuities in the muscularis externa allow segments of the colon to contract independently, leading to the formation of **haustra coli**, sacculations of the colon wall.

The muscularis externa of the large intestine produces two major types of contraction: segmentation and peristalsis. Segmentation is local and does not result in the propulsion of contents. Peristalsis results in the distal mass movement of the colonic contents. Mass peristaltic movements occur infrequently; in healthy persons, they usually occur once a day to empty the distal colon.

Submucosa and Serosa

The **submucosa** of the large intestine corresponds to the general description already given. Where the large intestine is directly in contact with other structures (as on much of its posterior surface), its outer layer is an adventitia; elsewhere, the outer layer is a typical serosa.

Cecum and Appendix

The **cecum** forms a blind pouch just distal to the ileocecal valve; the appendix is a thin, finger-like extension of this pouch. The histology of the cecum closely resembles that of the rest of the colon; the **appendix** differs from it in having a uniform layer of longitudinal muscle in the muscularis externa (Fig. 17.31 and Plate 17.10, page 688). The most conspicuous feature of the appendix is the large number of lymphatic nodules that extend into the submucosa. **In many adults, the normal structure of the appendix is lost, and the appendage is filled with fibrous scar tissue. Blockage of the opening between the appendix and the cecum, usually due to scarring, buildup of thick mucus, or stool that enters the lumen of the appendix from the cecum, may cause appendicitis (inflammation of the appendix). The appendix is also a common site for carcinoid, a type of tumor originating from enteroendocrine cells of lining mucosa (see Folder 17.3).**

FIGURE 17.31. Photomicrograph of a cross section through the vermiform appendix. The vermiform appendix displays the same four layers as those of the large intestine, except that its diameter is smaller. Typically, lymphatic nodules are seen within the entire mucosa and usually extend into the submucosa. Note the distinct germinal centers within the lymphatic nodules. The muscularis externa is composed of a relatively thick circular layer and a much thinner outer longitudinal layer. The appendix is covered by a serosa that is continuous with the mesentery of the appendix (*lower right*). $\times 10$.

Rectum and Anal Canal

The **rectum** is the dilated distal portion of the alimentary canal. Its upper part is distinguished from the rest of the large intestine by the presence of folds called **transverse rectal folds**. The mucosa of the rectum is similar to that of the rest of the distal colon, having straight, tubular intestinal glands with many goblet cells.

The most distal portion of the alimentary canal is the **anal canal**. It has an average length of 4 cm and extends from the upper aspect of the pelvic diaphragm to the anus (Fig. 17.32). The upper part of the anal canal has longitudinal folds called **anal columns**. Depressions between the anal columns are called **anal sinuses**. The anal canal is divided into three zones according to the character of the epithelial lining:

FIGURE 17.32. Drawing of the rectum and anal canal. The rectum and anal canal are the terminal portions of the large intestine. They are lined by the colorectal mucosa that possesses a simple columnar epithelium containing mostly goblet cells and numerous anal glands. In the anal canal, the simple columnar epithelium undergoes transition into a stratified columnar (or cuboidal) epithelium and then to a stratified squamous epithelium. This transition occurs in the area referred to as the *anal transitional zone*, which occupies the middle third of the anal canal between the colorectal zone and the squamous zone of the perianal skin.

- **Colorectal zone**, which is found in the upper third of the anal canal and contains simple columnar epithelium with characteristics identical to that in the rectum
- **Anal transitional zone (ATZ)**, which occupies the middle third of the anal canal. It represents a transition between the simple columnar epithelium of the rectal mucosa and the stratified

squamous epithelium of the perianal skin. The ATZ possesses a stratified columnar epithelium interposed between the simple columnar epithelium and the stratified squamous epithelium, which extends to the cutaneous zone of the anal canal (Fig. 17.33 and Plate 17.11, page 690).

FIGURE 17.33. Photomicrographs of the anal canal. **a.** This photomicrograph shows a longitudinal section through the wall of the anal canal. Note the three zones in the anal canal: the squamous zone (*SQZ*) containing stratified squamous epithelium; the anal transitional zone (*ATZ*) containing stratified squamous, stratified cuboidal, or columnar epithelium and simple columnar epithelium of the rectal mucosa; and the colorectal zone (*CRZ*) containing only simple columnar epithelium like the rest of the colon. Note the anal valve that demarcates the transition between the *ATZ* and *SQZ*. The internal anal sphincter is derived from the thickening of the circular layer of the muscularis externa. A small portion of the external anal sphincter is seen subcutaneously. $\times 10$. **b.** This high magnification of the area indicated by the *rectangle* in **a** shows the area of the anal transitional zone. Note the abrupt transition between stratified cuboidal and simple columnar epithelium. The simple columnar epithelium of anal glands extends into the submucosa. These straight, mucus-secreting tubular glands are surrounded by diffuse lymphatic tissue. $\times 200$.

- **Squamous zone**, which is found in the lower third of the anal canal. This zone is lined with stratified squamous epithelium that is continuous with that of the perineal skin.

In the anal canal, **anal glands** extend into the submucosa and even into the muscularis externa. These branched, straight tubular glands secrete mucus onto the anal surface through ducts lined with stratified columnar epithelium. Sometimes, the anal glands are surrounded by diffuse lymphatic tissue. They often lead to the formation of pathologic fistulas (an opening between the anal canal and the perianal skin).

Large apocrine glands, the **circumanal glands**, are found in the skin surrounding the anal orifice. In some animals, the secretion of these glands acts as a sex attractant. Hair follicles and sebaceous glands are also found at this site.

The submucosa of the anal columns contains the terminal ramifications of the superior rectal artery and the rectal venous plexus. Enlargements of these submucosal veins constitute **internal hemorrhoids**, which are related to elevated venous pressure in the portal circulation (**portal hypertension**). There are no teniae coli at the level of the rectum; the longitudinal layer of the muscularis externa forms a uniform sheet. The muscularis mucosae disappears at about the level of the ATZ, where the circular layer of the muscularis externa thickens to form the internal anal sphincter. The external anal sphincter is formed by striated muscle of the pelvic floor.

FOLDER 17.7

CLINICAL CORRELATION: COLORECTAL CANCER

Colorectal cancer (colon or rectal cancer) is one of the major causes of cancer-related deaths in the United States. Almost 100,000 cases of colon cancer and 40,000 cases of rectal cancers are diagnosed in the United States each year, leading to >50,000 deaths. Colorectal cancer commonly occurs between the ages of 60 and 79 years in individuals with a low-fiber and high-fat diet. Most colorectal cancers (about 98%) are adenocarcinomas and begin as small, benign clumps of cells that arise from the glandular epithelium. They form adenomatous polyps, which typically can be detected by a sigmoidoscopy or colonoscopy. In microscopic examinations, the irregular intestinal glands are lined by one or more layers of dark-stained cancer cells with or without mucus production (Fig. F17.7.1).

FIGURE F17.7.1. Macroscopic and microscopic features of adenocarcinoma of the colon. **a.** This photograph shows a surgically resected segment of the colon containing an elevated and centrally ulcerated mass. **b.** This low-magnification photomicrograph shows a section of a tumor that was taken from a free margin of the lesion to show both the typical mucosa of the large intestine (*left*) and the invasive adenocarcinoma (*top left*). The abrupt transition to adenocarcinoma is marked by a *dashed line*. Intestinal glands in the normal part of the epithelium are lined by a single layer of goblet and absorptive cells and occupy the entire thickness of the mucosa. In contrast, tissue invaded by the adenocarcinoma shows an irregular pattern of glands without the presence of mucous production. Cells and their nuclei are intensively stained with hematoxylin (hyperchromatic). Note that muscle fibers derived from the muscularis mucosae travel among colonic glands. $\times 120$. (Both images courtesy of Dr. Thomas C. Smyrk.)

Colon cancers vary in distribution throughout the large intestine. Approximately 38% of cancers are found in the cecum and ascending colon, 38% in the transverse colon, 18% in the descending colon, and 8% in the sigmoid colon. It is now thought that chromosomal instability associated with the stepwise accumulation of mutations in proto-oncogenes and suppressor genes plays a vital role in the development of colorectal cancer. Initially, when epithelial cells lose the **APC tumor suppressor gene**, they develop small polyps. Next, mutation in the **K-Ras proto-oncogene** transforms the polyp into a benign adenoma. These cells further undergo mutation and/or deletion of the **p53 tumor suppressor gene** and **DCC gene**, thus leading to the development of the invasive form of adenocarcinoma. The second pathway leading to the development of colorectal cancer is caused by genetic lesions in **DNA-mismatch repair genes** in the epithelial cell of the colon. Colorectal cancer in its early stage usually produces general symptoms, such as changes in bowel movements, persistent constipation or diarrhea, rectal cramping, or rectal bleeding, which may be an indication of a developing malignancy. With early detection, surgery, radiation, and/or chemotherapy can be effective treatments.

DIGESTIVE SYSTEM II:

ESOPHAGUS AND

GASTROINTESTINAL TRACT

OVERVIEW OF THE ESOPHAGUS AND GASTROINTESTINAL TRACT

- Extending from the **esophagus** to the **anal canal**, the **alimentary canal** is a hollow tube composed of four distinctive layers (from the lumen going outward): **mucosa**, **submucosa**, **muscularis externa**, and **serosa** (when organ is covered by peritoneum) or **adventitia** (when organ is surrounded by connective tissue).
- The **mucosa** is always associated with underlying **lamina propria** (loose connective tissue) and **muscularis mucosae** (smooth muscle layer). The type of mucosal epithelium varies from region to region, as does the thickness of lamina propria and muscularis mucosae.
- The **submucosa** consists of dense irregular connective tissue containing blood and lymphatic vessels, nerve plexus, and occasional glands.
- The **muscularis externa** mixes and propels the content of the canal. It consists of two layers of smooth muscle: The inner layer is circular and the outer layer is longitudinally oriented, with myenteric nerve plexus between them.
- The **serosa** or **adventitia** constitutes the outermost layer of the alimentary canal.

ESOPHAGUS

- The **mucosa** of the esophagus has nonkeratinized stratified squamous epithelium. The **submucosa** contains **esophageal glands proper** that lubricates and protects the mucosal surface. The **muscularis externa** is striated at its upper part and is gradually replaced by a smooth muscle layer in the lower part.

- At the **esophagogastric junction**, nonkeratinized stratified squamous epithelium changes abruptly to simple columnar epithelium of the gastric mucosa. Esophageal cardiac glands are present in the lamina propria at this junction.

STOMACH

- The stomach has three histologic regions: **cardiac** surrounding the esophageal orifice, **pyloric** near the gastroduodenal junction, and **fundic** (anatomically occupied by **fundus** and **body**).
- The **mucosa** of the fundic region forms a number of longitudinal folds (**rugae**). **Surface mucous cells** line the inner surface of the stomach and the **gastric pits**, which are the openings into the branched fundic glands. Surface mucous cells produce an insoluble, viscous, gel-like coat that contains bicarbonate ions to protect against physical and chemical injury of the gastric wall.
- The **fundic glands** produce gastric juice containing four major components: hydrochloric acid (HCl), pepsin (proteolytic enzyme), intrinsic factor (for vitamin B₁₂ absorption), and acid-protective mucus.
- The epithelium of the fundic gland has five major cell types: **mucous neck cells**, which produce soluble and low-alkaline mucus secretions; **parietal cells**, which are responsible for the production of HCl within the lumen of their intracellular canalicular system; **chief cells**, which secrete pepsinogen; **enteroendocrine cells**, which produce small regulatory gastrointestinal and paracrine hormones; and **stem cells**, which are precursors to all fundic gland cells.
- **Mucous neck cells** produce soluble and low-alkaline mucus secretions.
- **Parietal cells** are large cells in the middle of the gland and are responsible for the production of HCl within the lumen of their intracellular canalicular system. They also secrete intrinsic factor.
- **Chief cells** reside at the bottom of the fundic gland and secrete the protein pepsinogen. On contact with the low pH of gastric juice, pepsinogen is converted to pepsin, an active proteolytic enzyme.

- **Enteroendocrine cells** are found at every level of the fundic gland. They produce small regulatory gastrointestinal and paracrine hormones.
- **Stem cells** are precursors to all cells in the fundic gland and are located in the neck region and base of the gland.
- **Cardiac glands** are entirely composed of mucus-secreting cells with occasional interspersed enteroendocrine cells.
- **Pyloric glands** are branched and lined with cells resembling surface mucous cells and occasional enteroendocrine cells.

SMALL INTESTINE

- The **small intestine** is the longest component of the digestive tract and is divided into three anatomic regions: **duodenum** (with mucus-secreting Brunner glands in the submucosa), **jejunum**, and **ileum** (with Peyer patches in the submucosa).
- The mucosa of the small intestine is lined by simple columnar epithelium, and its absorptive surface is increased by the **plicae circulares** and **villi**. Simple tubular intestinal glands (or crypts) extend from the muscularis mucosae and open into the lumen at the base of the villi.
- The intestinal mucosal epithelium has at least five types of cells: **enterocytes**, which are absorptive cells specialized for the transport of substances from the lumen to the blood or lymphatic vessels; **goblet cells**, which are unicellular mucin-secreting glands interspersed among other cells of the intestinal epithelium; **Paneth cells**, which secrete antimicrobial substances (e.g., lysozyme, α -defensins); **enteroendocrine cells**, which produce various paracrine and endocrine gastrointestinal hormones; and **M cells**, which are specialized as antigen-transporting cells and cover lymphatic nodules in the lamina propria.
- Cells of the intestinal mucosal epithelium are found both in the intestinal glands and on the surface of the villi, and their ratio changes depending on the region.
- **Enterocytes** are absorptive cells specialized for the transport of substances from the lumen to the blood or lymphatic vessels.
- **Goblet cells** are unicellular mucin-secreting glands interspersed among other cells of the intestinal epithelium.

- **Paneth cells** are found at the bases of the intestinal glands, and their primary function is to secrete antimicrobial substances (e.g., lysozyme, α -defensins).
- **Enteroendocrine cells** produce various paracrine and endocrine gastrointestinal hormones.
- **M cells** (microfold cells) are specialized as antigen-transporting cells. They cover lymphatic nodules in the lamina propria.
- **Stem cells** are precursors to all cells in the intestinal gland and are located near the base of the gland.
- The **muscularis externa** coordinates contractions of the inner circular and the outer longitudinal layers, producing peristalsis that moves the intestinal contents distally. The autonomic **myenteric plexus** (Auerbach plexus) innervates the muscularis externa.

LARGE INTESTINE

- The **large intestine** is composed of the **cecum** (with its projecting **vermiform appendix**), **colon**, **rectum**, and **anal canal**. The appendix has a large number of lymphatic nodules that extend into the submucosa.
- The mucosa of the large intestine contains numerous straight tubular **intestinal glands** (crypts of Lieberkühn) that extend through the full thickness of this layer. The glands are lined by enterocytes (for resorption of water) and goblet cells (for lubrication).
- The **muscularis externa** of the colon has its outer layer condensed into three prominent longitudinal bands, the **teniae coli**, which lead to the formation of sacculations in the wall of the large intestine (haustra coli).
- In the **anal canal**, the simple columnar epithelium becomes stratified in the **anal transitional zone** (middle third of the anal canal). The lower part of the anal canal is covered by stratified squamous epithelium that is continuous with the perineal skin.

The **esophagus**, the first part of the alimentary canal, represents a muscular tube that conveys food and other substances from the oropharynx to the stomach. The **mucosa** that lines the length of the esophagus has a nonkeratinized stratified squamous epithelium. The underlying **lamina propria** is similar to the lamina propria throughout the alimentary tract; diffuse lymphatic tissue is scattered throughout, and lymphatic nodules are present. The deep layer of the mucosa, the **muscularis mucosae**, is composed of longitudinally organized bundles of smooth muscle fibers. The **submucosa** consists of dense irregular connective tissue that contains the larger blood and lymphatic vessels, nerve fibers, and ganglion cells. The nerve fibers and ganglion cells make up the submucosal plexus (Meissner plexus). The **muscularis externa** consists of two muscle layers, an inner circular layer and an outer longitudinal layer. The upper one-third of muscularis externa consists of striated muscle, a continuation of the muscle of the pharynx. Striated muscle and smooth muscle bundles are mixed and interwoven in the muscularis externa of the middle third of the esophagus. The muscularis externa of the distal one-third consists only of smooth muscle, as in the rest of the digestive tract.

Esophagus, monkey, hematoxylin and eosin (H&E) $\times 60$; inset $\times 400$.

A cross section of the wall of the esophagus is shown here. The **mucosa** (*Muc*) consists of stratified squamous epithelium (*Ep*), **lamina propria** (*LP*), and **muscularis mucosae** (*MM*). The boundary between the epithelium and lamina propria is distinct, although uneven, as a result of the presence of numerous deep connective tissue papillae. The basal layer of the epithelium stains intensely, appearing as a dark band that is relatively conspicuous at low magnification. The intense staining is due, in part, to the cytoplasmic basophilia of the basal cells. The small size of the basal cells results in a high nuclear-cytoplasmic ratio, which further intensifies the hematoxylin staining of this layer.

The **submucosa** consists of dense irregular connective tissue that contains the larger blood vessels and nerves. No glands are seen in the submucosa in this figure, but they are regularly present throughout this layer and are likely to be included in a section of the wall. Whereas the boundary between the epithelium and lamina propria is striking, the boundary between mucosa (*Muc*) and submucosa (*SubM*) is less well marked, although it is readily discernable.

The **muscularis externa** (*ME*) shown here is composed of two muscle layers, an inner circular layer and a much thinner outer longitudinal layer (*L*). In this specimen, the muscularis externa (*ME*) is composed largely of smooth muscle, but it also contains areas of striated muscle. Although the striations are not evident at this low magnification, the more densely stained eosinophilic areas (*asterisks*) prove to be striated muscle when observed at higher magnification. Reference to the *inset*, which is from an area in the *lower half* of the figure, substantiates this identification.

The *inset* shows circularly oriented striated and smooth muscle. The striated muscle stains more intensely with eosin but of greater significance are the distribution and number of nuclei. In the center of the *inset*, numerous elongated and uniformly oriented nuclei are present; this is smooth muscle (*SM*). Above and below, few elongated nuclei are present; moreover, they are largely at the periphery of the bundles. This is striated muscle (*StM*); the cross-striations are just perceptible in some areas. The specimen shown here is from the middle of the esophagus, where both smooth and striated muscles are present. The muscularis externa of the distal third of the esophagus would contain only smooth muscle, whereas that of the proximal third would consist of striated muscle. External to the muscularis externa is the **adventitia** (*Adv*) consisting of dense connective tissue.

Mucosa, esophagus, monkey, H&E $\times 300$.

As in other stratified squamous epithelia, new cells are produced in the basal layer, from which they move to the surface. During this migration, the shape and orientation of the cells change. This change in cell shape and orientation is also reflected in the appearance of the nuclei. In the deeper layers, the nuclei are spherical; in the more superficial layers, the nuclei are elongated and oriented parallel to the surface. Those nuclei can be seen throughout the epithelial layer, particularly the surface cells, indicating that the epithelium is not keratinized. In some instances, the epithelium of the upper regions of the esophagus may be parakeratinized or, more rarely, keratinized.

As shown in this figure, the **lamina propria** (*LP*) is a very cellular, loose connective tissue containing many lymphocytes (*Lym*), small blood vessels, and lymphatic vessels (*LV*). The deepest part of the mucosa is the muscularis mucosae (*MM*). A layer of smooth muscle defines the boundary between mucosa and submucosa. The nuclei of the smooth muscle cells of the muscularis mucosae appear spherical because the cells have been cut in cross section.

PLATE 17.2 ■ ESOPHAGUS AND STOMACH, CARDIAC REGION

The **esophagogastric junction** marks a change in function from that of a conduit (esophagus) to that of a digestive organ (stomach). The epithelium of the mucosa changes from stratified squamous (protective) to a simple columnar secretory epithelium that forms mucosal glands that secrete mucinogen, digestive enzymes, and hydrochloric acid. The very cellular lamina propria is rich in diffuse lymphatic tissue, emphasizing the role of this layer in the immune system.

Esophagogastric junction, esophagus-stomach, human, hematoxylin and eosin (H&E) $\times 100$.

The junction between the esophagus and stomach is shown here. The esophagus is on the *right*, and the cardiac region of the stomach is on the *left*. The *large rectangle* marks a representative area of the cardiac mucosa seen at higher magnification in the next figure; the *smaller rectangle* shows part of the junction examined at higher magnification in the figure on the *right*.

As noted in Plate 17.1 (page 670), the esophagus is lined by **stratified squamous epithelium** (*Ep*) that is indented on its undersurface by deep connective tissue papillae. When these are sectioned obliquely (as five of them have been), they appear as islands of connective tissue within the thick epithelium. Under the epithelium are the lamina propria, often infiltrated by lymphocytes (*L*), and the muscularis mucosae (*MM*). At the junction between the esophagus and the stomach (see also *middle right figure*), the stratified squamous epithelium of the esophagus ends abruptly, and the **simple columnar epithelium** of the stomach surface begins.

The surface of the stomach contains numerous and relatively deep depressions called gastric pits (*P*), or foveolae, that are formed by epithelium similar to, and continuous with, that of the surface. **Glands** (*GL*) open into the bottom of the pits; they are cardiac glands. The entire gastric mucosa contains glands. There are three types of gastric glands: cardiac, fundic, and pyloric. Cardiac glands are in the immediate vicinity of the opening of the esophagus, pyloric glands are in the funnel-shaped portion of the stomach that leads to the duodenum, and fundic glands are throughout the remainder of the stomach.

Cardiac region, stomach, human, H&E $\times 260$.

The **cardiac glands** and gastric pits (*P*) seen in the *top figure* are surrounded by a very cellular lamina propria. At this higher magnification, it can be seen that many cells of the lamina propria are lymphocytes and other cells of the immune system. Large numbers of lymphocytes (*L*) may be localized between the smooth muscle cells of the muscularis mucosae (*MM*), and thus, the muscularis mucosae in these locations appears to be disrupted. Also, a few intraepithelial lymphocytes are indicated by the *arrows*.

The cardiac glands (*GL*) are limited to a narrow region around the cardiac orifice. They empty their secretions via ducts (*D*) into the bottom of the gastric pits. They are not sharply delineated from the fundic region of the stomach that contains parietal and chief cells. Thus, at the boundary, occasional parietal cells are seen in the cardiac glands.

In certain animals (e.g., ruminants and pigs), the anatomy and histology of the stomach are different. In these, at least one part of the stomach is lined with stratified squamous epithelium.

Esophagogastric junction, esophagus-stomach, human, H&E $\times 440$.

The columnar cells of the stomach surface and **gastric pits** (*P*) produce mucus. Each surface and pit cell contains a mucous cup in its apical cytoplasm, thereby forming a glandular sheet of cells named **surface mucous cells** (*SMC*). The content of the mucous cup is usually lost during the preparation of the tissue, and thus, the apical cup portion of the cells appears empty in routine H&E paraffin sections such as the ones shown in this plate. Note the appearance of a loose connective tissue of the lamina propria (*LP*) that separates gastric pits (*P*).

Cardiac region, stomach, human, H&E $\times 440$.

The epithelium of the cardiac glands (*GL*) also consists of **mucous gland cells** (*MGC*). As seen in the photomicrograph, the nucleus of the gland cell is typically flattened; one side is adjacent to the base of the cell, whereas the other side is adjacent to the pale-staining cytoplasm. Again, mucus is lost during processing of the tissue, and this accounts for the pale-staining appearance of the cytoplasm. Although the **cardiac glands** are mostly unbranched, some branching is occasionally seen. The glands empty their secretions via ducts (*D*) into the bottom of the gastric pits. The cells forming the ducts are columnar, and the cytoplasm stains well with eosin. This makes it easy to distinguish the duct cells from mucous gland cells. Among the cells forming the duct portion of the gland are those that undergo mitotic division to replace both surface mucous and gland cells. Cardiac glands also contain enteroendocrine cells, but they are difficult to identify in routine H&E paraffin sections. Interrupted bundles of the muscularis mucosae (*MM*) smooth muscles are visible in close proximity to the gland.

D, ducts of cardiac glands
Ep, epithelium
GL, cardiac glands
L, lymphocytes
LP, lamina propria
MGC, mucous gland cells
MM, muscularis mucosae

P, gastric pits
 SMC, surface mucous cells
 arrows, intraepithelial lymphocytes

PLATE 17.3 ■ STOMACH I

Histologically, the stomach is divided into three regions: The **cardia**, nearest the esophagus, contains cardiac glands that secrete primarily mucinogen; the **pylorus**, proximal to the gastrointestinal (pyloric) sphincter, contains pyloric glands that secrete a mucinogen that resembles that of the *surface mucous cells*; and the **fundus**, the body or largest part of the stomach, contains the fundic (gastric) glands. Fundic glands contain **parietal (oxyntic) cells**, acidophilic cells that secrete 0.16 N HCl, and **chief cells**, basophilic cells that contain acidophilic secretory granules in the apical cytoplasm. The granules contain mostly pepsinogen. The glands in all parts of the stomach contain **enteroendocrine cells**.

Stomach, human, hematoxylin and eosin (H&E) ×40.

As with other parts of the gastrointestinal tract, the wall of the stomach consists of four layers: mucosa (*Muc*), submucosa (*SubM*), muscularis externa (*ME*), and serosa. The **mucosa** is the innermost layer and reveals three distinctive regions (*arrows*). The most superficial region contains the gastric pits; the middle region contains the necks of the glands, which tend to stain with eosin; and the deepest part of the mucosa stains most heavily with hematoxylin. The cell types of the deep (hematoxylin-staining) portion of the fundic mucosa are considered in the *bottom figure*. The cells of all three regions and their staining characteristics are considered in Plate 17.4 (page 676).

The inner surface of the empty stomach is thrown into long folds referred to as **rugae**. One such cross-sectioned fold is shown here. It consists of mucosa and submucosa (*asterisks*). The rugae are not permanent folds; they disappear when the stomach wall is stretched, as in the distended stomach. Also evident are mamillated areas (*M*), which are slight elevations of the mucosa that resemble cobblestones. The mamillated areas consist only of mucosa without submucosa.

The **submucosa** and **muscularis externa** stain predominantly with eosin; the muscularis externa appears darker. The smooth muscle of the muscularis externa gives an appearance of being homogeneous and uniformly solid. In contrast, the submucosa, being connective tissue, may contain areas with adipocytes and contains numerous profiles of blood vessels (*BV*). The **serosa** is so thin that it is not evident as a discrete layer at this low magnification.

Fundocardiac junction, stomach, human, H&E ×240.

This figure and the next figure show the **fundocardiac junction** between the cardiac and fundic regions of the stomach. This junction can be identified histologically on the basis of the structure of the mucosa. The

gastric pits (*P*), some of which are seen opening at the surface (*arrows*), are similar in both regions, but the glands are different. They are composed mostly of mucus-secreting cells and occasional enteroendocrine cells. The boundary between cardiac glands (*CG*) and fundic glands (*FG*) is marked by the *dashed line* in each figure.

The full thickness of the gastric mucosa is shown here, as indicated by the presence of the muscularis mucosae (*MM*) deep into the fundic glands. The muscularis mucosae below the cardiac glands is obscured by a large infiltration of lymphocytes forming a lymphatic nodule (*LN*).

Fundocardiac junction, stomach, human, H&E $\times 640$.

This figure provides a comparison between the cardiac and fundic glands at higher magnification. The **cardiac glands** (*CG*) consist of mucous gland cells arranged as a simple columnar epithelium; the nucleus is in the most basal part of the cell and is somewhat flattened. The cytoplasm appears as a faint network of lightly stained material. The lumina (*L*) of the cardiac glands are relatively wide. On the other hand, the **fundic glands** (*FG*) (*left of the dashed line*) are small, and a lumen is seen readily only in certain fortuitously sectioned glands. As a consequence, most of the glands appear to be cords of cells. Because this is a deep region of the fundic mucosa, most of the cells are chief cells. The basal portion of the chief cell contains the nucleus and extensive rough endoplasmic reticulum (rER), which accounts for its basophilia. The apical cytoplasm, normally occupied by secretory granules that were lost during the preparation of the tissue, stains poorly. Interspersed among the chief cells are parietal cells (*PC*). These cells typically have a round nucleus that is surrounded by eosinophilic cytoplasm. Among the cells of the lamina propria are some with pale elongated nuclei. These are smooth muscle cells (*SM*) that extend into the lamina propria from the muscularis mucosae.

BV, blood vessels

CG, cardiac glands

FG, fundic glands

PLATE 17.4 ■ STOMACH II

The epithelial lining of the alimentary canal is a regularly renewing epithelium; each portion has a characteristic turnover time and stem cell location. In the stomach, stem cells are located in the isthmus (above) the mucous neck cells. Cells that migrate upward to form the mucous cells of the gastric pit and surface have a turnover time of 3–5 days; cells that migrate downward to form the parietal cells, chief cells, and enteroendocrine cells of the glands have a turnover time of about 1 year. Another niche of stem cells is located in the base of the gland.

Fundic glands, stomach, monkey, hematoxylin and eosin (H&E) $\times 320$.

This figure shows an area of the **fundic mucosa** that includes the bottom of the gastric pits and the neck and deeper part of the fundic glands. It includes the areas marked by the *arrows* in the *top left* of Plate 17.3 (page 674). The **surface mucous cells (SMC)** of the gastric pits are readily identified because the mucous cup in the apical pole of each cell has an empty, washed-out appearance. Just below the gastric pits are the necks (*N*) of the fundic glands, in which **mucous neck cells (MNC)** and **parietal cells (PC)** can be identified. The mucous neck cells produce a mucous secretion that differs from that produced by the surface mucous cells. As seen here, the mucous neck cells display a cytoplasm that is lightly stained; there are no cytoplasmic areas that stain intensely.

Parietal cells are distinctive primarily because of the pronounced eosinophilic staining of their cytoplasm. Their nucleus is round, like that of the chief cell, but tends to be located closer to the basal lamina of the epithelium than to the lumen of the gland because of the pear-like shape of the parietal cell.

This figure also reveals the significant characteristics of **chief cells (CC)**, namely, the round nucleus in a basal location; the ergastoplasm, deeply stained with hematoxylin (particularly evident in some of the chief cells where the nucleus has not been included in the plane of section); and the apical, slightly eosinophilic cytoplasm (normally occupied by the secretory granules).

Submucosa, stomach, monkey, H&E $\times 320$.

This figure shows the bottom of the stomach mucosa, the **submucosa (SubM)**, and part of the muscularis externa (*ME*). The muscularis mucosae (*MM*) is the deepest part of the mucosa. It consists of smooth muscle cells arranged

in at least two layers. As seen in the photomicrograph, the smooth muscle cells immediately adjacent to the submucosa have been sectioned longitudinally and display elongated nuclear profiles. Just above this layer, the smooth muscle cells have been cut in cross section and display rounded nuclear profiles.

The submucosa consists of connective tissue of moderate density. Present in the submucosa are adipocytes (*A*), blood vessels (*BV*), and a group of ganglion cells (*GC*). These particular cells belong to the **submucosal plexus** (*Meissner plexus* [*MP*]). The *inset* shows some of the ganglion cells (*GC*) at higher magnification. These are the large cell bodies of the enteric neurons. Each cell body is surrounded by satellite cells intimately apposed to the neuron cell body. The *arrowheads* point to the nuclei of the satellite cells.

Gastric glands, stomach, silver stain $\times 160$.

Enteroendocrine cells constitute a class of cells that can be displayed with special histochemical or silver-staining methods but that are not readily evident in H&E sections. The distribution of cells demonstrable with special silver-staining procedures is shown here (*arrows*). Because of the staining procedure, these cells are properly designated as **argentaffin cells**. The surface mucous cells (*SMC*) in the section mark the bottom of the gastric pits and establish the fact that the necks of the fundic glands are represented in the section. The argentaffin cells appear *black* in this specimen. The relatively low magnification permits the viewer to assess the frequency of distribution of these cells.

Gastric glands, stomach, silver stain $\times 640$.

At higher magnification, the **argentaffin cells** (*arrows*) are almost totally blackened by the silver staining, although a faint nucleus can be seen in some cells. The silver stains the secretory product lost during the preparation of routine sections, and accordingly, in H&E-stained paraffin sections, the argentaffin cell appears as a clear cell. The special silver staining in this figure and in the figure on the *left* shows that many of the argentaffin cells tend to be near the basal lamina and away from the lumen of the gland.

A, adipocytes
 BV, blood vessels
 CC, chief cells
 GC, ganglion cells
 ME, muscularis externa
 MM, muscularis mucosae
 MNC, mucous neck cells
 MP, Meissner plexus

N, neck of fundic glands

PC, parietal cells

SMC, surface mucous cells

SubM, submucosa

arrows, argentaffin cells

arrowheads, nuclei of satellite cells

PLATE 17.5 ■ GASTRODUODENAL JUNCTION

The gastroduodenal junction marks the entry into the absorptive portion of the alimentary canal. Thickening of the circular layer of muscularis externa at this site forms the pyloric sphincter that regulates the passage of chyme from the stomach to the intestine. The mucous secretion of the pyloric glands helps to neutralize the chyme as it enters the intestine.

Gastroduodenal junction, stomach-duodenum, monkey, hematoxylin and eosin (H&E) $\times 40$.

The gastroduodenal junction between the stomach and the duodenum is shown here. Most of the mucosa in the micrograph belongs to the stomach; it is the **pyloric mucosa** (*PMuc*). The pyloric sphincter appears as a thickened region of smooth muscle below the pyloric mucosa. On the *far right* is the **duodenal mucosa**, the first part of the intestinal mucosa (*IMuc*). The area marked by the *rectangle* is shown at higher magnification in the next figure. It provides a comparison of the two mucosal regions and also shows the submucosal glands (Brunner glands).

The submucosa of the duodenum contains **submucosal (Brunner) glands**. These are below the muscularis mucosae; therefore, this structure serves as a useful landmark in identifying the glands. In the stomach, the **muscularis mucosae** is readily identified as narrow bands of muscular tissue (*MM*). It can be followed toward the right into the duodenum but is then interrupted in the region between the two *asterisks*.

This figure also shows the thickened region of the gastric muscularis externa, where the stomach ends. This is the pyloric sphincter (*PS*). Its thickness, mostly due to the amplification of the circular layer of smooth muscle of the muscularis externa, can be appreciated by comparison with the muscularis externa in the duodenum (*ME*).

Gastroduodenal junction, stomach-duodenum, monkey, H&E $\times 120$.

Examination of this region at higher magnification reveals that in addition to intestinal glands (*IGI*) within the mucosa, there are glands within the duodenal submucosa. These are **submucosal (Brunner) glands** (*BGI*). Some of the glandular elements (*arrows*) can be seen to pass from the submucosa to the mucosa, thereby interrupting the **muscularis mucosae** (*MM*). The submucosal glands empty their secretions into the duodenal lumen by means of ducts (*D*). In contrast, the pyloric glands (*PGI*) are relatively straight for most of their length but are coiled in the deepest part of the mucosa and are sometimes branched. They are restricted to the mucosa and empty into deep gastric pits. The boundary between the pits and glands is, however, hard to ascertain in H&E sections.

With respect to the mucosal aspects of gastroduodenal histology, as mentioned earlier, the glands of the stomach empty into gastric pits. These are depressions; accordingly, when the pits are sectioned in a plane that is oblique or at right angles to the long axis of the pit, as in this figure, the pits can be recognized as being depressions because they are surrounded by lamina propria. In contrast, the inner surface of the small intestine has villi (*V*). These are projections into the lumen of slightly varying height. When the villus is cross-sectioned or obliquely sectioned, it is surrounded by space of the lumen, as is one of the villi shown here. In addition, the villi have lamina propria (*LP*) in their core.

Gastroduodenal junction, stomach-duodenum, monkey, H&E $\times 640$.

The *rectangular area* in the next figure is considered at higher magnification here. It shows how the epithelium of the stomach differs from that of the intestine. In both cases, the epithelium is simple columnar, and the underlying lamina propria (*LP*) is highly cellular because of the presence of large numbers of lymphocytes. The boundary between gastric and duodenal epithelium is marked by the *arrow*. On the stomach side of the *arrow*, the epithelium consists of **surface mucous cells** (*SMC*). The surface cells contain an apical cup of mucous material that typically appears empty in an H&E-stained paraffin section. In contrast, the **absorptive cells** (*AC*) of the intestine do not possess mucus in their cytoplasm. Although goblet cells are found in the intestinal epithelium and are scattered among the absorptive cells, they do not form a complete mucous sheet. The intestinal absorptive cells also possess a striated border, which is shown in Plate 17.7 (page 682).

PLATE 17.6 ■ DUODENUM

The small intestine is the principal site for the digestion of food and absorption of the products of digestion. It is the longest component of the alimentary canal, measuring over 6 m, and is divided into three segments: **duodenum** (~25 cm), **jejunum** (~2.5 m), and **ileum** (~3.5 m). The first portion, the duodenum, receives a partially digested bolus of food (chyme) from the stomach as well as secretions from the stomach, pancreas, liver, and gallbladder that contain digestive enzymes, enzyme precursors, and other products that aid digestion and absorption.

The small intestine is characterized by **plicae circulares**, permanent transverse folds that contain a core of submucosa, and **villi**, finger- and leaf-like projections of the mucosa that extend into the lumen. Microvilli, multiple finger-like extensions of the apical surface of each intestinal epithelial cell (enterocyte), further increase the surface for absorption of metabolites.

Mucosal glands extend into the lamina propria. They contain the stem cells and developing cells that will ultimately migrate to the surface of the villi. In the duodenum, **submucosal glands** (Brunner glands) secrete an alkaline mucus that helps neutralize the acidic chyme. Enterocytes not only absorb metabolites digested in the intestinal lumen but also synthesize enzymes inserted into the membrane of the microvilli for terminal digestion of disaccharides and dipeptides.

Duodenum, monkey, hematoxylin and eosin (H&E) ×120.

This figure shows a segment of the duodenal wall. As in the stomach, the layers of the wall, in order from the lumen, are the **mucosa** (*Muc*), the **submucosa** (*SubM*), the **muscularis externa** (*ME*), and the **serosa** (*S*). Both longitudinal (*L*) and circular (*C*) layers of the muscularis externa can be distinguished. Although plicae circulares are found in the wall of the small intestine, including the duodenum, none is included in this photomicrograph.

A distinctive feature of the intestinal mucosa is the presence of finger- and leaf-like projections into the intestinal lumen, called **villi**. Most of the villi (*V*) shown here display profiles that correspond to their description as finger like. One villus, however, displays the form of a leaf-like villus (*asterisk*). The *dashed line* marks the boundary between the villi and the **intestinal glands** (also called *crypts of Lieberkühn*). The latter extend as far as the muscularis mucosae (*MM*).

Under the mucosa is the submucosa, containing the **Brunner glands** (*BGI*). These are branched tubular or branched tubuloalveolar glands whose secretory components, shown at higher magnification in the next figure, consist of columnar epithelium. A duct (*D*) through which the glands open into the lumen of the duodenum is shown here and, at higher magnification, in the next figure, where it is marked by an *arrow*.

Mucosa, duodenum, monkey, H&E ×240.

The histologic features of the duodenal mucosa are shown at higher magnification here. Two kinds of cells can be recognized in the epithelial layer that forms the surface of the villus: **enterocytes (absorptive cells)** and **goblet cells (GC)**. Most of the cells are absorptive cells. They have a striated border that will be seen at higher magnification in Plate 17.7 (page 682); their elongated nuclei are located in the basal half of the cell. Goblet cells are readily identified by the presence of the apical mucous cup, which appears empty. Most of the dark round nuclei also seen in the epithelial layer covering the villi belong to lymphocytes.

The **lamina propria (LP)** makes up the core of the villus. It contains large numbers of round cells whose individual identity cannot be ascertained at this magnification. Note, however, that these are mostly lymphocytes (and other cells of the immune system), which accounts for the designation of the lamina propria as diffuse lymphatic tissue. The lamina propria surrounding the intestinal glands (**IGI**) similarly consists largely of lymphocytes and related cells. The lamina propria also contains components of loose connective tissue and isolated smooth muscle cells.

The **intestinal glands (IGI)** are relatively straight and tend to be dilated at their base. The bases of the intestinal crypts contain the stem cells from which all of the other cells of the intestinal epithelium arise. They also contain Paneth cells. These cells possess eosinophilic granules in their apical cytoplasm. The granules contain lysozyme, a bacteriolytic enzyme thought to play a role in regulating intestinal microbial flora. The main cell type in the intestinal crypt is a relatively undifferentiated columnar cell. These cells are shorter than the enterocytes of the villus surface; they usually undergo two mitoses before they differentiate into absorptive cells or goblet cells. Also present in the intestinal crypts are some mature goblet cells and enteroendocrine cells.

 SubM, submucosa
 V, villi
 arrow, duct of Brunner gland
 asterisk, leaf-like villus
 dashed line, top figure, boundary between the base of villi and intestinal glands

The jejunum is the principal site of absorption of nutrients in the small intestine. The villi are more finger like than leaf like and are

covered largely with absorptive columnar epithelial cells (enterocytes), although goblet cells and enteroendocrine cells are also present. The stem cells for all of these cells and the Paneth cells that secrete the antibacterial enzyme lysozyme are found deep into the intestinal gland. Replicating cells line the lower half of the gland.

Jejunum, monkey, hematoxylin and eosin (H&E) $\times 22$.

This is a longitudinal section of the jejunum showing the permanent circular folds of the small intestine, the **plicae circulares** (*PC*). These folds or ridges are mostly arranged with their long axis at roughly right angles to the longitudinal axis of the intestine; therefore, the plicae circulares shown here are cut in cross section. The plicae circulares consist of **mucosa** (*Muc*) as well as **submucosa** (*SubM*). The broad band of tissue external to the submucosa is the **muscularis externa** (*ME*) and is not included in the plicae. (The serosa cannot be distinguished at this magnification.) Most of the **villi** (*V*) in this specimen have been cut longitudinally, thereby revealing their full length as well as the fact that some are slightly shorter than others. The shortening is considered to be due to the contraction of smooth muscle cells in the villi. Also seen here are the lacteals (*L*), which, in most of the villi, are dilated. Lacteals are lymphatic capillaries that begin in the villi and carry certain absorbed dietary lipids and proteins from the villi to the larger lymphatic vessels of the submucosa.

Plica circularis, jejunum, monkey, H&E $\times 60$.

Part of the plica circularis marked by the *bracket* in the previous figure is shown at higher magnification. Note the muscularis mucosae (*MM*), the **intestinal glands** (*GI*), and the **villi** (*V*). The boundary between the glands and the villi is marked by the *dashed line*. Some of the glands are cut longitudinally; some are cut in cross section; most of the villi have been cut longitudinally. In conceptualizing the mucosal structure of the small intestine, it is important to recognize that the glands are epithelial depressions that project into the wall of the intestine, whereas the villi are projections that extend into the lumen. The glands are surrounded by cells of the lamina propria; the villi are surrounded by the space of the intestinal lumen. The lamina propria with its lacteal (*L*) occupies a central position in the villus; the lumen occupies the central position of the gland. Also note that the lumen of the gland tends to be dilated at its base. Studies of enzymatically isolated preparations of mucosa show that the bases of the glands are often divided into two or three finger-like extensions resting on the muscularis mucosae. At this low magnification, the serosa (*S*) and two muscle layers of the muscularis externa (*ME*) are difficult to discern.

Intestinal villi, jejunum, monkey, H&E $\times 500$.

This figure shows portions of two adjacent villi at higher magnification. The epithelium consists chiefly of **enterocytes**. These are columnar absorptive cells that typically exhibit a **striated border** (*SB*), the light microscopic representation of the microvilli on the apical surface of each enterocyte. The dark band at the base of the striated border is due to the terminal web of the cell, a layer of actin filaments that extends across the apex of the cell to which the actin filaments of the cores of the microvilli attach. The nuclei of the enterocytes have essentially the same shape, orientation, and staining characteristics. Even if the cytoplasmic boundaries were not evident, the nuclei would be an indication of the columnar shape and orientation of the cells. The enterocytes rest on a basal lamina not evident in H&E-stained paraffin sections. The eosinophilic band (*arrow*) at the base of the cell layer, where one would expect a basement membrane, actually consists of flat lateral cytoplasmic processes from the enterocytes. These processes partially delimit the basal-lateral intercellular spaces (*asterisks*) that are dilated, as can be seen here, during active transport of absorbed substrates.

The epithelial cells with an expanded apical cytoplasm in the form of a cup are **goblet cells** (*GC*). In this specimen, the nucleus of almost every goblet cell is just at the base of the cup, and a thin cytoplasmic strand (not always evident) extends to the level of the basement membrane. The scattered round nuclei within the epithelium belong to lymphocytes (*Ly*).

The **lamina propria** (*LP*) and the lacteal (*L*) are located beneath the intestinal epithelium. The cells forming the lacteal are simple squamous epithelium (endothelium). Two nuclei of these cells (*EC*) appear to be exposed to the lumen of the lacteal; another elongated nucleus slightly removed from the lumen belongs to a smooth muscle cell (*M*) accompanying the lacteals.

dashed line, boundary between villi and intestinal glands

PLATE 17.8 ■ ILEUM

The ileum is the principal site of water and electrolyte reabsorption in the small intestine. It has essentially the same histologic features as the jejunum, with some characteristic differences. Villi in the ileum are more frequently leaf like, and lymphatic tissue in the lamina propria is organized into numerous small and large nodules found on the antimesenteric side of the ileum. The nodules fuse to form large accumulations of lymphatic tissue called **Peyer patches**.

The surface epithelium of the small intestine renews itself every 5 or 6 days. The stem cells are restricted to the bottom portion of the mucosal gland, and the zone of cell replication is restricted to the lower half of the gland. The cells migrate onto the villus and are lost from its tip. All of the epithelial cells, absorptive cells, and goblet cells, as well as enteroendocrine cells and Paneth cells, derive from the same stem cell population, but enteroendocrine cells migrate slowly, and Paneth cells do not migrate.

Ileum, monkey, hematoxylin and eosin (H&E) $\times 20$.

For the purposes of orientation, the **submucosa** (*SM*) and **muscularis externa** (*ME*) have been marked in the cross section through the ileum shown here. Just internal to the submucosa is the mucosa; external to the muscularis externa is the serosa. The mucosa reveals several longitudinally sectioned villi (*V*), which have been labeled, and other unlabeled villi, which can be identified easily on the basis of their appearance as islands of tissue completely surrounded by the space of the lumen. They are, of course, not islands because this appearance is due to the plane of section that slices completely through some of the villi obliquely or in cross section, thereby isolating them from their base. Below the villi are the intestinal glands, many of which are obliquely or transversely sectioned and can be readily identified, as was done in the preceding plates, because they are totally surrounded by lamina propria.

There are about 8-10 projections of tissue into the intestinal lumen that are substantially larger than the villi. These are the plicae circulares. As noted earlier, plicae generally have circular orientation, but they may travel in a longitudinal direction for short distances and may branch. In addition, even if all the plicae are arranged in a circular manner, if the section is somewhat oblique, the plicae will be cut at an angle, as appears to be the case with several plicae in this figure. One of the distinctive features of the small intestine is the presence of **single and aggregated lymph nodules** in the intestinal wall. Isolated nodules of lymphatic tissue are common in the proximal end of the intestinal canal. As one proceeds distally through the intestines, however, the lymph nodules occur in increasingly larger numbers. In the ileum, large aggregates of lymph nodules are regularly seen; they are referred to as **Peyer patches**. Several

lymphatic nodules (*LN*) forming a Peyer patch are shown in this figure. The nodules are located partly within the mucosa of the ileum and extend into the submucosa. Although not evident in the figure, the nodules are characteristically located opposite to where the mesentery connects to the intestinal tube.

Plica circularis, ileum, monkey, H&E $\times 40$.

Sometimes, in a cross section through the intestine, a plica displays a clear cross-sectional profile such as that shown here. Note, again, that the **submucosa** (*SM*) constitutes from the core of the plica circularis into the muscularis externa (*ME*). Although many of the **villi** in this figure present profiles (*V*) that would be expected if the villus were a finger-like projection, others clearly do not. In particular, one villus (marked with three *asterisks*) shows the broad profile of a longitudinally sectioned leaf-like villus. If this same villus were cut at a right angle to the plane shown here, it would appear as a finger-like villus.

Aggregated lymph nodule, ileum, monkey, H&E $\times 100$; inset $\times 200$.

Part of an aggregated **lymph nodule** and part of the overlying epithelium are shown here at higher magnification. The lymphocytes and related cells are so numerous that they virtually obscure the cells of the muscularis mucosae. Their location, however, can be estimated as being near the presumptive label (*MM??*), inasmuch as the muscularis mucosae is ordinarily adjacent to the base of the intestinal glands (*GI*). Moreover, on examination of this area at higher magnification (*inset*), groups of smooth muscle cells (*MM*) can be seen separated by numerous lymphocytes close to the intestinal glands (*GI*). Clearly, the lymphocytes of the nodule are on both sides of the muscularis mucosae and thus within both the mucosa and the submucosa.

In places, the lymph nodule is covered by the intestinal epithelium. Whereas the nature of the epithelium cannot be appreciated fully in the light microscope, electron micrographs (both scanning and transmission) have shown that among the epithelial cells are special cells, designated M cells, that sample the intestinal content (for antigen) and transfer this antigen to the dendritic cells and lymphocytes in the epithelial layer.

GI, intestinal glands
LN, lymphatic nodules
ME, muscularis externa
MM, muscularis mucosae
MM??, presumptive location of muscularis mucosae
SM, submucosa
V, villi
asterisks, leaf-like villus

PLATE 17.9 ■ COLON

The principal functions of the **colon** are reabsorption of electrolytes and water and elimination of undigested food and other waste. The mucosa has a smooth surface; neither plicae circulares nor villi are present. Numerous **simple glands** (crypts of Lieberkühn) extend through the full thickness of the mucosa. The glands, as well as the surface, are lined with a simple columnar epithelium that contains goblet cells, absorptive cells, and enteroendocrine cells but does not normally contain Paneth cells. Here, too, stem cells are restricted to the bottom portions of the glands (crypts), and the normal zone of replication extends about one-third of the height of the crypt.

Colon, monkey, hematoxylin and eosin (H&E) $\times 30$.

A cross section through the large intestine is shown at low magnification. It shows the four layers that make up the wall of the colon: the **mucosa** (*Muc*), **submucosa** (*SubM*), **muscularis externa** (*ME*), and **serosa** (*S*). Although these layers are the same as those in the small intestine, several differences should be noted. The large intestine has no villi, nor does it have plicae circulares. On the other hand, the muscularis externa is arranged in a distinctive manner, and this is evident in the photomicrograph. The longitudinal layer (*ME[l]*) is substantially thinner than the circular layer (*ME[c]*), except in three locations where the longitudinal layer of smooth muscle is present as a thick band. One of these thick bands, called a **tenia coli** (*TC*), is shown in this figure. Because the colon is cross-sectioned, the tenia coli is also cross-sectioned. The three teniae coli extend along the length of the large intestine as far as, but not into, the rectum.

The submucosa consists of a rather dense irregular connective tissue. It contains the larger blood vessels (*BV*) and areas of adipose tissue (see *A* in the next figure).

Mucosa, colon, monkey, H&E $\times 140$.

The mucosa (*Muc*), shown at higher magnification, contains straight, unbranched, **tubular glands** (crypts of Lieberkühn) that extend to the muscularis mucosae (*MM*). The *arrows* identify the openings of some of the glands at the intestinal surface. Generally, the lumen of the glands is narrow, except in the deepest part of the gland, where it is often slightly dilated (*asterisks*, *lower left figure*). Between the glands (*Gl*) is a **lamina propria** (*LP*) that contains considerable numbers of lymphocytes and other cells of the immune system. Note the submucosa (*SubM*) containing dense irregular connective tissue with areas occupied by adipose tissue (*A*). Two *rectangles* mark areas of the mucosa that are examined at higher magnification in the next figures.

Lamina propria, colon, monkey, H&E $\times 525$.

This figure reveals the **muscularis mucosae** (*MM*) and the cells in the **lamina propria** (*LP*), many of which can be recognized as lymphocytes and plasma cells. The smooth muscle cells of the muscularis mucosae are arranged in two layers. Note that the smooth muscle cells marked by the *arrowheads* show rounded nuclei; however, other smooth muscle cells appear as more or less rounded eosinophilic areas. These smooth muscle cells have been cut in cross section. Just above these cross-sectioned smooth muscle cells are others that have been cut longitudinally; they display elongated nuclei and elongated strands of eosinophilic cytoplasm. Also note the epithelial lining of the lower half of the intestinal glands, the lumens of which are marked by *asterisks*. The majority of the cells are goblet cells (*GC*); however, there are several visible mitotic figures (*M*). These represent dividing intermediate cells (stem cells) that are capable of cell division and differentiation into either absorptive or goblet cells.

Intestinal glands, colon, monkey, H&E $\times 525$.

The cells that line the surface of the colon and the glands are principally **absorptive cells** (*AC*) and **goblet cells** (*GC*). The absorptive cells have a thin striated border that is evident where the *arrows* show the opening of the glands. Interspersed among the absorptive cells are the goblet cells (*GC*). The number of absorptive cells decreases deeper into the gland, whereas the goblet cells increase in number. Other cells in the gland are enteroendocrine cells, not easily identified in routine H&E-stained paraffin sections, and, in the deep part of the gland, undifferentiated cells of the replicative zone, derived from the stem cells in the base of the crypt. The undifferentiated cells are readily identified if they are undergoing division, by virtue of the mitotic figures (*M*) they display (see figure on the *left*).

PLATE 17.10 ■ APPENDIX

The appendix (vermiform appendix) is typically described as a worm- or finger-like structure [*L. vermis, worm; forma, form*]. It arises from the cecum (the first segment of the large intestine; the others, in order, are the ascending, transverse, and descending colons; the sigmoid colon; the rectum; and the anal canal) that forms a blind-ending tube ranging from 2.5 cm to as much as 13 cm in length (average length of ~8 cm). Because it is a blind-ended pouch, intestinal contents may be trapped or sequestered in the appendix, often leading to inflammation and infection. In infants and children, it is both relatively and absolutely longer than in adults and contains numerous **lymphatic nodules**, suggesting that it has an immunologic role. Recent evidence indicates that it (and the cecum and terminal ileum) may be the “bursa equivalent” in mammals, that is, the portion of the immature immune system in which potential B lymphocytes achieve immunocompetence (equivalent to the *bursa of Fabricius* in birds).

The wall of the appendix is much like that of the small intestine, having a complete longitudinal layer of muscularis externa, but it lacks both plicae circulares and villi. Thus, the mucosa is similar to that of the colon, having simple glands. Even this resemblance is often obliterated, however, by the large number and size of the lymphatic nodules that usually fuse and extend into the submucosa. In later life, the amount of lymphatic tissue in the appendix regresses, and there is a consequent reduction in size. In many adults, the normal structure is lost, and the appendage is filled with fibrous scar tissue.

Appendix, human, hematoxylin and eosin (H&E) $\times 25$.

Cross section of an appendix from a preadolescent showing the various structures composing its wall. The lumen (*L*), mucosa (*Muc*), submucosa (*Subm*), muscularis externa (*ME*), and serosa (*S*) are identified.

Appendix, human, H&E $\times 80$; inset $\times 200$.

This micrograph is a higher magnification of the *boxed area* in the previous figure. It reveals the straight tubular **glands** (*GI*) that extend to the muscularis mucosae. Below is the **submucosa** (*Subm*) in which the **lymphatic nodules** (*LN*) and considerable diffuse lymphatic tissue are present. Note the distinct germinal centers (*GC*) of the lymph nodules and the cap region (*Cap*)

that faces the lumen. The more superficial part of the submucosa blends and merges with the mucosal lamina propria because of the numerous lymphocytes in these two sites. The deeper part of the submucosa is relatively devoid of lymphocyte infiltration and contains large blood vessels (*BV*) and nerves. The muscularis externa (*ME*) is composed of a relatively thick circular layer and a much thinner outer longitudinal layer. The serosa (*S*) is only partially included in this micrograph.

The *inset* is a higher magnification of the *rectangular area* in the *lower figure*. Note that the epithelium of the glands in the appendix is similar to that of the large intestine. Most of the epithelial cells contain mucin, hence the light appearance of the apical cytoplasm. The lamina propria, as noted, is heavily infiltrated with lymphocytes, and the muscularis mucosae at the base of the glands is difficult to recognize (*arrows*).

BV, blood vessel
Cap, cap of lymphatic nodule
GC, germinal center
Gl, gland
L, lumen
LN, lymphatic nodule
ME, muscularis externa
Muc, mucosa
S, serosa
Subm, submucosa
arrows, muscularis mucosae at the base of glands

PLATE 17.11 ■ ANAL CANAL

At the anal canal, there is a transition from the simple columnar epithelium of the intestinal mucosa to the keratinized stratified

squamous epithelium of the skin. Located between these two distinctly different epithelia is a narrow region (anal transitional zone) where the epithelium is first stratified columnar (or stratified cuboidal) and then nonkeratinized stratified squamous.

At the level of the anal canal, the muscularis mucosae disappears. At the same level, the circular layer of the muscularis externa thickens to become the internal anal sphincter. The external anal sphincter is formed by the striated muscles of the pelvic floor.

Anal canal, human, hematoxylin and eosin (H&E) ×40.

A view of the anal canal is shown at low magnification. Mucosa characteristic of the large intestine (**colorectal zone**) is seen on the *upper left* of the micrograph. This region is the upper part of the anal canal, and the intestinal glands are the same as those present in the colon. The muscularis mucosae (*MM*) is readily identified as the narrow band of tissue under the glands. Both the intestinal glands and the muscularis mucosae terminate within the *left rectangular area* of the field, and here, at the *diamond*, there is the first major change in the epithelium. This area called the **anal transitional zone** is examined at higher magnification in the *bottom left figure*. The *right rectangular area* includes the stratified squamous epithelium (*StS*) and its transition into stratified squamous keratinized epithelium [*StS(k)*] of the skin in the **squamous zone** of the anal canal and is examined at higher magnification in the *bottom right figure*.

Between the two *diamonds* in the *rectangular areas* shown is epithelium of the lower part of the anal canal. Below this epithelium, there is a lymphatic nodule that has a well-formed germinal center. Isolated lymphatic nodules (*LN*) beneath mucous membranes should not be construed to have fixed locations. Rather, they may or may not be present, according to local demands.

Also, at this low magnification, note the internal anal sphincter muscle (*IAS*), that is, the thickened, most distal portion of the circular layer of smooth muscle of the muscularis externa. Beneath the skin on the right is the subcutaneous part of the external anal sphincter muscle (*EAS*). It is composed of striated muscle fibers, which are seen in cross section.

Anal transitional zone, anal canal, human, H&E ×160; inset ×300.

The junction between the simple columnar (*SC*) and the stratified (*ST*) epithelium called the **anal transitional zone** is marked with a *diamond*. The simple columnar epithelium of the upper part of the anal canal contains numerous goblet cells, and as in the mucosa of the colon, this epithelium is continuous with the epithelium of the intestinal glands (*IG*). These glands continue to about

the same point as the muscularis mucosae (*MM*). Characteristically, the lamina propria contains large numbers of lymphocytes (*Lym*), particularly so in the region marked. A higher magnification of the stratified columnar epithelium (*StCol*) and stratified cuboidal epithelium (*StC*) found in the transition zone is shown in the *inset*.

Squamous zone, anal canal, human, H&E $\times 160$.

The final change in epithelial type occurs at the **squamous zone of the anal canal**, which is shown here. On the *right* is the stratified squamous epithelium of skin (*StS[k]*). The keratinized nature of the surface is apparent. Conversely, the stratified squamous epithelium (*StS*) below the level of the *diamond* is not keratinized, and nucleated cells can be seen all the way to the surface. Again, numerous lymphocytes (*Lym*) are located in the underlying connective tissue, and many have migrated into the epithelium in the nonkeratinized area.

EAS, external anal sphincter
IAS, internal anal sphincter
IG, intestinal glands
LN, lymphatic nodules
Lym, lymphocytes
MM, muscularis mucosae
SC, simple columnar epithelium

HISTOLOGY

■ LIVER

Overview

The **liver** is the largest mass of glandular tissue in the body and the largest internal organ, weighing approximately 1,500 g

and accounting for nearly 2.5% of adult body weight. It is located in the upper right and partially in the upper left quadrants of the abdominal cavity, protected by the rib cage. The liver is enclosed in a capsule of fibrous connective tissue (Glisson capsule); a serous covering (visceral peritoneum) surrounds the capsule, except where the liver adheres directly to the diaphragm or the other organs.

The liver is anatomically divided by deep grooves into two large lobes (the right and left lobes) and two smaller lobes (the quadrate and caudate lobes; Fig. 18.1). This anatomic division has only topographic significance because it relates the lobes of the liver to other abdominal organs. Division of the liver into functional or surgical segments that correspond to the blood supply and bile drainage is more clinically important.

FIGURE 18.1. Anatomic structure of the liver. This diagram shows the gross view of the diaphragmatic and visceral surfaces of the liver, with labeled anatomic landmarks found on both surfaces. The enlarged cross-sectional area of the liver (*bottom*) shows the general microscopic organization of the liver into lobules. Note the presence of hepatic portal triads at the periphery of each lobule, with the terminal hepatic venule (central vein) in the center of the lobule.

In the embryo, the liver develops as an **endodermal evagination** from the wall of the foregut (specifically the site that will become the duodenum) to form the **hepatic diverticulum**. The diverticulum proliferates, giving rise to the **hepatocytes**, which become arranged in cellular (liver) cords, thus forming the parenchyma of the liver. The original stalk of the hepatic diverticulum becomes the **common bile duct**. An outgrowth from the common bile duct forms the **cystic diverticulum** that gives rise to the **gallbladder** and **cystic duct**.

Liver Physiology

Many circulating **plasma proteins** are produced and secreted by the liver. The liver plays an important role in the uptake, storage, and distribution of both nutrients and vitamins from the bloodstream. It also maintains the blood glucose level and regulates circulating levels of **very low-density lipoproteins (VLDLs)**. In addition, the liver degrades or conjugates numerous toxic substances and drugs, but overexposure to these toxins can lead to damage. The liver is also an **exocrine organ**; it produces a **bile secretion** that contains bile salts, phospholipids, and cholesterol. Finally, the liver performs important **endocrine-like functions**.

The liver produces most of the body's circulating plasma proteins.

The **circulating plasma proteins** produced by the liver include the following:

- **Albumins**, which are involved in regulating plasma volume and tissue fluid balance by maintaining the plasma colloid

osmotic pressure

- **Lipoproteins**, in particular, VLDLs. The liver synthesizes most VLDLs, which participate in the transport of triglycerides from the liver to other organs. The liver also produces small amounts of other plasma lipoproteins, such as **low-density lipoproteins (LDLs)** and **high-density lipoproteins (HDLs)**. LDLs transport cholesterol esters from the liver to other tissues. HDLs remove cholesterol from the peripheral tissues and transport it to the liver (see Folder 18.1).

FOLDER 18.1

CLINICAL CORRELATION: LIPOPROTEINS

Lipoproteins are multicomponent complexes of proteins and lipids that are involved in the transport of cholesterol and triglycerides in the blood. Cholesterol and triglycerides do not circulate freely in the plasma because lipids, on their own, would be unable to remain in suspension. The association of the protein with the lipid-containing core makes the complex sufficiently hydrophilic to remain suspended in the plasma.

Lipoproteins serve a variety of functions in cellular membranes and the transport and metabolism of lipids. Lipoprotein precursors are produced in hepatocytes. The lipid component is produced in the smooth endoplasmic reticulum (sER); the protein component is produced in the rough endoplasmic reticulum (rER). The lipoprotein complexes pass to the Golgi, where secretory vesicles containing electron-dense lipoprotein particles bud off and are then released at the cell surface bordering the perisinusoidal space to reach the bloodstream. Several hormones, such as estrogen and thyroid hormones, regulate the secretion of lipoproteins.

In general, four classes of lipoproteins have been defined by their characteristic density, molecular weight, size, and chemical composition: **chylomicrons**, **VLDLs**, **LDLs**, and **HDLs**. These lipoproteins differ in chemical composition and can be isolated from plasma according to their flotation properties, from largest and least dense to smallest and most dense.

Chylomicrons, the lightest of all lipoproteins, are made only in the small intestine. Their main function is to transport the large amount of absorbed fat to the bloodstream.

VLDLs are denser and smaller than chylomicrons; they are synthesized predominately in the liver and to a lesser extent in the small intestine. The very low-density lipoproteins (VLDLs) are rich in triglycerides. Their function is to transport most

of the triglycerides from the liver to other organs. Liver VLDLs are associated with circulating **apolipoprotein B-100**, also synthesized in the liver, which aids in secretion of VLDLs. In congenital liver disease, such as **abetalipoproteinemia**, and, to a lesser degree, in acute and chronic disorders, the liver is unable to produce apolipoprotein B-100, leading to blockage in the secretion of VLDLs. In liver biopsy specimens from these individuals, large lipid droplets occupy most of the hepatocyte cytoplasm.

LDLs and **HDLs** are produced in the plasma; however, small amounts of these fractions are produced by the liver. Low-density lipoproteins (LDLs) are denser than VLDLs, and high-density lipoproteins (HDLs) are denser than LDLs. The function of LDLs is to transport cholesterol esters from the liver to the peripheral organs. The HDLs are involved in the transport of cholesterol from the peripheral tissues to the liver. High levels of LDL are associated with an increased risk of cardiovascular disease; high levels of HDL or low levels of LDL are associated with decreased risk.

- **Glycoproteins**, which include proteins involved in iron transport, such as haptoglobin, transferrin, and hemopexin
- **Prothrombin** and **fibrinogen**, important components of the blood-clotting cascade
- **Nonimmune α -globulins** and **β -globulins**, which also help maintain plasma colloid osmotic pressure and serve as carrier proteins for various substances (see Chapter 10, Blood, page 299)

The liver stores and converts lipid-soluble vitamins.

Several lipid-soluble **vitamins** are taken up from the bloodstream and then stored or biochemically modified by the liver, including:

- **Vitamin A (retinol)**, an important vitamin in vision. Vitamin A is the precursor of retinal, which is required for the synthesis of rhodopsin in the eye. The liver plays a major role in the uptake, storage, and maintenance of circulating levels of vitamin A. When the vitamin A levels in the blood decrease, the liver mobilizes its storage sites in the hepatic stellate cells (see page 702). Vitamin A is then

released into the circulation in the form of **retinol** bound to **retinol-binding protein (RBP)**. The liver also synthesizes RBP; RBP synthesis is regulated by the plasma levels of **vitamin A**. Night blindness and multiple skin disorders are related to vitamin A deficiency.

- **Vitamin D (cholecalciferol)**, an important vitamin in calcium and phosphate metabolism. Vitamin D is acquired from dietary vitamin D₃ and is also produced in the skin during exposure to ultraviolet light by conversion of 7-dehydrocholesterol. Unlike vitamin A, vitamin D is not stored in the liver but is distributed to skeletal muscles and adipose tissue. The liver plays an important role in vitamin D metabolism by converting vitamin D₃ to **25-hydroxycholecalciferol**, the predominant form of circulating vitamin D. Further conversion takes place in the kidney to 1,25-hydroxycholecalciferol, which is 10 times more active than vitamin D₃. Vitamin D is essential for the development and growth of the skeletal system and teeth. Deficiency of vitamin D is associated with rickets and disorders of bone mineralization.
- **Vitamin E**, which represents a group of lipid-soluble tocopherols and tocotrienols. Most vitamin E in the body is in the form of **α-tocopherol**, a powerful, chain-breaking antioxidant that prevents the propagation of free radicals. Vitamin E is transported to the liver in chylomicrons and is bound to α-tocopherol transfer protein (α-TTP). Secretion of α-tocopherol from hepatocytes is linked to VLDL assembly. Individuals with fatty liver disease and nonalcoholic steatohepatitis (NASH) have decreased levels of circulating vitamin E.
- **Vitamin K**, which is important in hepatic synthesis of prothrombin and several other clotting factors. Like vitamin D, it is derived from two sources: dietary vitamin K and synthesis in the small intestine by intestinal bacterial flora. Vitamin K is transported to the liver with chylomicrons, where it is rapidly absorbed, partially used, and then partially secreted with the VLDL fraction. Vitamin K deficiency is associated with hypoprothrombinemia and bleeding disorders.

The liver is a key organ in the supply, storage, metabolism, and excretion of iron and copper.

The liver functions in the storage, metabolism, and homeostasis of iron and copper. It synthesizes almost all proteins involved in **iron recovery** from damaged or senescent red blood cells, including transferrin, haptoglobin, and hemopexin. **Transferrin** is a plasma iron transport protein. **Haptoglobin** binds with high affinity to free hemoglobin in the plasma; this complex is removed by macrophages in the liver (and spleen) to preserve iron. **Hemopexin** is involved in the transport of free heme in the blood. Hepatocytes are the major sites of long-term storage of iron. For details related to iron recovery and its storage in the liver, see pages 701–702.

The liver plays an important role in the disposition of **copper**. Copper is absorbed from the gastrointestinal tract into the portal circulation, where it binds to albumins and amino acids such as histidine. It then passes through the liver, where hepatocytes are the primary site of copper uptake and accumulation in the liver. Copper excretion into bile is regulated by an enzyme called **copper ATPase (Wilson ATPase)**, which promotes incorporation of copper into apoceruloplasmin (an unstable enzyme without the copper) to form **ceruloplasmin**, the major copper-carrying protein in the blood. Ceruloplasmin is a 151-kDa glycoprotein enzyme, contains six copper atoms in its structure, and comprises more than 95% of the copper found in the plasma. **Mutations of the ATP7B gene encoding Wilson ATPase are responsible for Wilson disease, an autosomal recessive disorder characterized by impaired synthesis of ceruloplasmin and biliary excretion of copper. Copper accumulates in the liver and leads to progressive liver damage. In addition, copper accumulates in the brain and other tissues. Affected individuals may show symptoms of liver failure and neuropsychiatric manifestations. Treatment is lifelong with either an oral chelating agent with copper-binding capacity or zinc salts. Liver transplantation is necessary for patients who do not respond to medical treatment.**

The liver degrades drugs and toxins.

Hepatocytes are involved in **degradation of drugs, toxins**, and other proteins foreign to the body (**xenobiotics**). Many drugs and toxins are not hydrophilic; therefore, they cannot be eliminated effectively from the circulation by the kidneys. The liver converts these substances into more soluble forms. This process is performed by the hepatocytes in two phases:

- **Phase I (oxidation)** includes hydroxylation (adding an $-OH$ group) and carboxylation (adding a $-COOH$ group) to a foreign compound. This phase is performed in the hepatocyte smooth endoplasmic reticulum (sER) and mitochondria. It involves a series of biochemical reactions with proteins collectively named cytochrome P450.
- **Phase II (conjugation)** includes conjugation with glucuronic acid, glycine, or taurine. This process makes the product of phase I even more water soluble so that it can be easily removed by the kidney.

The liver is involved in many other important pathways related to carbohydrate, lipid, and protein metabolism.

The liver is important in **carbohydrate metabolism** as it maintains an adequate supply of nutrients for cell processes. In **glucose** metabolism, the liver phosphorylates absorb glucose from the gastrointestinal tract to **glucose-6-phosphate**. Depending on energy requirements, glucose-6-phosphate is either stored in the liver in the form of **glycogen** or used in the glycolytic pathways. During fasting, glycogen is broken down by the process of **glycogenolysis**, and glucose is released into the bloodstream.

In addition, the liver functions in **lipid metabolism**. Fatty acids derived from plasma are consumed by hepatocytes using **β -oxidation** to provide energy. The liver also produces **ketone bodies** that are used as fuel by other organs. (The liver cannot use them as an energy source.) The involvement in **cholesterol** metabolism (synthesis and uptake from the blood) is also an important function of the liver. Cholesterol is used in the formation of bile salts, synthesis of VLDLs, and biosynthesis of organelles.

The liver is also involved in **protein metabolism**. It is the site of both protein synthesis and amino acid uptake and metabolism. The liver has also the capacity to deaminate amino acids; thus, it synthesizes most of the **urea** in the body from ammonium ions derived from protein and nucleic acid degradation. Finally, the liver is involved in the synthesis and conversion of **nonessential amino acids**.

Bile production is an exocrine function of the liver.

The liver carries out numerous **metabolic conversions** involving substrates delivered by blood from the digestive tract, pancreas, and spleen. Some of these products are involved in the production of **bile**, an exocrine secretion of the liver. Bile contains conjugated and degraded waste products that are returned to the intestine for disposal as well as substances that bind to metabolites in the intestine to aid in absorption (Table 18.1). Bile is carried from the parenchyma of the liver by bile ducts that fuse to form the **hepatic duct**. The cystic duct then carries the bile into the **gallbladder**, where it is concentrated. Bile is returned, via the cystic duct, to the common bile duct, which delivers bile from the liver and gallbladder to the duodenum (see Fig. 18.17).

TABLE 18.1

Composition of Bile

Component	Function
Water	Serves as solvent in which other components are carried
Phospholipids (i. e., lecithin) and cholesterol	Function as metabolic substrates for other cells in the body; act as precursors of membrane components and steroids; largely reabsorbed in the gut and recycled
Bile salts (also called <i>bile acids</i>) Primary (secreted by liver): cholic acid, chenodeoxycholic acid	Act as emulsifying agents that aid in the digestion and absorption of lipids from the gut and help to keep the cholesterol and phospholipids of the bile in solution; largely recycled between the liver and gut

Secondary (converted by bacterial flora in the intestine): deoxycholic acid, lithocholic acid

Bile pigments, principally the glucuronide of bilirubin produced in the spleen, bone marrow, and liver by the breakdown of hemoglobin

Detoxify bilirubin, the end product of hemoglobin degradation, and carry it to the gut for disposal

Electrolytes: Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , and HCO_3^-

Establish and maintain bile as an isotonic fluid; also largely reabsorbed in the gut

The endocrine-like functions of the liver are represented by its ability to modify the structure and function of many hormones.

The **liver modifies the action of hormones** released by other organs. The liver's endocrine-like functions involve modification of the following hormones:

- **Thyroxine**, a hormone secreted by the thyroid gland as tetraiodothyronine (T_4), which is converted in the liver to the biologically active form, **triiodothyronine (T_3)**, by deiodination.
- **Growth hormone (GH)**, a hormone secreted by the pituitary gland. The action of GH is amplified by liver-produced **insulin-like growth factor 1 (IGF-1)** and inhibited by **somatostatin**, which is secreted by enteroendocrine cells of the gastrointestinal tract. **Genetic IGF-1 deficiencies are found in certain ethnic groups whose members are less than average in height, such as Bayaka pygmies in Central Africa. Hormonal studies indicate that these individuals have normal GH levels; however, the level of IGF-1 in the adolescent population is reduced to one-third of that in control adolescents. Because IGF-1 is the principal factor responsible for normal pubertal growth, members of this**

ethnic population do not undergo accelerated growth spurt typical of puberty, which results in a short stature of less than 150 cm (5 feet).

- **Insulin** and **glucagon**, both pancreatic hormones. These hormones are degraded in many organs, but the liver and kidney are the most important sites of their degradation.
- In addition, **vitamin D₃** is converted by the liver to **25-hydroxycholecalciferol**, a biologically active metabolite of vitamin D₃ and the predominant form of circulating vitamin D (page 693).

Blood Supply to the Liver

The liver has a **unique dual blood supply** consisting of a venous (portal) supply via the **hepatic portal vein** and an arterial supply via the **hepatic artery**. Both vessels enter the liver at a hilum or **porta hepatis**, the same site at which the common bile duct carries the bile secreted by the liver and the lymphatic vessels leave the liver. Therefore, bile flows in a direction opposite to that of the blood.

The liver receives blood that is initially supplied to the intestines, pancreas, and spleen.

The liver is unique among organs because it receives its major blood supply (about 75%) from the hepatic portal vein, which carries venous blood that is largely depleted of oxygen. The blood delivered to the liver by the **hepatic portal vein** comes from the digestive tract and the major abdominal organs, such as the pancreas and spleen.

The portal blood carried to the liver contains the following substances:

- Nutrients and toxic materials absorbed in the intestine
- Blood cells and breakdown products of blood cells from the spleen
- Endocrine secretions of the pancreas and enteroendocrine cells of the gastrointestinal tract

Thus, the liver is placed directly in the pathway of blood vessels that convey substances absorbed from the digestive tract. Although the liver is the first organ to receive metabolic substrates and nutrients, it is also the first exposed to toxic substances that have been absorbed.

The **hepatic artery**, a branch of the celiac trunk, carries oxygenated blood to the liver, providing the remaining 25% of its blood supply. Because blood from the two sources mixes just before it perfuses the hepatocytes of the liver parenchyma, the liver cells are never exposed to fully oxygenated blood.

Within the liver, the distributing branches of the portal vein and hepatic artery, which supply the sinusoidal capillaries (sinusoids) that bathe the hepatocytes, and the draining branches of the bile duct system, which lead to the common hepatic duct, course together in a relationship termed the **portal triad**. Although a convenient term, it is a misnomer because one or more vessels of the lymphatic drainage system of the liver always travel with the vein, artery, and bile duct (Fig. 18.2).

FIGURE 18.2. Blood supply to the liver: the portal triad. The portal triad is composed of the branches of the hepatic artery, portal

vein, and bile duct. Blood from the terminal branches of the hepatic artery and portal vein enters the hepatic sinusoids. The mixture of venous and arterial blood is transported by the sinusoids toward the terminal hepatic venule (central vein). Blood then drains into the sublobular veins, the tributaries of the hepatic vein. Note the small vessels and capillary network in the perivascular connective tissue surrounding each hepatic triad within the portal canal. Also note the periportal space (of Mall), located between the portal canal and the outermost hepatocytes. This space is also filled with a small amount of connective tissue in which blind-ended lymphatic capillaries are located; these form larger lymphatic vessels that accompany branches of the hepatic artery.

The **sinusoids** are in intimate contact with the hepatocytes and provide for the exchange of substances between the blood and liver cells. The sinusoids lead to a **terminal hepatic venule (central vein)** that, in turn, empties into the **sublobular veins**. Blood leaves the liver through the **hepatic veins**, which empty into the inferior vena cava.

Structural Organization of the Liver

As introduced previously, the liver is made up of the following structures:

- **Parenchyma**, consisting of organized plates of hepatocytes, which, in the adult, are normally one cell thick and are separated by sinusoidal capillaries. In young individuals up to 6 years of age, the liver cells are arranged in plates with two cells thick.
- **Connective tissue stroma** that is continuous with the fibrous capsule of Glisson. Blood vessels, nerves, lymphatic vessels, and bile ducts travel within the connective tissue stroma.
- **Sinusoidal capillaries (sinusoids)**, the vascular channels between the plates of hepatocytes
- **Perisinusoidal spaces (spaces of Disse)**, which lie between the sinusoidal endothelium and the hepatocytes

Liver lobules

There are three ways to describe the structure of the liver in terms of a functional unit: the classic lobule, the portal

lobule, and the liver acinus. The classic lobule is the traditional way to describe the organization of the liver parenchyma, and it is relatively easy to visualize. It is based on the distribution of the branches of the portal vein and hepatic artery within the organ and the pathway that blood from them follows as it ultimately perfuses the liver cells.

The classic hepatic lobule is a roughly hexagonal mass of tissue.

The **classic lobule** (Fig. 18.3 and Plate 18.1, page 722) consists of stacks of anastomosing plates of hepatocytes, one cell thick, separated by the anastomosing system of sinusoids that perfuse the cells with the mixed portal and arterial blood. Each lobule measures about 2.0 mm $\times$ 0.7 mm. At the center of the lobule is a relatively large venule, the **terminal hepatic venule (central vein)**, into which the sinusoids drain. The plates of cells radiate from the central vein to the periphery of the lobule, as do the sinusoids. At the angles of the hexagon are the **portal canals**, loose stromal connective tissue characterized by the presence of the **portal triads** (hepatic artery, portal vein, and bile duct). This connective tissue is ultimately continuous with the fibrous capsule of the liver. The portal canal is bordered by the outermost hepatocytes of the lobule. At the edges of the portal canal, between the connective tissue stroma and the hepatocytes, is a small space called the **periportal space (space of Mall)**, which in some species (e.g., the rabbit; Fig. 18.4) is easily identified. This space is one of the sites where lymph originates in the liver.

FIGURE 18.3. Diagram of a classic liver lobule. A classic liver lobule can be schematically diagramed as a six-sided polyhedral prism with portal triads (hepatic artery, portal vein, and bile duct) at each corner. The blood vessels of the portal triads send distributing branches along the sides of the lobule, and these branches open into the hepatic sinusoids. The long axis of the lobule is traversed by the terminal hepatic venule (central vein), which receives blood from the hepatic sinusoids. Note that a wedge of the tissue has been removed from the lobule for better visualization of the terminal hepatic venule. Interconnecting sheets or plates of hepatocytes are disposed in a radial pattern from the terminal hepatic venule to the periphery of the lobule.

FIGURE 18.4. Photomicrograph of the portal canal in rabbit liver. This high-magnification photomicrograph of rabbit liver from a routine hematoxylin and eosin (H&E) preparation shows the portal canal located at the angles of hepatic lobules. The portal canal is bordered by linearly arranged outermost hepatocytes of the lobule. Each portal is occupied by a portal triad consisting of the portal vein, hepatic artery, and bile duct, all surrounded by loose stromal connective tissue. Note longitudinally sectioned nuclei of cholangiocytes of the intrahepatic bile ductule, which drains into the bile duct. At the periphery of the portal canal, between the connective tissue stroma and the hepatocytes, is a space called the *periportal* space (of Mall), which, in this image, contains two irregular profiles of lymphatic vessels lined by endothelial cells. $\times 320$. (Courtesy of Dr. Nathan Swailes, University of Iowa.)

In some species (e.g., the pig; Fig. 18.5a), the classic lobule is easily recognized because the portal areas are connected by relatively thick layers of connective tissue. In humans, however, there is normally very little interlobular connective tissue. For this reason, when examining histologic sections of the liver, it is necessary to draw imaginary lines between portal areas surrounding a central vein to get some sense of the size of the classic lobule (Fig. 18.5b).

FIGURE 18.5. Photomicrographs of pig and human livers. **a.** This photomicrograph shows a cross section of a pig liver lobule stained by the Mallory-Azan method to visualize connective tissue components. Note the relatively thick interlobular connective tissue (*stained blue*) surrounding the lobules. The terminal hepatic venule (central vein) is visible in the center of the lobule. $\times 65$. **b.** Photomicrograph of human liver from a routine hematoxylin and eosin (H&E) preparation. Note that in contrast to the pig liver, the lobules of the human liver lack connective tissue septa. The plates of hepatocytes of one lobule merge with those of adjacent lobules. The boundaries of a lobule can be approximated, however, by drawing a line (*dashed line*) from one portal canal to the next, thus circumscribing the lobule. $\times 65$.

The portal lobule emphasizes the exocrine functions of the liver.

The major exocrine function of the liver is bile secretion. Thus, the morphologic axis of the **portal lobule** is the interlobular bile duct of the portal triad of the classic lobule. Its outer margins are imaginary lines drawn between the three central veins that are closest to that portal triad (Fig. 18.6a). These lines define a roughly triangular block of tissue that includes those portions of three classic lobules that secrete the bile that drains into its axial bile duct. This concept allows a description of hepatic parenchymal structure comparable to that of other exocrine glands.

FIGURE 18.6. Comparison of three models of liver organization and function. **a.** The outlines of a classic hepatic lobule, portal lobule, and liver acinus are visible on this section of the liver tissue. Note that the hexagonal-shaped classic lobule (*red*) has the terminal hepatic venule (central vein) at the center of the lobule and the portal canals containing portal triads at the peripheral angles of the lobule. The triangular portal lobule (*green*) has a portal canal at the center of the lobule and terminal hepatic venules (central veins) at the peripheral angles of the lobule. A diamond-shaped liver acinus (*multicolor*) has distributing vessels at the equator and terminal hepatic venules (central veins) at each pole. **b.** The liver acinus is a functional interpretation of liver organization. It consists of adjacent sectors of neighboring hexagonal fields of classic lobules partially separated by distributing blood vessels. The zones marked 1, 2, and 3 designate areas that receive the most nutrient-dense and oxygenated blood supply (zone 1) to the least (zone 3). The terminal hepatic venules (central veins) in this interpretation are located at the pointed edges of the acinus instead of in the center, as in the classic lobule. The portal triads (terminal branches of the portal

vein and hepatic artery) and the smallest bile ducts are shown at the corners of the hexagon that outlines the cross-sectioned profile of the classic lobule.

The liver acinus is the structural unit that provides the best correlation between blood perfusion, metabolic activity, and liver pathology.

The **liver acinus** is lozenge shaped and represents the smallest functional unit of the hepatic parenchyma. The **short axis of the acinus** is defined by the terminal branches of the portal triad that lie along the border between two classic lobules. The **long axis of the acinus** is a line drawn between the two central veins closest to the short axis. Therefore, in a two-dimensional view (Fig. 18.6b), the liver acinus occupies parts of adjacent classic lobules. This concept allows a description of the exocrine secretory function of the liver comparable to that of the portal lobule.

The hepatocytes in each liver acinus are described as being arranged in three concentric elliptical zones surrounding the short axis (see Fig. 18.6b):

- **Zone 1** is closest to the short axis and the blood supply from penetrating branches of the portal vein and hepatic artery. This zone corresponds to the periphery of the classic lobules.
- **Zone 3** is farthest from the short axis and closest to the terminal hepatic vein (central vein). This zone corresponds to the most central part of the classic lobule that surrounds the terminal hepatic vein.
- **Zone 2** lies between zones 1 and 3 but has no sharp boundaries.

The zonation is important in the description and interpretation of patterns of degeneration, regeneration, and specific toxic effects in the liver parenchyma relative to the degree or quality of vascular perfusion of the hepatic cells. As a result of the sinusoidal blood flow, the oxygen gradient, metabolic activity of the hepatocytes, and distribution of hepatic enzymes vary across the three zones. The distribution

of liver damage resulting from ischemia and exposure to toxic substances can be explained using this zonal interpretation.

Cells in **zone 1** are the first to receive oxygen, nutrients, and toxins from the sinusoidal blood and the first to show morphologic changes after **bile duct occlusion** (bile stasis). These cells are also the last to die if circulation is impaired and the first to regenerate. Conversely, cells in **zone 3** are the first to show ischemic necrosis (**centrilobular necrosis**) in situations of **reduced perfusion** and the first to show fat accumulation. They are the last to respond to toxic substances and bile stasis. Normal variations in enzyme activity, the number and size of cytoplasmic organelles, and the size of cytoplasmic glycogen deposits are also seen between zones 1 and 3. Cells in **zone 2** have functional and morphologic characteristics and responses intermediate to those of zones 1 and 3.

Blood vessels of the parenchyma

The blood vessels that occupy the **portal canals** are called **interlobular vessels**. Only the interlobular vessels that form the smallest portal triads send blood into the sinusoids. The larger interlobular vessels branch into distributing vessels that are located at the periphery of the lobule. These distributing vessels send inlet vessels to the sinusoids (Fig. 18.7). In the **sinusoids**, the blood flows centripetally toward the central vein. The central vein courses through the central axis of the classic liver lobule, becoming larger as it progresses through the lobule and empties into a sublobular vein. Several sublobular veins converge to form larger hepatic veins that empty into the inferior vena cava.

FIGURE 18.7. Diagram of the flow of blood and bile in the liver. This schematic diagram of a part of a classic lobule shows the components of the portal triads, hepatic sinusoids, terminal hepatic venule (central vein), and associated plates of hepatocytes. *White arrows* indicate the direction of the blood flow in the sinusoids. Note that the direction of bile flow (*green arrows*) is opposite that of the blood flow.

The structure of the **portal vein** and its branches within the liver is typical of veins in general. The lumen is much

larger than that of the artery associated with it. The structure of the **hepatic artery** is like that of other arteries (i.e., it has a thick muscular wall). In addition to providing arterial blood directly to the sinusoids, the hepatic artery provides arterial blood to the connective tissue and other structures in the larger portal canals. Capillaries in these larger portal canals return the blood to the interlobular veins before they empty into the sinusoid.

The **central vein** is a thin-walled vessel receiving blood from the hepatic sinusoids. The endothelial lining of the central vein is surrounded by small amounts of spirally arranged connective tissue fibers. The central vein, so named because of its central position in the classic lobule, is actually the terminal venule of the system of hepatic veins and thus is more properly called the **terminal hepatic venule**. The **sublobular vein**, the vessel that receives blood from the terminal hepatic venules, has a distinct layer of connective tissue fibers, both collagenous and elastic, just external to the endothelium. The sublobular veins and the **hepatic veins**, into which they drain, travel alone. Because they are solitary vessels, they can be readily distinguished in a histologic section from the portal veins that are members of a triad. There are no valves in hepatic veins.

FOLDER 18.2

CLINICAL CORRELATION: CONGESTIVE HEART FAILURE, ACETAMINOPHEN OVERDOSE, AND LIVER NECROSIS

Liver injury may be triggered by hemodynamic changes in the circulatory system. In congestive heart failure, the heart is unable to provide sufficient oxygenated blood to meet the metabolic requirements of tissues and organs, including the liver, which is readily affected by hypoperfusion and hypoxia (low blood oxygen content). Zone 3 of the liver acinus is the first to be affected by this condition. The hepatocytes in this zone are the last to receive blood as it passes along the sinusoids; as a result, these cells receive a blood supply already depleted in oxygen. Examination of a liver biopsy specimen from an individual with congestive heart failure shows a distinct pattern of liver necrosis. Hepatocytes in zone 3, which is located around the central vein, undergo ischemic necrosis. Typically, no noticeable changes are seen in zones 1 and 2, representing the periphery of a

classic lobule. Necrosis of this type is referred to as **centrilobular necrosis**. Figure F18.2.1 shows the centrilobular portion of a classic lobule. The multiple round vacuoles indicate lipid accumulation, and the atrophic changes are the result of dying hepatocytes undergoing autophagocytosis. Centrilobular necrosis as a result of hypoxia is referred to as **cardiac cirrhosis**; however, unlike true cirrhosis, nodular regeneration of hepatocytes is minimal.

FIGURE F18.2.1. Photomicrograph of centrilobular necrosis in human liver. This photomicrograph shows a routine hematoxylin and eosin (H&E) liver biopsy specimen from an individual with congestive heart failure. Pathologic changes (referred to as *ischemic necrosis*) are most severe in hepatocytes in zone 3. This zone surrounds the terminal hepatic venule (central vein). This type of necrosis is referred to as *centrilobular necrosis*. Note the presence of multiple round vacuoles, which indicates extensive lipid accumulation. No noticeable changes are seen in the periphery of the lobule, which is zone 1 and much of zone 2. $\times 320$.

Centrilobular necrosis can also occur in individuals who ingest a large amount of **acetaminophen (paracetamol, Tylenol)**, one of the most widely used over-the-counter painkillers. Acetaminophen overdoses, either accidental or intentional, are the leading cause of acute liver failure in the United States, accounting for nearly 500 deaths annually. Ingested acetaminophen is transported to the liver via the portal circulation, where it is converted in hepatocytes with the assistance of cytochromes P450 into a highly reactive toxic intermediate known as *N*-acetyl-p-benzoquinone imine (NAPQI). At therapeutic doses, NAPQI is efficiently detoxified by glutathione, forming an inert acetaminophen-glutathione conjugate that is excreted in the urine. However, at high dosage levels of acetaminophen, excess NAPQI depletes hepatic glutathione. Unconjugated NAPQI covalently binds to proteins and organelles in hepatocytes (mainly in zone 3), causing rapid cell death and centrilobular liver necrosis that can lead to acute liver failure and death.

Hepatic sinusoids are lined with a thin discontinuous endothelium.

The **discontinuous sinusoidal endothelium** has a discontinuous basal lamina that is absent over large areas. The discontinuity of the endothelium is evident in two ways:

- **Large fenestrae**, without diaphragms, are present within the endothelial cells.
- Large gaps are present between neighboring endothelial cells.

Hepatic sinusoids differ from other sinusoids in that a second cell type, the **stellate sinusoidal macrophage**, or **Kupffer cell** (Fig. 18.8 and Plate 18.2, page 724), is a regular part of the vessel lining.

FIGURE 18.8. Electron micrograph of two hepatic sinusoids of the liver. One hepatic sinusoid (*top*) displays a stellate sinusoidal macrophage (Kupffer cell). The remainder of the sinusoid as well as the other sinusoid is lined by thin endothelial cell cytoplasm. Surrounding each sinusoid is the perisinusoidal space (space of Disse), which contains numerous *hepatocyte microvilli*. Also present in the perisinusoidal space is a hepatic stellate cell (Ito cell) with a large lipid droplet and several smaller droplets. Its nucleus conforms to the curve of the lipid droplet. $\times 6,600$.

Stellate sinusoidal macrophages (Kupffer cells)

Kupffer cells represent a mixed population of cells from two different origins with different phenotypes and divergent functionality.

Most tissues have mixed populations of macrophages with different embryologic origins. Microglia in the brain, Kupffer cells in the liver, Langerhans cells in the skin, and mesangial cells in the kidney are examples of **yolk sac-derived macrophages** that originated from erythro-myeloid progenitor cells early in development. In contrast, most intestinal macrophages are **bone marrow-derived macrophages**. These macrophages originate from hematopoietic stem cells, differentiate into **monocytes**, and enter the blood circulation via bone marrow. They travel through the bloodstream to designated tissues and differentiate into macrophages. Recent studies indicate that yolk sac-derived macrophages highly express profibrotic factors, whereas bone marrow-derived macrophages are involved in immune response reactions.

Kupffer cells in the adult liver also represent a mixed population of cells from these two different origins. Both populations of Kupffer cells are phagocytic and demonstrate different phenotypes and divergent functionality. Under experimental conditions, the phagocytic capacity of Kupffer cells can be assessed by measuring the uptake of different molecules, such as colloid carbon injected into the circulation (Fig. 18.9).

FIGURE 18.9. Photomicrograph of rabbit liver with carbon-labeled Kupffer cells. This high-magnification photomicrograph of the centrilobular area of rabbit liver is stained routinely in hematoxylin and eosin (H&E). To visualize Kupffer cells and test their phagocytic capacity under experimental conditions, colloid carbon was injected into the portal vein 30 minutes before the liver samples were collected for histologic study. Note the terminal hepatic venule (central vein) with plates of hepatocytes radiating from the central vein to the periphery of the hepatic lobule. Cells marked with *arrows* represent Kupffer cells, which have accumulated carbon particles. Note the distribution of Kupffer cells within hepatic sinusoids. $\times 300$. (Courtesy of Dr. Nathan Swailes, University of Iowa.)

The two populations of Kupffer cells are described as follows:

- **Yolk sac - derived cells.** These cells migrate from the yolk sac during early development and colonize the developing liver. Kupffer cells developed from this lineage are self-sustaining and represent a resident **self-renewing phagocytic population** in the liver. They are largely independent of bone marrow hematopoietic stem cell development and, under normal conditions, are not replaced by monocyte-derived macrophages.

- **Bone marrow - derived cells.** These cells represent monocytes that originate from bone marrow. When yolk sack - derived Kupffer cells are damaged (e.g., in liver cirrhosis, hemochromatosis, hepatitis), arriving monocytes undergo environmentally induced changes and replace Kupffer cells. Monocyte-derived Kupffer cells do not divide, and they are replenished by an **influx of circulating monocytes** that enter the liver from the circulation.

The **activation process of Kupffer cells** mirrors that of other antigen-presenting cells, as described in Chapter 14, Immune System and Lymphatic Tissues and Organs (pages 498–500). They follow one of two activation pathways, giving rise to M1 (classically activated) or M2 (alternatively activated) macrophage phenotypes. M1-activated Kupffer cells participate in the inflammatory response, whereas M2-activated Kupffer cells express immune-modulatory properties. **Maintaining a balance between both phenotypes of Kupffer cells is important in the course of pathologic changes in the liver. For instance, depletion of M1-activated Kupffer cells and expansion of M2-activated cells may promote healing and tissue repair during active hepatitis (an inflammatory process of the liver).**

Kupffer cells are antigen-presenting cells that are involved in the immune system response.

Kupffer cells represent liver-resident macrophages that comprise 15% of the cells in the liver and account for 80%–90% of the total macrophages of the body. These antigen-presenting cells serve as the first line of defense against microorganisms and endotoxins that enter the liver via the hepatic portal circulation from the intestines. They initiate an immune response, recruit additional immune cells, and are essential in the clearance of viruses such as hepatitis viruses type B (HBV) and type C (HCV). Kupffer cells capture pathogens by recognizing pathogen-associated molecular patterns (PAMPs) via pattern recognition receptors (PRRs) such as toll-like receptors (TLRs) or nod-like receptors (NLRs) expressed on their surface (see page 309).

The scanning electron microscope (SEM) and transmission electron microscope (TEM) clearly show that the Kupffer cells form part of the lining of the sinusoid. Previously, they had been described as lying on the luminal surface of the endothelial cells. This older histologic description was probably based on the fact that processes of the Kupffer cells occasionally overlap endothelial cells on the luminal side. Cellular processes of Kupffer cells often seem to span the sinusoidal lumen and may even partially occlude it. Kupffer cells do not form junctions with neighboring endothelial cells.

Kupffer cells are involved in removing senescent red blood cells and recovering iron.

The presence of red blood cell fragments and iron (in the form of ferritin) in the cytoplasm of Kupffer cells suggests that they are involved in removing damaged or senescent red blood cells and recovering iron. Together with red pulp macrophages in the spleen and macrophages in bone marrow, Kupffer cells recycle between 90% and 95% of the body's iron necessary to maintain efficient erythropoiesis. The iron recovered from phagocytosed red blood cells is either stored within Kupffer cells, incorporated into iron-containing proteins, or exported from the cell back into the blood. Because free iron is toxic to the cell (water and oxygen in the cell convert Fe^{3+} ions into insoluble rust-like oxides), the stored iron needs to be sheltered from the cytoplasm. **Ferritin**, a 474-kDa multimeric protein in a shape of a hollow sphere (like a tennis ball), performs this function and can protect and store up to 4,500 iron ions. After Fe^{3+} ions enter the ferritin shell, they form small crystallites along with phosphate and hydroxide ions. In this state, Fe^{3+} ions are safely stored in isolation from the cytoplasm within the shell of the ferritin molecule. Ferritin also regulates intracellular iron levels by releasing iron from the core of the protein into the cytoplasm. Fe^{3+} ions are then picked up by **ferroportin (Fpn)-1**, a 62.5-kDa transmembrane protein that mediates iron export from the Kupffer cell directly into the blood of liver sinusoids. Here, Fe^{3+} ions are loaded onto **transferrin**, a 79.5-kDa protein that mediates iron

transport through the blood. Each transferrin molecule flows through the blood carrying two Fe^{3+} ions and delivers them to a transferrin receptor on the surface of a target cell.

Some ferritin molecules loaded with iron may be converted into **iron deposition complexes** known as **hemosiderin granules**. These structures are surrounded by lysosomes and represent aggregated forms of partially digested ferritin molecules (Fig. 18.10). The amount of iron stored in Kupffer cells increases following **splenectomy** when the liver becomes essential for red blood cell disposal. Also, multiple blood transfusions may lead to **iron overload**. Excess hemosiderin granules deposited in macrophages and other cells in the body are detectable by magnetic resonance imaging (MRI) techniques owing to their solid crystalline superparamagnetic iron core that contributes to a decrease in T2 signal intensity. This signal is distinguishable from other soluble paramagnetic iron sources, such as plasma transferrin, ferritin, and hemoglobin. In individuals with an iron overload disorder, such as **hemosiderosis** (excess iron deposition in macrophages of the spleen, bone marrow, and Kupffer cells) or **hemochromatosis** (accumulation of hemosiderin in parenchymal cells of the liver, pancreas, heart, and other organs), noninvasive quantification of iron with MRI techniques has been implemented to replace tissue and organ biopsy. MRI is now considered the standard of care in diagnosing and monitoring iron overload diseases.

FIGURE 18.10. Hemochromatosis of the liver. a. This photomicrograph of a liver biopsy specimen, from an individual with an iron overload condition called *hemochromatosis*, is routinely stained with hematoxylin and eosin (H&E). It shows the portal canal containing a portal triad (portal vein, hepatic artery, and bile duct) surrounded by an extensive amount of fibrous tissue. Note that at this lower magnification, the hepatocytes have visible coarse golden brown granules of hemosiderin within the cytoplasm. $\times 85$. (Courtesy of Dr. Nathan Swailes, University of Iowa.) b. The higher magnification of the area indicated by the *upper rectangle* shows in much better resolution the cytoplasm of hepatocytes filled with the hemosiderin granules. In addition, multiple elongated profiles of Kupffer cells that accumulated hemosiderin are also clearly visible along the liver sinusoids. $\times 220$. c. This higher magnification of the area indicated by the *lower rectangle* shows an enlargement of the connective tissue in the portal canal. Note that this area is infiltrated by monocyte-derived macrophages containing hemosiderin granules (encircled by a *dashed line*). In addition, there is an infiltration of lymphocytes that indicates a chronic phase of this disease. $\times 220$. d. This high-magnification photomicrograph of a liver biopsy specimen from an individual with hereditary hemochromatosis stained with Prussian blue iron stain. *Blue color* indicates areas with extensive accumulation of hemosiderin within hepatocytes $\times 320$. (Courtesy of Dr. Joseph Grande, Mayo Clinic.)

Perisinusoidal space (space of Disse)

The perisinusoidal space is the site of exchange of materials between blood and liver cells.

The **perisinusoidal space (space of Disse)** lies between the basal surfaces of hepatocytes and the basal surfaces of endothelial cells and Kupffer cells that line the sinusoids. Small, irregular microvilli project into this space from the basal surface of the hepatocytes (Fig. 18.11).

FIGURE 18.11. Electron micrograph showing the perisinusoidal space (of Disse). The perisinusoidal space (*D*) is located between the hepatocytes (*H*) and the sinusoid. A gap (*large arrow*) separates the endothelial cells (*En*) that line the sinusoid. Such gaps allow easy passage of small substances between the sinusoid and the perisinusoidal space. Numerous microvilli extend from the hepatocytes into the perisinusoidal space. These processes are long and frequently branch (*small arrow*). A red blood cell (*RBC*) is within the sinusoid. $\times 18,000$.

The microvilli increase the surface area available for exchange of materials between hepatocytes and plasma by as much as 6 times. Because of the large gaps in the endothelial layer and the absence of a continuous basal lamina, no significant barrier exists between the blood plasma in the sinusoid and the hepatocyte plasma membrane. Proteins and lipoproteins synthesized by the hepatocyte are transferred into the blood in the perisinusoidal space; this pathway is for liver secretions other than bile.

In the fetal liver, the space between blood vessels and hepatocytes contains islands of blood-forming cells. In cases of chronic anemia in the adult, blood-forming cells may again appear in the perisinusoidal space.

Hepatic stellate cells (Ito cells)

The hepatic stellate cells (Ito cells) store vitamin A; however, in pathologic conditions, they differentiate into myofibroblasts and synthesize collagen.

The other cell type found in the perisinusoidal space is the **hepatic stellate cell** (commonly called an **Ito cell**). These cells of mesenchymal origin are the primary storage site for hepatic **vitamin A** in the form of **retinyl esters** within cytoplasmic lipid droplets (see Fig. 18.8). Vitamin A is released from the hepatic stellate cell as **retinol** (alcohol form) bound to **retinol-binding protein (RBP)**. It is then transported from the liver to the retina, where its stereoisomer 11-*cis*-retinal binds to the protein opsin to form **rhodopsin**, the visual pigment of rods and cones of the retina. Oils derived from the fish livers (e.g., cod liver oil) have

been important nutritional sources of vitamin A; today, they are taken in the form of dietary supplements.

In certain pathologic conditions, such as chronic inflammation or liver cirrhosis, hepatic stellate cells lose their lipid and vitamin A storage capability and differentiate into cells with characteristics of myofibroblasts. These cells appear to play a significant role in hepatic fibrogenesis; they synthesize and deposit type I and type III collagen within the perisinusoidal space, resulting in liver fibrosis. This collagen is continuous with the connective tissue of the portal space and the connective tissue surrounding the central vein. An increased amount of perisinusoidal fibrous stroma is an early sign of liver response to toxic substances. The cytoplasm of hepatic stellate cells contains contractile elements, such as desmin and smooth muscle α -actin filaments. During cell contraction, they increase the vascular resistance within the sinusoids by constricting the vascular channels, leading to portal hypertension. In addition, hepatic stellate cells play a role in remodeling the extracellular matrix during recovery from liver injury.

Lymphatic Pathway

Hepatic lymph originates in the perisinusoidal space.

Plasma that remains in the perisinusoidal space drains into the periportal connective tissue, where a small space, the **periportal space (space of Mall)** (Fig. 18.12), is described between the stroma of the portal canal and the outermost hepatocytes. From this collecting site, the fluid then enters lymphatic capillaries that travel with the other components of the portal triad.

FIGURE 18.12. Canals of Hering and the intrahepatic ductule. **a.** Photomicrograph showing an area near a portal canal. *Arrows* indicate regions where bile canaliculi are draining into the *canals of Hering*. Note that the canal of Hering is partially lined by hepatocytes and partially by cholangiocytes. It drains into the *intrahepatic bile ductule* surrounded by hepatocytes, in contrast to the interlobular bile duct, which is embedded in the connective tissue of the portal canal. The terminal branch of a *portal vein* (*lower right*) accompanied by a small bile ductule is evident. $\times 800$. **b.** Electron micrograph showing an intrahepatic bile ductule. The ductule collects bile from the canals of Hering. It is close to the hepatocytes, but the actual connection between bile canaliculi and the intrahepatic ductule is not evident in this plane of section. The ductule is composed of cholangiocytes (*CH*) surrounded by a complete basal lamina (*BL*). The narrow space (*asterisks*) into which microvilli of hepatocytes project is the periportal space (of Mall), not the perisinusoidal space (of Disse). $\times 6,000$.

The lymph moves in progressively larger vessels, in the same direction as the bile (i.e., from the level of the hepatocytes, toward the portal canals and eventually to the hilum of the liver). Approximately 80% of the hepatic lymph follows this

pathway and drains into the thoracic duct, forming the major portion of the thoracic duct lymph.

Hepatocytes

Hepatocytes make up the anastomosing cell plates of the liver lobule.

Hepatocytes are large, polygonal cells measuring between 20 and 30 μm in each dimension. They constitute approximately 80% of the cell population of the liver.

Hepatocyte nuclei are large and spherical and occupy the center of the cell. Many cells in the adult liver are binucleate; most cells in the adult liver are tetraploid (i.e., they contain the 4*d* amount of DNA). Heterochromatin is present as scattered clumps in the nucleoplasm and as a distinct band beneath the nuclear envelope. Two or more well-developed nucleoli are present in each nucleus.

Hepatocytes are relatively long-lived for cells associated with the digestive system; their average life span is about 5 months. In addition, liver cells are capable of considerable regeneration when liver tissue is lost to hepatotoxic processes, disease, or surgery.

The **hepatocyte cytoplasm** is generally acidophilic. The following specific cytoplasmic components may be identified by routine and special staining procedures:

- Basophilic regions that represent rough endoplasmic reticulum (rER) and free ribosomes
- Numerous mitochondria; as many as 800 – 1,000 mitochondria per cell can be demonstrated by vital staining or enzyme histochemistry.
- Multiple small Golgi complexes visible in each cell after specific staining
- Large numbers of peroxisomes demonstrated by immunocytochemistry
- Deposits of glycogen stained by means of the periodic acid-Schiff (PAS) procedure. However, in a well-preserved hematoxylin and eosin (H&E) preparation, glycogen is also

visible as irregular spaces, usually giving a fine foamy appearance to the cytoplasm.

- Lipid droplets of various sizes seen after appropriate fixation and Sudan or toluidine blue staining (Plate 18.2, page 724). In routinely prepared histologic sections, round spaces are sometimes seen that represent dissolved lipid droplets. The number of lipid droplets increases after injection or ingestion of certain hepatotoxins, including ethanol.
- Lipofuscin pigment within lysosomes seen with routine H&E staining in various amounts. Well-delineated brown granules can also be visualized by the PAS method.

As noted previously, the hepatocyte is polyhedral; for convenience, it is described as having six surfaces, although there may be more. A schematic section of a cuboidal hepatocyte is shown in Figure 18.13. Two of its surfaces face the perisinusoidal space. The plasma membrane of two surfaces faces a neighboring hepatocyte and a bile canaliculus. Assuming that the cell is cuboidal, the remaining two surfaces, which cannot be seen in the diagram, would also face neighboring cells and bile canaliculi. The surfaces that face the perisinusoidal space correspond to the basal surface of other epithelial cells; the surfaces that face neighboring cells and bile canaliculi correspond to the lateral and apical surfaces, respectively, of other epithelial cells.

FIGURE 18.13. Schematic diagram of a plate of hepatocytes interposed between hepatic sinusoids. This diagram shows a one-cell-thick plate of hepatocytes interposed between two sinusoids. If it is assumed that the cell is cuboidal, two sides of each cell (shown) would face hepatic sinusoids, two sides of each cell (shown) would face bile canaliculi, and the additional two sides (not shown) would face bile canaliculi. Note the location and features of a hepatic stellate cell (Ito cell) filled with cytoplasmic vacuoles containing vitamin A. The sparse collagen fibers found in the perisinusoidal space (of Disse) are produced by the hepatic stellate cells (Ito cells). In certain pathologic conditions, these cells lose their storage vacuoles and differentiate into myofibroblasts that produce collagen fibers, leading to liver fibrosis. Observe that the stellate sinusoidal macrophage (Kupffer cell) forms an integral part of the sinusoidal lining. *rER*, rough endoplasmic reticulum; *sER*, smooth endoplasmic reticulum.

Peroxisomes are numerous in hepatocytes.

Hepatocytes have as many as 200 – 300 **peroxisomes** per cell. They are relatively large and vary in diameter from 0.2 to 1.0 μm (Fig. 18.14a). Peroxisomes' primary function is lipid metabolism contributing to the breakdown and detoxification of fatty acids. Peroxisomes are also a major site of metabolism of reactive oxygen intermediates (ROIs). They contain many oxidative enzymes that generate toxic **hydrogen peroxide (H_2O_2)**. The enzyme catalase, also residing within peroxisomes, degrades hydrogen peroxide to oxygen and water. These reactions are involved in many detoxification processes occurring in the liver (e.g., detoxification of alcohol). In fact, about one-half of the ethanol that is ingested is converted to acetaldehyde by enzymes contained in liver peroxisomes. In humans, **catalase** and **α -amino acid oxidase**, as well as **alcohol dehydrogenase**, are found in peroxisomes. In addition, peroxisomes almost exclusively metabolize very long-chain fatty acids (**β -oxidation of very long-chain fatty acids**) and branched-chains fatty acids (**α -oxidation of branched-chain fatty acids**) and are also involved in gluconeogenesis and synthesis of bile acids, which are derived from cholesterol. For detailed description of peroxisomes see Chapter 2: Cell Cytoplasm (pages 64-65).

FIGURE 18.14. Electron micrographs of a hepatocyte. a. This electron micrograph shows organelles and other cytoplasmic structures near the nucleus (*N*), including peroxisome (*P*), mitochondrion (*M*), glycogen inclusions (*GI*), smooth endoplasmic reticulum (*sER*), and rough endoplasmic reticulum (*rER*). In the *lower left*, the membranes of the *rER* have been cut in a tangential plane showing the ribosomes (encircled by a *dashed line*) on the cytoplasmic face of the membrane. $\times 12,000$. b. This micrograph shows a region of cytoplasm near a bile canaliculus (*C*). It includes a lysosome (*L*), mitochondria (*M*), and both *sER* and *rER*. Note the microvilli in the bile canaliculus. $\times 18,000$.

Smooth endoplasmic reticulum (sER) can be extensive in hepatocytes.

The sER in hepatocytes may be extensive but varies with metabolic activity (Fig. 18.14b). The sER contains enzymes involved in the degradation and conjugation of toxins and drugs and synthesis of cholesterol and the lipid portion of lipoproteins. When challenged by drugs, toxins, or metabolic stimulants, a hepatocyte's sER may become the predominant organelle in the cell. In addition to stimulating sER activity, certain drugs and hormones induce the synthesis of new sER

membranes and their associated enzymes. The sER undergoes hypertrophy after administration of alcohol, drugs (i.e., phenobarbital, anabolic steroids, and progesterone), and certain chemotherapeutic agents used to treat cancer. Stimulation of the sER by ethanol enhances its ability to detoxify other drugs, certain carcinogens, and some pesticides but increases the hepatocyte-damaging effects of some toxic compounds, such as carbon tetrachloride (CCl₄) and 3,4-benzpyrene.

The large Golgi apparatus in hepatocytes consists of as many as 50 Golgi units.

Examination of hepatocytes with the TEM shows the **Golgi apparatus** to be much more elaborate than those seen in routine histologic specimens. Heavy metal preparations (Golgi stains) of thick sections of the liver give an indication of the extent of the Golgi network. As many as 50 Golgi units, each consisting of three to five closely stacked cisternae, plus many large and small vesicles, are found in hepatocytes. These “units” are actually the branches of the tortuous Golgi apparatus seen in heavy metal preparations. Elements of the Golgi apparatus concentrated near the bile canaliculus are believed to be associated with the exocrine secretion of bile. Golgi cisternae and vesicles near the sinusoidal surfaces of the cell, however, contain electron-dense granules 25–80 nm in diameter that are believed to be VLDL and other lipoprotein precursors. These substances are subsequently released into the circulation as part of the endocrine secretory function of the hepatocytes. Similar dense globules are seen in dilated portions of the sER and, occasionally, in the dilated ends of rER cisternae, where they are synthesized.

Lysosomes concentrated near the bile canaliculus correspond to the peribiliary dense bodies seen in histologic sections.

Hepatocyte **lysosomes** are so heterogeneous that they can only be positively identified, even at the TEM level, by histochemical means. In addition to normal lysosomal enzymes, the TEM reveals the following components:

- Pigment granules (lipofuscin)
- Partially digested cytoplasmic organelles
- Myelin figures

Hepatocyte lysosomes may also be a normal storage site for iron (as a ferritin complex) and a site of iron accumulation in certain storage diseases.

The number of lysosomes increases in a variety of pathologic conditions, ranging from simple obstructive bile stasis to viral hepatitis and anemia. However, although the range of normal liver function—particularly the rate of bile secretion—is quite wide, no statistically significant morphologic changes take place in the Golgi apparatus or lysosomes of the peribiliary cytoplasm to correlate with the rate of bile secretion.

Biliary Tree

The **biliary tree** is the three-dimensional system of channels of increasing diameter that bile flows through from the hepatocytes to the gallbladder and then to the intestine. In the adult human liver, there are more than 2 km of interconnecting bile ductules and ducts of different sizes and shapes. These structures are not only passive conduits; they are also capable of modifying bile flow and changing its composition in response to hormonal and neural stimulation.

The biliary tree is lined by cholangiocytes, which monitor bile flow and regulate its content.

Cholangiocytes are epithelial cells that line the biliary tree. Small bile ductules are lined by small cholangiocytes, mainly cuboidal in shape, but as the diameter of the bile duct increases, they become progressively larger and more columnar in shape. When examined in the TEM, cholangiocytes are identified by their organelle-scant cytoplasm, the presence of tight junctions between adjacent cells, and the presence of complete basal lamina. The apical domain of cholangiocytes appears similar to that of hepatocytes with microvilli

projecting into the lumen. In addition, each cholangiocyte contains a primary cilium that senses changes in bile flow, resulting in alterations of cholangiocyte secretion (Fig. 18.15).

FIGURE 18.15. Scanning electron micrograph of the luminal surface of the bile duct. The bile duct is lined by epithelial lining cells called *cholangiocytes*. Their apical surfaces exhibit numerous short microvilli projecting into the lumen of the bile duct. Each cholangiocyte possesses a long primary cilium, which sense changes in the luminal flow of bile. Note that all cilia are bent in the same direction of bile flow. $\times 3,600$. (Courtesy of Dr. Tetyana V. Masyuk.)

The bile canaliculus is a small canal formed by apposed grooves on the surface of adjacent hepatocytes.

The smallest branches of the biliary tree are the **bile canaliculi** into which the hepatocytes secrete bile. They form

a complete loop around four sides of the idealized six-sided hepatocyte (Fig. 18.16 and Plate 18.2, page 724). They are approximately 0.5 μm in luminal diameter and are isolated from the rest of the intercellular compartment by tight junctions, which form part of a junctional complex that also includes zonulae adherentes and desmosomes. Microvilli of the two adjacent hepatocytes extend into the canalicular lumen. Adenosine triphosphatase (ATPase) and other alkaline phosphatases may be localized on the plasma membranes of the canaliculi, suggesting that bile secretion into this space is an active process. Bile flow is centrifugal, that is, from the region of the terminal hepatic venule (central vein) toward the portal canal (a direction opposite to the blood flow). Near the portal canal but still within the lobule, bile canaliculi transform into the short **canals of Hering**.

FIGURE 18.16. Photomicrograph of bile canaliculi. This high-magnification photomicrograph shows several one-cell-thick plates of hepatocytes separated by hepatic sinusoids. The plane of section in certain areas is parallel to the bile canaliculi. In this plane, the

canaliculi reveal their arrangement on four sides of the hepatocytes (*arrows*). *Arrowheads* indicate those bile canaliculi that appear only in cross-sectional profile. $\times 1,240$.

A characteristic feature of the canal of Hering is its lining composed of two types of cells, hepatocytes and cholangiocytes.

The **canal of Hering** is a channel partially lined by hepatocytes and partially by cuboidal-shaped cholangiocytes. Similar to cholangiocytes, hepatocytes possess microvilli at their apical surface and tight junctions, and their basal domain rests on a basal lamina, which is characteristic of the entire distal biliary epithelium. Functionally, as demonstrated by video microscopy, the canal of Hering exhibits contractile activity that assists with unidirectional bile flow toward the portal canal. *Because the canal of Hering represents the smallest and most proximal tributary of the biliary tree containing cholangiocytes, it is often involved in the same diseases that affect small bile ducts. Functional disturbances in contractile activity as well as injury or destruction of the canals of Hering may contribute to intrahepatic cholestasis (obstruction of the bile flow).*

The canal of Hering serves as a reservoir for liver progenitor cells.

Owing to their location at the crucial interface between hepatocytes and cholangiocytes, it has been proposed that **hepatic stem cells** are present either in the canals of Hering or in their vicinity. This hypothesis is supported by the appearance of liver cell precursors near the canals of Hering in most pathologic conditions characterized by extensive damage to hepatocytes. These cells would then migrate and differentiate into either hepatocytes or bile duct cells. The three-dimensional reconstruction of ductular reactions in liver necrosis suggests that small cholangiocytes lining the canals of Hering proliferate extensively and migrate into the parenchyma of the liver. In immunocytochemical staining, these cells express dual markers of both biliary and hepatocyte

antigens and appear to be involved in the repair of liver tissue damaged by chronic pathologic processes. The presence of hepatic stem cells in this location has several clinical implications. For example, laboratory studies suggest that in future, hepatic stem cells may ultimately be used therapeutically in the treatment of liver diseases.

The bile ductule is the part of the biliary tree that is lined entirely by cholangiocytes.

Bile from the canal of Hering continues to flow into the intrahepatic bile ductule (see Fig. 18.12), which is lined entirely by cholangiocytes. Three-dimensional analysis of immunocytochemical-stained serial sections of the liver reveals that the canal of Hering often crosses the boundary of the lobule and continues as a bile ductule in the periportal space (of Mall) (see Figs. 18.4 and 18.12). The main distinction between the canal of Hering and the bile ductule is not its location within the lobule but whether the structure is partially or completely lined by cholangiocytes.

Intrahepatic bile ductules carry bile to hepatic ducts.

Intrahepatic bile ductules have a diameter of about 1.0–1.5 μm and carry bile to the interlobular bile ducts that form part of the portal triad. Interlobular bile ducts range from 15 to 40 μm in diameter and are lined by cholangiocytes that are cuboidal near the lobules and gradually become columnar as the ducts near the porta hepatis. The columnar cells have well-developed microvilli, as do those of the extrahepatic bile ducts and gallbladder. As the bile ducts get larger, they gradually acquire a dense connective tissue investment containing numerous elastic fibers. Smooth muscle cells appear in this connective tissue as the ducts approach the hilum. Interlobular ducts join to form the right and left hepatic ducts, which, in turn, join at the hilum to form the common hepatic duct (Fig. 18.17).

FIGURE 18.17. Diagram showing the relationship of hepatic, pancreatic, and gallbladder ducts. The gallbladder is a blind pouch joined to a single cystic duct in which numerous mucosal folds form the spiral valve (of Heister). The cystic duct joins with the common hepatic duct, and together they form the common bile duct that leads into the duodenum. At the entry to the duodenum, the common bile duct is joined by the main pancreatic duct (of Wirsung) to form the hepatopancreatic ampulla (of Vater), and together they enter the second part of the duodenum. Sphincters can be found at the distal part of these ducts. The sphincters of the common bile duct (of Boyden), the main pancreatic duct, and the hepatopancreatic ampulla

(of Oddi) control the flow of bile and pancreatic secretion into the duodenum. When the common bile duct sphincter contracts, bile cannot enter the duodenum; it backs up and flows into the gallbladder, where it is concentrated and stored.

In some individuals, the **ducts of Luschka** are located in the connective tissue between the liver and the gallbladder, near the neck of the gallbladder. These ducts connect with the cystic duct, not with the lumen of the gallbladder. They are histologically similar to the intrahepatic bile ducts and may be remnants of aberrant embryonic bile ducts.

Extrahepatic bile ducts carry bile to the gallbladder and duodenum.

The **common hepatic duct** is about 3 cm long and is lined with tall columnar epithelial cells that closely resemble those of the gallbladder. All of the layers of the alimentary canal (see pages 632–633) are represented in the duct, except the muscularis mucosae. The **cystic duct** connects the common hepatic duct to the gallbladder. It has numerous spirally arranged mucosal folds that form the **spiral valve (of Heister)**. The cystic duct carries bile into and out of the **gallbladder**. The duct and spiral valve contain smooth muscle fibers responsive to pharmacologic, hormonal, and neural stimuli. However, there is no histologic evidence of a sphincter muscle in the cystic duct, which mainly functions as a passive conduit for bile. Distal to the junction with the cystic duct, the fused duct is called the **common bile duct** and extends for about 7 cm to the wall of the duodenum at the **hepatopancreatic ampulla (of Vater)**. Immediately proximal to the hepatopancreatic ampulla, a thickening in the circular layer of smooth muscle fibers, forms the **sphincter of the common bile duct (of Boyden)**, which controls the flow of bile into the ampulla. In addition, a thickening of the muscularis externa of the duodenum at the ampulla constitutes the **sphincter of the hepatopancreatic ampulla (of Oddi)**, which projects into the lumen of the duodenum as the **major duodenal papilla**. Because the hepatopancreatic ampulla (of Vater) contains openings for the common bile duct and the **pancreatic**

duct, it acts as a valve to regulate the flow of bile and pancreatic juice into the duodenum.

The adult human liver secretes, on average, about 1 L of bile a day.

The bile fulfills two major functions. It is involved in the **absorption of fat** and is used by the liver as a vehicle for **excretion of cholesterol, bilirubin, iron, and copper**. The composition of bile and the specific functions of most of its components are listed in Table 18.1. As noted in the table, the following components of the bile are recycled via the portal circulation:

- About 90% of the **bile salts**, a component of bile, are reabsorbed by the gut and transported back to the liver in the portal blood. The bile salts are then reabsorbed and secreted by hepatocytes. Hepatocytes also synthesize new bile salts to replace those that are lost.
- **Cholesterol** and the phospholipid **lecithin**, as well as most of the **electrolytes** and water delivered to the gut with the bile, are also reabsorbed and recycled.

Bilirubin glucuronide, the detoxified end product of hemoglobin breakdown, is not recycled. It is excreted with the feces and gives them their color. Failure to absorb bilirubin or failure to conjugate it or secrete glucuronide can produce **jaundice**.

Bile flow from the liver is regulated by hormonal and neural control. The rate of blood flow to the liver and the concentration of bile salts in the blood exert regulatory effects on bile flow. Bile flow is increased when hormones such as cholecystokinin (CCK), gastrin, and motilin are released by enteroendocrine cells during digestion. Steroid hormones (i.e., estrogen during pregnancy) decrease bile secretion from the liver. In addition, parasympathetic stimulation increases bile flow by prompting contraction of the gallbladder and relaxation of the sphincter of the hepatopancreatic ampulla (of Oddi). Bile that leaves the liver via the common hepatic duct flows

through the cystic duct to the gallbladder. Following stimulation, the gallbladder contracts steadily and delivers the bile to the duodenum via the common bile duct.

The liver has both sympathetic and parasympathetic innervations.

The liver (and gallbladder) receives nerves from both sympathetic and parasympathetic divisions of the autonomic nervous system. The nerves enter the liver at the porta hepatis and ramify through the liver in the portal canals along with the members of the portal triad. **Sympathetic fibers** innervate blood vessels, and increased stimulation in this system causes an increase in vascular resistance, decreased hepatic blood volume, and a rapid increase in serum levels of glucose. **Parasympathetic fibers** are assumed to innervate the large ducts (those that contain smooth muscle in their walls) and possibly blood vessels; their stimulation promotes glucose uptake and utilization. The cell bodies of parasympathetic neurons are often present near the porta hepatis.

■ GALLBLADDER

The **gallbladder** is a pear-shaped, distensible sac with a volume of about 50 mL in humans (see Fig. 18.17). It is attached to the visceral surface of the liver. The gallbladder is a secondary derivative of the embryonic foregut, arising as an evagination of the primitive bile duct that connects the embryonic liver to the developing intestine.

The gallbladder concentrates and stores bile.

The gallbladder is a blind pouch that leads, via a neck, to the cystic duct. Through this duct, it receives dilute bile from the hepatic duct. The gallbladder can store and remove about 90% of the water from the incoming bile, which results in an increase in bile salts, cholesterol, and bilirubin concentrations up to 10-fold. Hormones secreted by the enteroendocrine cells of the small intestine, in response to

the presence of fat in the proximal duodenum, stimulate contractions of the smooth muscle of the gallbladder. These contractions help discharge concentrated bile into the common bile duct, which carries it to the duodenum.

The mucosa of the gallbladder has several characteristic features.

The empty or partially filled gallbladder has numerous deep **mucosal folds** (Fig. 18.18). The mucosal surface consists of **simple columnar epithelium** (Fig. 18.19). The tall epithelial cells (cholangiocytes) exhibit the following features:

FIGURE 18.18. Photomicrograph of the wall of the gallbladder. The mucosa of the gallbladder consists of a lining of simple columnar epithelial cells and a lamina propria of loose connective tissue, which typically exhibits numerous deep folds in the mucosa. Beneath this layer is a relatively thick layer, the muscularis externa. There is no muscularis mucosa or submucosa. The smooth muscle bundles of the muscularis externa are randomly oriented. External to the muscle is an

adventitia containing adipose tissue and blood vessels. The portion of the gallbladder not attached to the liver displays a typical serosa instead of an adventitia. $\times 175$.

FIGURE 18.19. Electron micrographs of gallbladder epithelium. a. The tall columnar cells display features typical of absorptive cells, with microvilli on their apical surface, an apical junctional complex separating the lumen of the gallbladder from the lateral intercellular space, and numerous mitochondria in the apical portion

of the cell. $\times 3,000$. b. During active fluid transport, salt is pumped from the cytoplasm into the intercellular space, and water follows the salt. Both salt and water then diffuse into the cell from the lumen. As this process continues, the intercellular space becomes greatly distended (*arrows*). Fluid moves from the engorged intercellular space (*arrows*) across the basal lamina into the underlying connective tissue (CT) and then into blood vessels. The increase in the size of the lateral intercellular space during active fluid transport is evident with the light microscope. $\times 3,000$.

- Numerous but short and not well-developed apical **microvilli**
- Apical **junctional complexes** that join adjacent cells and form a barrier between the lumen and the intercellular compartment
- Localized concentrations of **mitochondria** in the apical and basal cytoplasm
- Complex **lateral plications**

These cells closely resemble the absorptive cells of the intestine. In addition to sharing the abovementioned characteristics, the lateral plasma membranes of both cells contain Na^+/K^+ -activated ATPase and their apical cytoplasm feature secretory vesicles filled with glycoproteins.

The **lamina propria** of the mucosa is particularly rich in fenestrated capillaries and small venules, but there are no lymphatic vessels in this layer. The lamina propria is also very cellular, containing large numbers of lymphocytes and plasma cells. The characteristics of the lamina propria resemble those of the colon, another organ specialized for the absorption of electrolytes and water.

Mucin-secreting glands are sometimes present in the lamina propria in the normal human gallbladder, especially near the neck of the organ, but they are more commonly found in inflamed gallbladders. Cells that appear identical to enteroendocrine cells of the intestine are also found in these glands.

The wall of the gallbladder lacks a muscularis mucosa and submucosa.

External to the lamina propria is a **muscularis externa** that has numerous collagen and elastic fibers among the bundles of

smooth muscle cells. Despite its origin as a foregut-derived tube, the gallbladder does not have a muscularis mucosa or submucosa. The smooth muscle bundles are somewhat randomly oriented, unlike the layered organization of the intestine. Contraction of the smooth muscle reduces the volume of the bladder, forcing its contents out through the cystic duct.

External to the muscularis externa is a thick layer of dense connective tissue (see Fig. 18.18). This layer contains large blood vessels, an extensive lymphatic network, and the autonomic nerves that innervate the muscularis externa and the blood vessels (cell bodies of parasympathetic neurons are found in the wall of the cystic duct). The connective tissue is also rich in elastic fibers and adipose tissue. The layer of tissue where the gallbladder attaches to the liver surface is referred to as the **adventitia**. The unattached surface is covered by a **serosa** or visceral peritoneum consisting of a layer of mesothelium and a thin layer of loose connective tissue.

In addition, deep diverticula of the mucosa, called **Rokitansky - Aschoff sinuses**, sometimes extend through the muscularis externa (Fig. 18.20 and Plate 18.3, page 726). They are thought to presage pathologic changes and develop as the result of hyperplasia (excessive growth of cells) and herniation of epithelial cells through the muscularis externa. Also, bacteria may accumulate in these sinuses, causing chronic inflammation that is a risk factor for the formation of gallstones.

FIGURE 18.20. Photomicrograph of the Rokitansky - Aschoff sinuses in the wall of the gallbladder. This photomicrograph shows

deep invaginations of the mucosa extending into the muscularis externa. These invaginations are referred to as *Rokitansky-Aschoff sinuses*. $\times 120$.

Concentration of the bile requires the coupled transport of salt and water.

The epithelial cells of the gallbladder **actively transport Na^+ , Cl^- , and HCO_3^-** from the cytoplasm into the intercellular compartment of the epithelium. ATPase is located in the lateral plasma membranes of the epithelial cells. This active transport mechanism is essentially identical to that described in Chapter 17, Digestive System II: Esophagus and Gastrointestinal Tract (Folder 17.4, page 648), for the enterocytes of the small intestine and the absorptive cells of the colon. The epithelial cells of the gallbladder also express two types of **aquaporin water channels** (AQP1 and AQP8), integral membrane channel proteins that facilitate rapid passive movement of water (see Chapter 20, Urinary System, Folder 20.5, page 791). The presence of water channels on apical and basolateral plasma membranes of the gallbladder epithelial cells suggests that they may be involved in both water absorption and secretion.

Electrolytes are actively transported across the plasma membrane of epithelial cells of the gallbladder.

Active transport of Na^+ , Cl^- , and HCO_3^- across the lateral plasma membrane into the intercellular (paracellular) compartment causes the concentration of electrolytes in the intercellular space to increase. The increased electrolyte concentration creates an osmotic gradient between the intercellular space and the cytoplasm and between the intercellular space and the lumen. Water moves from the cytoplasm and from the lumen into the intercellular space because of the osmotic gradient (i.e., it moves down its concentration gradient; see Fig. 18.19b). Although the intercellular space can distend to a degree often visible with the light microscope, this ability is limited. The movement of electrolytes and water into the space creates hydrostatic pressure that forces a nearly isotonic fluid out of the

intercellular compartment into the subepithelial connective tissue (the lamina propria). The fluid that enters the lamina propria quickly passes into the numerous fenestrated capillaries and venules that closely underlie the epithelium.

Studies of fluid transport in the gallbladder first demonstrated the essential role of the intercellular compartment in transepithelial transport of an isotonic fluid from the lumen to the vasculature. The final modification of bile is mainly the result of the active transport of Na^+ , Cl^- , and HCO_3^- and the passive, aquaporin-mediated transport of water across the plasma membrane of epithelial cells of the gallbladder.

■ PANCREAS

Overview

The **pancreas** is an elongated gland described as having a head, body, and tail. The **head** is an expanded portion that lies in the C-shaped curve of the duodenum (Fig. 18.21). It is joined to the duodenum by connective tissue. The centrally located **body** of the pancreas crosses the midline of the human body, and the **tail** extends toward the hilum of the spleen. The **pancreatic duct (of Wirsung)** extends through the length of the gland and empties into the duodenum at the **hepatopancreatic ampulla (of Vater)**, through which the common bile duct from the liver and gallbladder also enters the duodenum. The **hepatopancreatic sphincter (of Oddi)** surrounds the ampulla, and it not only regulates the flow of bile and pancreatic juice into the duodenum but also prevents reflux of intestinal contents into the pancreatic duct. In some individuals, an **accessory pancreatic duct (of Santorini)** is present, a vestige of the pancreas' origin from two embryonic endodermal primordia that evaginate from the foregut.

FIGURE 18.21. Diagram of pancreas, duodenum, and associated excretory ducts. The main pancreatic duct (of Wirsung) traverses the length of the pancreas and enters the duodenum after joining with the common bile duct. An accessory pancreatic duct (of Santorini) is commonly present, as shown, and empties into the duodenum at a separate minor duodenal papilla. The site of entry of the common bile duct and main pancreatic duct into the duodenum is typically marked by a major duodenal papilla visible on the inner surface of the duodenum.

A thin layer of loose connective tissue forms a capsule around the gland. From this capsule, septa extend into the gland, dividing it into ill-defined lobules. Within the

lobules, a stroma of loose connective tissue surrounds the parenchymal units. Between the lobules, larger amounts of connective tissue surround the larger ducts, blood vessels, and nerves. In the connective tissue surrounding the pancreatic duct, small mucous glands are present that empty into the duct.

The pancreas is an exocrine and endocrine gland.

Unlike the liver, in which the exocrine and secretory (endocrine) functions reside in the same cell, the dual functions of the pancreas are relegated to two structurally distinct components:

- The **exocrine component** synthesizes and secretes enzymes into the duodenum that are essential for digestion in the intestine.
- The **endocrine component** synthesizes and secretes the hormones **insulin** and **glucagon** into the blood. These hormones regulate glucose, lipid, and protein metabolism in the body.

The exocrine pancreas is found throughout the organ; within the exocrine pancreas, distinct cell masses called **islets of Langerhans** are dispersed and constitute the endocrine pancreas.

Exocrine Pancreas

The exocrine pancreas is a serous gland.

Histologically, the **exocrine pancreas** closely resembles the parotid gland, with which it can be confused. The secretory units are acinar or tubuloacinar in shape and are formed by a simple epithelium of pyramidal serous cells (Fig. 18.22a and Plate 18.4, page 728). The cells have a narrow free (luminal) surface and a broad basal surface. Periacinar connective tissue is minimal.

FIGURE 18.22. Pancreatic acinus and its duct system. **a.** In this photomicrograph of a thin, hematoxylin and eosin (H&E)-stained plastic section, an intercalated duct can be seen originating within a pancreatic acinus. The cells forming the duct within the acinus are the centroacinar cells. The eosinophilic zymogen granules are clearly seen in the apical cytoplasm of the parenchymal cells. $\times 860$. **b.** In this schematic diagram, observe the origin of the intercalated duct. Note the location and shapes of the centroacinar cells within the acinus. They represent the initial lining of the intercalated duct, which drains into an intralobular collecting duct.

The serous secretory cells of the acinus produce the digestive enzyme precursors secreted by the pancreas. **Pancreatic acini** are unique among glandular acini; the initial duct that leads from the acinus, the **intercalated duct**, actually begins within the acinus (Figs. 18.22b and 18.23). The

duct cells located inside the acinus are referred to as **centroacinar cells**.

FIGURE 18.23. Electron micrograph of the pancreatic acinus and intercalated duct. Note that the pancreatic acinus is formed from pyramidal acinar cells. Their basal area contains nucleus surrounded by extensive rough endoplasmic reticulum (*rER*) and Golgi apparatus. The apical portion exhibits well-preserved zymogen granules. The origin of the intercalated duct lined by the centroacinar cells is visible on this electron micrograph. $\times 5,800$. (Courtesy of Dr. Holger Jastrow.)

Acinar cells are characterized by distinct basophilia in the basal cytoplasm and acidophilic **zymogen granules** in the apical cytoplasm (see Figs. 18.22a and 18.23). Zymogen granules are most numerous in the pancreas of fasting individuals. The squamous centroacinar cells lack both ergastoplasm and secretory granules (see Fig. 18.23); thus, they stain very lightly with eosin. This weak staining helps identify them in routine histologic sections.

Zymogen granules contain a variety of digestive enzymes in an inactive form.

Pancreatic enzymes can digest most food substances. The inactive enzymes, or proenzymes, contained in pancreatic zymogen granules are listed here along with the specific substances they digest when activated:

- **Proteolytic endopeptidases** (trypsinogen, chymotrypsinogen) and **proteolytic exopeptidases** (procarboxypeptidase, proaminopeptidase) digest proteins by cleaving their internal peptide bonds (endopeptidases) or by cleaving amino acids from the carboxyl or amino end of the peptide.
- **Amylolytic enzymes** (α -amylase) digest carbohydrates by cleaving the glycosidic linkages of glucose polymers.
- **Lipases** digest lipids by cleaving ester bonds of triglycerides, producing free fatty acids.
- **Nucleolytic enzymes** (deoxyribonuclease and ribonuclease) digest nucleic acids, producing mononucleotides.

The **pancreatic digestive** enzymes are activated only after they reach the lumen of the small intestine. Initially, proteolytic activity of **enterokinases** in the glycocalyx of the

microvilli of the intestinal absorptive cells converts trypsinogen to **trypsin**, another potent proteolytic enzyme. Trypsin then catalyzes the conversion of the other inactive enzymes as well as the digestion of proteins in the chyme.

The cytoplasmic basophilia of the pancreatic acinar cells when observed with the TEM appears as an extensive array of rER and free ribosomes. The presence of these numerous organelles correlates with the high level of protein synthetic activity of the acinar cells (Fig. 18.24). A well-developed Golgi apparatus is present in the apical cytoplasm and is involved in concentration and packaging of the secretory products. Mitochondria are small and, although found throughout the cell, are concentrated among the rER cisternae. Acinar cells are joined to one another by **junctional complexes** at their apical poles, thus forming an isolated lumen into which small microvilli extend from the apical surfaces of the acinar cells and into which the zymogen granules are released by exocytosis.

FIGURE 18.24. Electron micrograph of the apical cytoplasm of several pancreatic acinar cells. One pancreatic acinar cell is outlined by the *dashed line*. Nuclei (*N*) of adjoining cells are evident at the *bottom left* and *right* of the electron micrograph. The apical cytoplasm contains extensive rough endoplasmic reticulum (*rER*), mitochondria (*M*), zymogen-containing secretory granules (*Z*), and Golgi profiles (*G*). At the apices of these cells, a lumen (*L*) is present,

into which the zymogen granules are discharged. A junctional complex (*JC*) is indicated near the lumen. $\times 20,000$.

Duct System of the Exocrine Pancreas

The centroacinar cells (see Figs. 18.22a and 18.23) are the sites where the duct system of the exocrine pancreas arises. They have a centrally placed, flattened nucleus and attenuated cytoplasm, which is typical of a squamous cell.

Centroacinar cells are intercalated duct cells located in the acinus.

Centroacinar cells are continuous with the cells of the short intercalated duct that lies outside the acinus. The structural unit of the acinus and centroacinar cells resembles a small balloon (the acinus) into which a drinking straw (the intercalated duct) has been pushed. The **intercalated ducts** are short and drain into intralobular collecting ducts. There are no striated (secretory) ducts in the pancreas.

The complex, branching network of intralobular ducts drains into the larger **interlobular ducts**, which are lined with a low columnar epithelium in which enteroendocrine cells and occasional goblet cells may be found. The interlobular ducts, in turn, drain directly into the **main pancreatic duct (of Wirsung)**, which runs the length of the gland parallel to its long axis, giving this portion of the duct system a herringbone-like appearance (see Fig. 18.21). A second large duct, the **accessory pancreatic duct (of Santorini)**, arises in the head of the pancreas.

The intercalated ducts add bicarbonate and water to the exocrine secretion.

The pancreas secretes about 1 L of fluid per day, about equal to the initial volume of the hepatic bile secretion. Whereas bile is concentrated in the gallbladder, the entire volume of the pancreatic secretion is delivered to the duodenum. Although the acini secrete a small volume of protein-rich fluid, the **intercalated duct cells** secrete a large volume of fluid rich

in sodium and bicarbonate. The bicarbonate serves to neutralize the acidity of the chyme that enters the duodenum from the stomach and to establish the optimal pH for the activity of the major pancreatic enzymes.

Pancreatic exocrine secretion is under hormonal and neural control.

Two hormones secreted by the enteroendocrine cells of the duodenum, **secretin** and **cholecystokinin (CCK)**, are the principal regulators of the exocrine pancreas (see Table 17.1, page 646). Entry of the acidic chyme into the duodenum stimulates the release of the following hormones into the blood:

- **Secretin**, a polypeptide hormone (27 amino acid residues) that stimulates the duct cells to secrete a large volume of fluid with a high HCO_3^- concentration but little or no enzyme content
- **Cholecystokinin (CCK)**, a polypeptide hormone (33 amino acid residues) that causes the acinar cells to secrete their proenzymes

The coordinated action of the two hormones results in the secretion of a large volume of enzyme-rich, alkaline fluid into the duodenum. In addition to hormonal influences, the pancreas also receives autonomic innervation. Sympathetic nerve fibers are involved in the regulation of pancreatic blood flow. Parasympathetic fibers stimulate activity of acinar as well as centroacinar cells. Cell bodies of neurons occasionally seen in the pancreas belong to parasympathetic postganglionic neurons.

Endocrine Pancreas

The endocrine pancreas is a diffuse organ that secretes hormones that regulate blood glucose levels.

The **islets of Langerhans**, the **endocrine component** of the pancreas, are scattered throughout the organ in cell groupings of varying size (Fig. 18.25). It is estimated that 1–3 million

islets constitute about 1% - 2% of the volume of the human pancreas but are most numerous in the tail. Individual islets may contain only a few cells or many hundreds of cells (Plate 18.4, page 728). Their polygonal cells are arranged in short, irregular cords that are profusely invested with a network of fenestrated capillaries. The definitive endocrine cells of the islets develop between 9 and 12 weeks of gestation.

FIGURE 18.25. Photomicrograph of the pancreas. This hematoxylin and eosin (H&E)-stained specimen shows many pancreatic lobules separated by connective tissue septa that are continuous with the thin surrounding capsule of the gland. The pancreatic lobules consist largely of the exocrine acini and their intralobular duct system. Most of the lobules exhibit small, round, lighter staining profiles, which are the islets of Langerhans (*arrows*). Adjacent to the lobules, at the

lower left, is a large interlobular duct that serves the exocrine pancreas. ×25.

In H&E-stained sections, the islets of Langerhans appear as clusters of pale-staining cells surrounded by more intensely staining pancreatic acini. It is not practical to attempt to identify the several cell types found in the islets in routinely prepared specimens (Fig. 18.26). After Zenker-formol fixation and staining by the Mallory-Azan method, however, it is possible to identify three principal cell types designated **A (α, alpha)**, **B (β, beta)**, and **D (δ, delta) cells** (Table 18.2). With this method, the A cells stain red, the B cells stain brownish orange, and the D cells stain blue. About 5% of the cells appear to be unstained after this procedure. TEM allows identification of the principal cell types by the size and density of their secretory granules. Different makeup of cells in the islets of Langerhans can also be demonstrated by using the immunofluorescence method (Fig. 18.27).

TABLE 18.2

Principal Cell Types in Pancreatic Islets

Cell Type	%	Cytoplasmic Staining with Mallory-Azan	Product	Granules (TEM)
A	15–20	Red	Glucagon	About 250 nm; dense, eccentric core surrounded by a light substance
B	60–70	Brownish orange	Insulin	About 300 nm; many with a dense, crystalline (angular) core surrounded by a light substance
D	5–10	Blue	Somatostatin	About 325 nm; homogeneous matrix

TEM, transmission electron microscope.

FIGURE 18.26. Photomicrographs of islets of Langerhans. **a.** In this routine hematoxylin and eosin (H&E) preparation, it is difficult to identify specific islet cell types without special stains. At best, one can identify small cells (*arrows*) at the periphery of the islet that are probably A cells. $\times 360$. **b.** This photomicrograph shows an islet of Langerhans obtained from a rat pancreas stained with a special Grimelius silver stain that reacts with glucagon-secreting cells. The silver-impregnated A cells in the rat pancreas are arranged around the periphery of the islet, which is not the case in the human pancreas. $\times 360$.

FIGURE 18.27. Islet of Langerhans in human adult pancreas. This immunofluorescence image shows the islet of Langerhans and distribution of glucagon-secreting A cells (*green*) and insulin-secreting B cells (*red*) in the adult pancreas. Cells were counterstained with a 4',6-diamidino-2-phenylindole (DAPI) stain that reacts with nuclear DNA and exhibits blue fluorescence over the nuclei. Note that B cells comprise most of the islet cells and A cells are scattered throughout the islets. $\times 280$. (From Scharfmann R, Xiao X, Heimberg H, et al. Beta cells within single human islets originate from multiple progenitors. *PLoS ONE*. 2008;2:e3559.)

In addition to the three principal islet cells, three minor islet cell types have also been identified by using a combination of the TEM and immunocytochemistry (Table 18.3).

TABLE 18.3 Minor Cell Types in Pancreatic Islets			
Cell Type	Secretion	Location (in	Actions

Addition to Islet)			
PP cell (F cell)	Pancreatic polypeptide		Stimulates gastric chief cells Inhibits bile secretion and intestinal motility Inhibits pancreatic enzymes and HCO_3^- secretion
D ₁ cell	Vasoactive intestinal peptide (VIP)	Also in exocrine acini and duct epithelium ^a	Similar to those of glucagon (hyperglycemic and glycogenolytic) Affects secretory activity and motility in gut Stimulates pancreatic exocrine secretion
EC cell	Secretin, motilin, substance P	Also in exocrine acini and duct epithelium ^a	Secretin: acts locally to stimulate HCO_3^- secretion in pancreatic juice and pancreatic enzyme secretion Motilin: increases gastric and intestinal motility Substance P: has neurotransmitter properties
Epsilon cell	Ghrelin	Epithelium lining the fundus of the stomach ^b	Stimulates appetite

PP, protein polypeptide; EC, enterochromaffin cell.

^aThis localization further emphasizes the ontogeny of the pancreas from the embryonic gut.

^bGhrelin is produced in the stomach by P/D₁ (G_R) cells.

Except for B cells, islet cells are counterparts of the enteroendocrine cells of the gastrointestinal mucosa.

Each islet cell type can be correlated with a specific hormone, and each has a specific location in the islet.

B cells constitute approximately 60%–70% of the total islet cells in humans and are generally located in its central

portion. They secrete **insulin** (see Table 18.2). B cells contain numerous secretory granules about 300 nm in diameter with a dense polyhedral core and a pale matrix. The polyhedral core is believed to be crystallized insulin.

A cells constitute approximately 15%–20% of the human islet population and are generally located peripherally in the islets. They secrete **glucagon** (see Table 18.2). A cells contain secretory granules about 250 nm in diameter that are more uniform in size and more densely packed in the cytoplasm than the granules of B cells. The granules are sites of stored glucagon (Fig. 18.28).

FIGURE 18.28. Electron micrograph of pancreatic islet cells. The portion of the cell in the *upper part* of the illustration is an A cell. It contains characteristic granules (*arrows*) showing a dense spherical core surrounded by a clear area and then a membrane. This cell also displays a characteristically well-developed Golgi apparatus. The cell at the *bottom* of the illustration is a D cell. It contains numerous membrane-bound granules of moderately low density (*arrowheads*). $\times 15,000$.

D cells constitute about 5% - 10% of the total pancreatic endocrine tissue and are also located peripherally in the islets. D cells secrete **somatostatin**, which is contained in secretory granules that are larger than those of the A and B cells (300 - 350 nm) and contain material of low to medium electron density (see Fig. 18.28).

The **minor islet cells** constitute about 5% of the islet tissue and may be represented by the pale cells seen after Mallory-Azan staining. Their characteristics and functions are summarized in Table 18.3.

Evidence suggests that some cells may secrete more than one hormone. Immunocytochemical staining has localized several hormones in addition to glucagon in the A-cell cytoplasm. These include gastric inhibitory peptide (GIP), cholecystokinin (CCK), and adrenocorticotrophic hormone (ACTH) endorphin. Although there is no clear morphologic evidence for the presence of G cells (gastrin cells) in the islets, gastrin may also be secreted by one or more of the islet cells. Certain pancreatic islet cell tumors secrete large amounts of gastrin, thereby producing excessive acid secretion in the stomach (Zollinger - Ellison syndrome).

Functions of pancreatic hormones

Hormones secreted by the endocrine pancreas regulate metabolic functions either systemically, regionally (in the gastrointestinal tract), or locally (in the islet itself).

Insulin, the major hormone secreted by the islet tissue, decreases blood glucose levels.

Insulin is the most abundant endocrine secretion. Its principal effects are on the liver, skeletal muscle, and adipose tissue. Insulin has multiple individual actions in each of these tissues. In general, insulin stimulates the following processes:

- **Uptake of glucose** from the circulation. Specific cell membrane glucose transporters (GLUT4) are upregulated and

inserted into the cell membrane of skeletal muscle cells and adipocytes.

- **Storage of glucose** by activation of glycogen synthase and inhibition of glycogen phosphorylase in muscle cells and liver. These actions lead to subsequent **glycogen** synthesis (**glycogenesis**).
- **Utilization of glucose** by promotion of **glycolysis** within cells. This is achieved by activation of pyruvate dehydrogenase and phosphofructokinase in skeletal muscle cells and liver.
- **Breakdown of chylomicrons** and other LDLs into free fatty acids by activation of lipoprotein lipase (LPL). The increased level of free fatty acids increases triglycerides, leading to the formation of lipid droplets (**lipogenesis**).
- **Synthesis of proteins** in skeletal muscle cells and hepatocytes by increasing cellular uptake of amino acids and activation of the mammalian target of rapamycin (mTOR) pathway, which stimulates ribosomal production and decreases cellular proteolysis

Absence or inadequate amounts of **insulin** lead to elevated blood glucose levels and the presence of glucose in the urine, a condition known as **diabetes mellitus**. Diabetes mellitus is a worldwide public health crisis and affects about 8.3% of the U.S. population. Complications of diabetes mellitus can be cardiovascular (endothelial cells dysfunction with damage to their basement membrane; e.g., hypertension, heart disease, and stroke), renal, retinopathic, or neuropathic. Reduced expression of insulin and insulin growth factors in the central nervous system (CNS) has been linked to Alzheimer disease (Folder 18.3).

FOLDER 18.3

CLINICAL CORRELATION: INSULIN PRODUCTION AND ALZHEIMER DISEASE

Insulin and **insulin growth factors** (IGF-I and IGF-II) are expressed by nerve cells in several regions of the brain. Insulin resistance, a characteristic of diabetes mellitus, is linked to neural degeneration, cognitive dysfunction, and dementia. The

reduced rate of insulin and IGF production in the brain contributes to the degeneration of brain cells, an early symptom of **Alzheimer disease (AD)**. Postmortem examination of the brain tissue from individuals diagnosed with AD confirms that levels of insulin and IGFs are significantly reduced in the hippocampus (the part of the brain responsible for memory), frontal lobes, and hypothalamus, but not in the cerebellum (which is generally not affected by AD). Further research into these abnormalities in insulin production may lead to the development of novel AD therapies that target insulin and IGF.

Glucagon, secreted in amounts second only to insulin, increases blood glucose levels.

The actions of **glucagon** are essentially reciprocal to those of insulin. Glucagon stimulates the release of glucose into the bloodstream and stimulates **gluconeogenesis** (synthesis of glucose from metabolites of amino acids) and **glycogenolysis** (breakdown of glycogen) in the liver. Glucagon also stimulates proteolysis to promote gluconeogenesis, mobilizes fats from adipose cells (**lipolysis**), and stimulates hepatic lipase.

Somatostatin inhibits insulin and glucagon secretion.

Somatostatin is secreted by the D cells of the islets. It is identical to the hormone secreted by the hypothalamus that regulates somatotropin (GH) release from the anterior pituitary gland. Although the precise role of somatostatin in the islets is unclear, it has been shown to inhibit both insulin and glucagon secretion. It also suppresses the exocrine secretion of the pancreas.

The molecular characteristics of the major and some minor islet hormones are summarized in Table 18.4.

TABLE 18.4 Characteristics of Pancreatic Hormones

Hormone	Molecular Weight (Daltons)	Structure
Insulin	5,700 - 6,000	Two protein chains linked by disulfide bridges: α -chain, 21 amino acids; β -

		chain, 30 amino acids
Glucagon	3,500	Linear polypeptide: 29 amino acids
Somatostatin	1,638	Cyclic polypeptide: 14 amino acids
VIP	3,300	Linear polypeptide: 28 amino acids
Pancreatic polypeptide	4,200	Linear polypeptide: 36 amino acids

VIP, vasoactive intestinal peptide.

Regulation of islet activity

A **blood glucose level** above the normal 70 mg/100 mL (70 mg/dL) stimulates the release of insulin from β cells, leading to uptake and storage of glucose by the liver and muscle. The resultant decrease in the blood glucose level stops insulin secretion. Some amino acids also stimulate insulin secretion, either alone or in concert with elevated blood glucose levels. Increased blood fatty acid levels also stimulate insulin release, as do circulating gastrin, CCK, and secretin. CCK and glucagon, released in the islet by the A cells, act as paracrine secretions to stimulate B-cell secretion of insulin.

Blood glucose levels below 70 mg/100 mL stimulate the release of glucagon; blood glucose levels significantly above 70 mg/100 mL inhibit glucagon secretion. Glucagon is also released in response to low levels of fatty acids in the blood. Insulin inhibits the release of glucagon by A cells, but because of the cascading circulation in the islet (explained later), this inhibition is affected by a hormonal action of insulin carried in the general circulation.

The islets have both **sympathetic** and **parasympathetic innervations**. About 10% of the islet cells have nerve endings directly on their plasma membrane. Well-developed gap junctions are located between islet cells. Ionic events triggered by synaptic transmitters at the nerve endings are carried from cell to cell across these junctions. Autonomic nerves may have direct effects on hormone secretion by A and B cells.

Parasympathetic (cholinergic) stimulation increases secretion of both insulin and glucagon; sympathetic (adrenergic) stimulation increases glucagon release but inhibits insulin release. This neural control of insulin and

glucagon may contribute to the availability of circulating glucose in stress reactions.

FOLDER 18.4

FUNCTIONAL CONSIDERATIONS: INSULIN SYNTHESIS, AN EXAMPLE OF POST-TRANSLATIONAL PROCESSING

Insulin is produced in B cells of the pancreas. It is a small protein consisting of two polypeptide chains joined by disulfide bridges. Its biosynthesis presents a clear example of the importance of post-translational processing in the achievement of the final, active structure of a protein.

Insulin is originally synthesized as a single 110-amino-acid polypeptide chain with a molecular weight of about 12 kDa. This polypeptide is called **preproinsulin**. Preproinsulin contains an amino-terminus signal sequence (24 amino acids in length) that is required for the precursor hormone to enter the rough endoplasmic reticulum (rER). As the molecule is inserted into the cisternae of the rER, the preproinsulin signal sequence is proteolytically cleaved to form **proinsulin**. Post-translational processing reduces the preproinsulin to a polypeptide with a molecular weight of about 9,000 Da. Proinsulin is a single polypeptide chain of 81–86 amino acids that has the approximate shape of the letter G (Fig. F18.4.1). Two disulfide bonds connect the bar of the G to the top loop. Proinsulin is further modified by the formation of internal disulfide bonds and removal of a C chain that produces biologically active insulin.

FIGURE F18.4.1. Post-translational processing of insulin. Insulin is synthesized as preproinsulin, a single polypeptide chain that undergoes post-translational modifications. Initially, the signal sequence is removed within the cisternae of the rough endoplasmic reticulum (*rER*). The shortened polypeptide chain, now known as *proinsulin*, is transported to the Golgi apparatus. Here, it is further modified by the formation of internal disulfide bonds and removal of a C chain that produces biologically active insulin.

During packaging and storage of proinsulin in the Golgi apparatus, a cathepsin-like enzyme cleaves most of the side of the

loop, leaving the bar of the G as an **A chain** of 21 amino acids cross-linked by the disulfide bridges to the top of the loop, which becomes the **B chain** of 30 amino acids. The 35-amino-acid peptide removed from the loop is called a **C peptide** (connecting peptide). It is stored in the secretory vesicles and released with the insulin in equimolar amounts. No physiologic function has been identified for the C peptide.

Because C peptide has a longer half-life than insulin, higher concentrations of C peptides are detected in the peripheral blood. For these reasons, measurement of circulating levels of C peptides provides important clinical information about the secretory activity of B cells. Because C peptide is cleared from the body by the kidney, measurement of its urinary excretion provides useful information about B-cell insulin secretion. C peptide measurements are frequently used to assess the residual B-cell function in patients treated with insulin, to distinguish between types 1 and 2 diabetes, and in the diagnosis and treatment of **insulinoma** (tumor of B cells). C peptide levels may also be used to monitor the progress of pancreas or islet cell transplantation.

The blood supply to the pancreas provides a cascading perfusion of the islets and acini.

As mentioned earlier, islets of Langerhans comprise only 1% - 2% of the total mass of the pancreas; however, they receive about 10% - 15% of the pancreatic blood flow. There are two predominant blood flow patterns in the islets of Langerhans. The most common pattern occurs when blood enters the islets at the center, initially perfusing the core of the islet and then spreading to the periphery. In the second pattern, several arterioles enter the periphery of the islets and branch into fenestrated capillaries to perfuse the core of the islet. In humans, it is likely that the capillaries first perfuse the A and D cells, peripherally, before the blood reaches the B cells, centrally. Larger vessels that travel in septa that penetrate the central portion of the islet are also accompanied by A and D cells so that blood reaching the B cells has always first perfused the A and D cells. [Recent in vivo fluorescence imaging studies show distinct blood flow dynamics in the islets of Langerhans. These studies suggest that blood flow is regulated by blood glucose levels in addition to the complex](#)

interaction among vasodilators and vasoconstrictors, gastrointestinal peptides, and the autonomic nervous system.

Large **efferent capillaries** leave the islet and branch into the capillary networks that surround the acini of the exocrine pancreas. This cascading flow resembles the portal systems of other endocrine glands (pituitary, adrenal).

Secretions of the islet cells have regulatory effects on the acinar cells.

- Insulin, the vasoactive intestinal peptide (VIP), and cholecystikinin (CCK) stimulate exocrine secretion.
- Glucagon, pancreatic polypeptide (PP), and somatostatin inhibit exocrine secretion.

DIGESTIVE SYSTEM III:

LIVER, GALLBLADDER, AND

PANCREAS

OVERVIEW OF THE LIVER

- The **liver** is the largest internal organ and largest mass of glandular tissue in the body.
- The liver plays an important role in the uptake, storage, and distribution of nutrients. It produces the majority of circulating **plasma proteins** (e.g., albumins), stores iron, converts vitamins, and degrades drugs and toxins.
- The liver also acts as an exocrine organ (produces **bile**) and performs endocrine-like functions.

- The liver has a **dual blood supply**: a venous supply via the **hepatic portal vein** and an arterial supply via the **hepatic artery**.

STRUCTURE OF THE LIVER

- Structural components of the **liver** include **parenchyma** (plates of hepatocytes), **connective tissue stroma**, **sinusoidal capillaries** (hepatic sinusoids), and **perisinusoidal spaces** (of Disse).
- There are three ways to describe the structure of the liver in terms of a functional unit: the **classic lobule** (polygonal in shape), the **portal lobule** (triangular in shape), and the **liver acinus** (a diamond-shaped area that has three zones and best correlates to blood perfusion, metabolic activity, and liver pathology).
- **Hepatocytes** (as seen in the classic lobule) are organized into irregular anastomosing plates that radiate toward a central vein. Corners of the polygonal classic lobule are occupied by the **portal triad**, which contains branches of portal vein, hepatic artery, bile ducts, and small lymphatic vessels.
- **Hepatic sinusoids** form irregular vascular channels that run parallel and between the plates of hepatocytes. They receive mixed blood (~75%) from the venous portal circulation and arterial blood (~25%) from the systemic circulation.
- Hepatic sinusoids are lined with a thin discontinuous endothelium. The **perisinusoidal space (space of Disse)** lies between hepatocytes and the endothelium; it is the site of exchange of materials between the blood and liver cells.
- The sinusoidal endothelium includes specialized **stellate sinusoidal macrophages (Kupffer cells)**, which are part of immune defense system and remove worn-out red blood cells and recycle iron molecules.

- Hepatic stellate cells (Ito cells) reside in perisinusoidal spaces and are loaded with lipid droplets for storage of vitamin A. In pathologic conditions, Ito cells may differentiate into myofibroblasts.

HEPATOCTES

- Hepatocytes (constitute 80% of liver cells) are large, polygonal cells with spherical nuclei (often binucleated) and acidophilic cytoplasm containing sER, rER, numerous mitochondria and peroxisomes, and multiple small Golgi complexes.
- The basal surface of hepatocytes is in contact with the perisinusoidal space (of Disse), whereas the apical surface is connected to the adjacent hepatocyte to form a bile canaliculus.
- Bile canaliculi drain into the short canals of Hering, which are partially lined by hepatocytes and cuboidal cholangiocytes (cells lining the biliary tree).
- Canals of Hering harbor specific hepatic stem cells.

BILIARY TREE

- The biliary tree is lined by simple cuboidal or columnar epithelial cells called cholangiocytes, which monitor bile flow and regulate its content.
- Bile (produced by hepatocytes) is collected by the bile canaliculi and drains to the canals of Hering. From there, it continues to flow into the intrahepatic bile ductules and further into the interlobular bile ducts (part of the portal triad). Interlobular ducts eventually merge to form the left and right hepatic ducts that exit the liver in the porta hepatis.
- Extrahepatic bile ducts carry the bile to the gallbladder and eventually into the duodenum.

OVERVIEW OF THE GALLBLADDER

- The **gallbladder** is a pear-shaped, distensible sac that concentrates (removes 90% of water) and stores bile.
- **Mucosa** of the gallbladder has numerous deep folds (to increase surface area), a **lamina propria** rich in blood vessels, and a well-developed **muscularis externa** (no muscularis mucosae or submucosa).
- The tall columnar **cholangiocytes** are specialized for water uptake from bile. They express aquaporins (water channel proteins) that facilitate a rapid passive movement of water.
- Deep diverticula of the mucosa, called **Rokitansky-Aschoff sinuses**, often extend through the muscularis externa.
- Contraction of the **muscularis externa** reduces the volume of the gallbladder, forcing bile out through the cystic duct and common bile duct to the duodenum.

OVERVIEW OF THE PANCREAS

- The **pancreas** is an **exocrine** and **endocrine** gland located in the retroperitoneal space of the abdomen.
- The **exocrine component** synthesizes and secretes hydrolytic digestive enzymes into the duodenum that are essential for digestion in the intestine. It contains serous acini, which comprise most of the mass of the pancreas.
- **Pancreatic acini** are unique because their intercalated ducts arise within the acinus; therefore, nuclei of duct cells located inside the acinus are referred to as **centroacinar cells** (a characteristic feature of the pancreas).
- The pancreatic acinar cell is pyramidal in shape with **secretory (zymogen) granules** located in the apical cytoplasm. Golgi complexes, rER, and a large nucleus are located at the basal domain of the cell.

- Intercalated ducts secrete large amounts of sodium and bicarbonates to neutralize the acidity of the chyme that enters the duodenum from the stomach.
- Intercalated ducts drain pancreatic acini into intralobular ducts, larger interlobular ducts, and finally into the pancreatic duct, which empties into the duodenum.
- The endocrine component (islets of Langerhans) synthesizes and secretes hormones into the blood that regulate glucose, lipid, and protein metabolism.
- Islets of Langerhans are dispersed in the pancreas and contain three primary types of cells: A cells (which produce glucagon), B cells (which produce insulin), and D cells (which produce somatostatin).

PLATE 18.1 ■ LIVER I

The liver is the largest mass of glandular tissue in the body and the largest internal organ. It is unique because it receives its major blood supply from the hepatic portal vein, which carries venous blood from the small intestine, pancreas, and spleen. Thus, the liver is directly in the pathway that conveys materials absorbed in the intestine. The liver is the first organ exposed to metabolic substrates and nutrients as well as to noxious and toxic substances absorbed from the intestine. One of the major roles of the liver is to degrade or conjugate toxic substances to render them harmless. It can, however, be seriously damaged by excess exposure to such substances.

Each liver cell has both exocrine and endocrine functions. The exocrine secretion of the liver, called bile, contains conjugated and degraded waste products that are delivered back to the intestine for disposal. It also contains substances that bind to metabolites in the intestine to aid absorption. A series of ducts of increasing diameter and complexity, beginning with bile canaliculi between individual hepatocytes and ending with the common bile duct, delivers bile from the liver and gallbladder to the duodenum.

The endocrine secretions of the liver are released directly into the blood that supplies the liver cells; these secretions include albumin, nonimmune α - and β -globulins, prothrombin, and glycoproteins, including fibronectin. Glucose, released from

stored glycogen, and triiodothyronine (T_3), the more active deiodination product of thyroxine, are also released directly into the blood.

Functional units of the liver, described as *lobules* or *acini*, are made up of irregular interconnecting sheets of hepatocytes separated from one another by the blood sinusoids.

Liver, human, hematoxylin and eosin (H&E) $\times 65$;
inset $\times 65$.

At the low magnification shown here, large numbers of hepatic cells appear to be uniformly disposed throughout the specimen. They are organized in discrete lobules (boundaries of a single lobule can be approximated by the *dashed line*) with the central vein (*CV*) in the middle. The **hepatocytes** are arranged in one-cell-thick plates, but when sectioned, they appear as interconnecting cords one or more cells thick, depending on the plane of section. The **sinusoids** appear as light areas between the cords of cells; they are more clearly shown in the next figure (*asterisks*).

Also present in this figure is a **portal canal**. It is a connective tissue septum that carries the branches of the hepatic artery (*HA*) and portal vein (*PV*), bile ducts (*BD*), and lymphatic vessels and nerves. The artery and vein, along with the bile duct, are collectively referred to as a **portal triad**.

The hepatic artery and the portal vein are easy to identify because they are found in relation to one another within the surrounding connective tissue of the portal canal. The vein is typically thin walled; the artery is smaller in diameter and has a thicker wall. The **bile ducts** are composed of a simple cuboidal or columnar epithelium, depending on the size of the duct. Multiple profiles of the blood vessels and bile ducts may be evident in the canal because of either branching or their passage out of the plane of section and then back in again.

The vessel through which blood leaves the liver is the hepatic vein. It is readily identified because it travels alone (*inset*) and is surrounded by an appreciable amount of connective tissue (*CT*) often containing small lymphatic nodules (*L*). If more than one profile of a vein is present within this connective tissue, but no arteries or bile ducts are present, the second vessel will also be a hepatic vein. Such is the case in the *inset*, where a profile of a small hepatic vein is seen just above the larger hepatic vein (*HV*).

Liver lobule, liver, human, H&E $\times 160$.

The **terminal hepatic venules** or **central veins (CV)** are the most distal branches of the hepatic vein, and like the hepatic vein, they also travel alone. Their distinguishing features are the sinusoids (indicated by *asterisks*) that penetrate the wall of the vein and the paucity of surrounding connective tissue. These characteristics are shown to advantage in Plate 18.2 (page 724).

It is best to examine low-magnification views of the liver to define the boundaries of a lobule. A lobule is best identified when it is cut in cross section. The central vein then appears as a circular profile, and the hepatic cells appear as cords radiating from the central vein. Such a lobule is outlined by the *dashed line* in the previous figure.

The limits of the lobule are defined, in part, by the portal canal. In other directions, the plates of the lobule do not appear to have a limit; that is, they have become contiguous with plates of an adjacent lobule. One can estimate the dimensions of the lobule, however, by approximating a circle with the central vein as its center and incorporating those plates that exhibit a radial arrangement up to the point where a portal canal is present. If the lobule has been cross-sectioned, the radial limit is set by the location of one or more of the portal canals as indicated by the bile ducts (*BD*) in this figure.

CV, central vein (terminal hepatic venule)

HA, hepatic artery

HV, hepatic vein

L, lymphatic nodule

PV, portal vein

asterisks, bottom figure, blood sinusoids

dashed line, top figure, approximates the limits of a lobule

PLATE 18.2 ■ LIVER II

There are three ways of describing the liver parenchyma in terms of a functional unit, “*classic*” *lobules*, *portal lobules*, or *acini*. The **classic lobule** is a roughly hexagonal block of tissue that has at its center the terminal hepatic venule (central vein) and at its six corners the **portal canals**. Each portal canal contains a **portal triad**, each comprising a branch of the portal vein, hepatic artery, and bile duct. The **portal lobule** is a triangular construct that emphasizes the exocrine secretory function. It has as its axis the bile duct of the portal triad of the classic lobule, and its outer margins are imaginary lines drawn between the central veins closest to that portal triad. The **liver acinus** is most closely correlated with blood perfusion, metabolic activity, and liver pathology. The acinus is a small diamond- or lozenge-shaped mass of tissue that has as its short axis the fine branches of the portal triad that lie along the border of two classic lobules and as its long axis a line drawn between the two central veins closest to the short axis. The hepatocytes in each acinus are described as arranged in three concentric elliptical zones around the short axis; zone 1 is closest to, and zone 3 is farthest from, the axis.

Central vein, liver, human, hematoxylin and eosin (H&E) ×500; inset ×800.

The **central vein** and surrounding hepatocytes from the *lower* figure of Plate 18.1 (page 722) are shown here at higher magnification. The cytoplasm of the **hepatocytes** in this specimen has a foamy appearance because of the extraction of glycogen and lipid during tissue preparation. The boundaries between individual hepatocytes are discernible in some locations, but not between those cells where the knife has cut across the boundary in an oblique plane. Frequently, when cell boundaries are observed at still higher magnification (*inset*), a very small circular or oval profile is observed midway along the boundary. These profiles represent the bile canaliculi (*BC*).

The cells that line the **sinusoids** (*S*) show little, if any, cytoplasmic detail in routine preparations. **Perisinusoidal macrophages** (Kupffer cells [*KC*]) are generally recognized by their ovoid nuclei and the projection of the cell into the lumen. The endothelial cell, in contrast, is a squamous cell that has a smaller,

attenuated, or elongated nucleus. Some nuclei of this description are evident in the micrograph.

The termination of two of the sinusoids and their union with the central vein (*CV*) is indicated by the *curved arrows*. Note that the wall of the vein is strengthened by connective tissue, mostly collagen, which appears as homogeneous eosin-stained material (*asterisks*). Fibroblasts (*F*) within this connective tissue can be identified and distinguished from the endothelial cell (*EN*) lining of the vein.

Hepatic sinusoids, liver, rat, glutaraldehyde - osmium fixation, toluidine blue $\times 900$.

This figure shows a plastic-embedded liver specimen fixed by the method normally used for electron microscopy. In contrast to the H&E-stained preparation, it demonstrates to advantage the cytologic detail of the hepatocytes and the sinusoids (*S*). The **hepatocytes** are deeply colored with toluidine blue. Note that the cytoplasm exhibits irregular magenta masses (*arrows*). This is glycogen that has been retained by the glutaraldehyde fixation and stained metachromatically by toluidine blue. Also evident are lipid droplets (*L*) of varying size that have been preserved and stained black by the osmium used as the secondary fixative. The quantities of lipid and glycogen are variable and, under normal conditions, reflect dietary intake. Examination of the hepatocyte cytoplasm also reveals small, punctate, *dark blue* bodies contrasted against the *lighter blue* background of the cell. These are the mitochondria. Another feature of this specimen is the clear representation of the **bile canaliculi** (*BC*) between liver cells. They appear as empty circular profiles when cross-sectioned and as elongated channels (*lower right*) when longitudinally sectioned.

The sinusoidal lining cells are of two distinct types. The **Kupffer cells** (*KC*) are the more prominent cells. They exhibit a large nucleus and a substantial amount of cytoplasm. They protrude into the lumen and may give the appearance of occluding it. However, they do not block the channel. The surface of the Kupffer cell exhibits a very irregular or jagged contour because of the numerous processes that provide the cell with an extensive surface area. The **endothelial cell** (*EN*) has a smaller nucleus, attenuated cytoplasm, and a smooth surface contour.

A third cell type, the less frequently observed perisinusoidal lipocyte (Ito cell), is not seen in this micrograph. This cell would appear as a light cell containing numerous lipid droplets. The lipid droplets contain stored vitamin A.

PLATE 18.3 ■ GALLBLADDER

The gallbladder concentrates and stores bile for delivery to the duodenum. Bile is concentrated by the active transport of salt from the bile and the passive movement of water in response to the salt transport. The mucosa is characterized by a tall columnar absorptive epithelium that closely resembles that of the intestine and the colon in both its morphology and function. The epithelial cells are characterized by numerous short apical microvilli, apical junctional complexes, concentrations of mitochondria in the apical and basal cytoplasm, and complex lateral plications. In addition, Na^+/K^+ -activated ATPase is localized on the lateral plasma membrane of the epithelial cell.

Gallbladder, human, hematoxylin and eosin (H&E) $\times 45$.

The gallbladder is a hollow, pear-shaped organ that concentrates and stores the bile. The full thickness of its wall is shown here. It is composed of a mucosa (*Muc*), muscularis (*Mus*), adventitia (*Adv*), and, on its free surface (not shown), a serosa. The **mucosa** is considered at higher magnification in the next figure.

The **muscularis** consists of interlacing bundles of smooth muscle (*SM*). The **adventitia** (*Adv*) consists of irregular dense connective tissue through which the larger blood vessels (*BV*) travel and, more peripherally, of varying amounts of adipose tissue (*AT*).

The mucosa is thrown into numerous folds that are particularly pronounced when the muscularis is highly contracted. Note the presence of several outpouchings of the mucosa, called *Rokitansky-Aschoff sinuses* (RAS). This is the usual histologic appearance of the gallbladder unless, of course, steps are taken to fix and preserve it in a distended state. Occasionally, the section cuts through a recess in a fold, and the recess may then resemble a gland (*arrows*). The mucosa, however, does not possess glands, except in the neck region, where some mucous glands are present (see *lower right figure*).

Mucosa, gallbladder, human, H&E $\times 325$.

The **mucosa** consists of a tall simple columnar absorptive epithelium (*Ep*) resting on a lamina propria of loose connective tissue

(*CT*) containing blood vessels (*BV*). The epithelium has characteristics that distinguish it from the absorptive epithelium of other organs, such as the intestines. Only one cell type, the tall columnar cell, is present in the epithelial layer (see *upper right figure*). The nuclei are in the basal portion of the cell. The cells possess a thin apical striated border. However, this is not always evident in routine H&E-stained sections. The cytoplasm stains rather uniformly with eosin. This staining pattern reflects the cell's absorptive function and is in contrast to the staining of cells that produce protein. The cells' absorptive function is further demonstrated by their distended intercellular spaces at the basal aspect (see *upper right figure arrows*). This feature is associated with the transport of fluid across the epithelium and, as noted earlier, commonly seen in intestinal absorptive cells.

Mucosa, gallbladder, human, H&E ×550.

The **lamina propria** underlying the epithelium is usually very cellular. In this specimen, in addition to lymphocytes (*L*), a relatively common finding, a large number of plasma cells (*PC*) is also present within the lamina propria. (The high concentration of plasma cells suggests chronic inflammation.) Another feature of note in the lamina propria is the presence of several outpouchings of the mucosa, called *Rokitansky-Aschoff sinuses* (*RAS*), other than those seen in the mucosa and noted earlier. These are readily apparent in the *top left* figure, and part of the wall of the Rokitansky-Aschoff sinus is shown at higher magnification in the next figure.

Mucosa, gallbladder neck, human, H&E ×550.

The smaller of the two gland-like structures visible in the connective tissue (*CT*) of lamina propria is composed of **mucous cells** (*MC*) and represents a section through a **mucous gland** (*MG*). This specimen was taken from a site near the neck of the gallbladder where mucous glands are often present. Note the characteristic flattened nuclei at the base of the cell and the lightly stained appearance of the cytoplasm, features characteristic of mucin-secreting cells. In contrast, the epithelium of the large gland-like profile that is only partially included in the micrograph has rounded or ovoid nuclei. This epithelial-lined structure is not a true gland but represents an

invagination of the mucous membrane that extends into and often through the thickness of the muscularis. These invaginations are known as **Rokitansky - Aschoff sinuses** (*RAS*).

PLATE 18.4 ■ PANCREAS

The **pancreas** is an elongated extramural digestive gland with a head nestled in the C-shaped bend of the duodenum, a body that crosses the midline of the abdomen, and a tail extending across the back of the abdomen. It is a mixed gland containing both an exocrine component and an endocrine component that have distinctive characteristics. The **exocrine component** is a compound tubuloacinar gland with a branching network of ducts that convey the exocrine secretions to the duodenum. These secretions consist primarily of inactive forms of potent proteolytic enzymes as well as amylase, lipase, nucleases, and electrolytes, particularly HCO_3^- .

The **endocrine component** is isolated as highly vascularized islets of epithelioid tissue (islets of Langerhans). The islet cells secrete a variety of polypeptide and protein hormones, most notably insulin and glucagon, which regulate glucose metabolism throughout the other tissues of the body. Other hormones secreted by islet cells include somatostatin, pancreatic polypeptide, vasoactive intestinal peptide, secretin, motilin, and substance P. All of these substances, with the exception of insulin, are also secreted by the population of enteroendocrine cells in the intestine, the organ from which the pancreas is derived during embryonic development. Whereas insulin and glucagon act primarily in the endocrine regulation of distant cells, the other hormones (and glucagon) have significant roles in the paracrine regulation of the insulin-secreting B cells of the pancreatic islet.

Pancreas, human, hematoxylin and eosin (H&E)
×160; inset ×360.

The pancreas is surrounded by a delicate capsule of moderately dense connective tissue. Septa from the capsule divide the pancreas into lobules, one of which is shown here, bounded by connective tissue (*CT*). Larger blood vessels (*BV*) travel in the connective tissue septa; nerves also travel in the septa, but they are seen infrequently. Within the lobule are numerous acini of the exocrine component, an **intralobular duct** (*InD*), intercalated ducts (not readily evident at this low magnification), and **islets of Langerhans** (*IL*; *dashed line*). Also within the lobule are small blood vessels and connective tissue serving as a stroma for the parenchymal elements of the gland.

The islet of Langerhans (*IL*) in this photomicrograph is shown among the far more numerous acini. (Islets are most numerous in the tail of the pancreas and least numerous in the head.) Cells within the islets are arranged as irregular cords. In routine preparations, it is not possible to identify the various cell types within the islets. Note, however, that B cells are the most numerous; these produce insulin. The next most numerous are A cells; these produce glucagon. The *inset* also shows numerous capillaries (*arrows*). The labels *A* and *B* are not intended to identify specific cells but rather to show those parts of the islets where A and B cells are found in greatest number.

Pancreas, human, H&E $\times 600$.

Acini of the pancreas consist of serous cells. In sections, the acini present circular and irregular profiles. The lumen of the acinus is small, and only in fortuitous sections through an acinus is the lumen included (*asterisks*). The nucleus is characteristically in the base of the acinar cell. There is a region of intense basophilia adjacent to the nucleus. This is the ergastoplasm (*Er*), and it reflects the presence of rough endoplasmic reticulum (*rER*) that is active in the synthesis of pancreatic enzymes. Some acini reveal a centrally positioned cell with cytoplasm that shows no special staining characteristics in H&E-stained paraffin sections. These are **centroacinar cells** (*CC*) that represent the origin of the intercalated ducts.

This figure demonstrates particularly well the morphology and relationships of the intercalated ducts. Note, first, the cross-sectioned **intralobular duct** (*Ind*) consisting of cuboidal epithelium. (There are no striated ducts in the pancreas.) Leading to the intralobular duct is an **intercalated duct** (*ID*), which is seen in cross section at the furthest distance from the intralobular duct and then, in longitudinal section, in the *center* of the illustration as it travels toward the intralobular duct. The lumen is evident where the intercalated duct is seen in cross section, but is not evident where it is seen in longitudinal section due to the plane of section cutting chiefly through the cells rather than the lumen. As a consequence, this figure provides a good view of the nuclei of the duct cells. They are elongated, with their long axis oriented in the direction of the duct. In addition, they display a staining pattern similar to that of centroacinar cells and different from that of nuclei of the parenchymal cells.

Once the cells of the intercalated duct have been identified in one part of the section, their staining characteristics and location can be used to identify the intercalated ducts in other parts of the lobule, several of which are marked (*ID*).

HISTOLOGY

■ OVERVIEW OF THE RESPIRATORY SYSTEM

The **respiratory system** consists of the paired lungs and a series of air passages that lead to and from the lungs. Within the lung, the air passages branch into increasingly smaller tubes until the very smallest air spaces, called **alveoli**, are reached (Fig. 19.1).

FIGURE 19.1. Diagram of respiratory passages. The nasal cavities, nasopharynx, oropharynx, larynx, trachea, bronchi, and bronchioles constitute the conducting portion of the respiratory system. The respiratory portion of the system, where gas exchange occurs, is

composed of respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli.

Three principal functions are performed by this system: (1) **air conduction**, (2) **air filtration**, and (3) **gas exchange (respiration)**. Gas exchange occurs in the alveoli. In addition, air passing through the **larynx** is used to produce speech, and air passing over the **olfactory mucosa** in the **nasal cavities** carries stimuli for the sense of smell. The respiratory system also participates, to a lesser degree, in endocrine functions (hormone production and secretion) as well as regulation of **immune responses** to inhaled antigens.

Lungs develop from the laryngotracheal diverticulum of the foregut endoderm and its surrounding thoracic splanchnic mesenchyme.

Embryologic development of the **upper part of the respiratory system** containing the nasal cavities, paranasal sinuses, nasopharynx, and oropharynx develops with the oral cavity. The **lower part of the respiratory system** containing the larynx, trachea, bronchi with their divisions, and lungs begins as a ventral evagination of the foregut called the **laryngotracheal (respiratory) diverticulum**. Thus, the epithelium of the respiratory system is of endodermal origin. This initial diverticulum grows into the thoracic splanchnic mesenchyme surrounding the foregut. As its distal end enlarges, the diverticulum forms a bulb-shaped **lung bud**. This lung bud divides into the left and right **bronchial buds**, which enlarge to form the primordium of the left and right **primary bronchi**. Bronchial buds together with the surrounding thoracic mesenchyme differentiate into **lobar bronchi** with subsequent progressive divisions into segmental bronchi. Each **segmental bronchus** with its surrounding mesenchyme further differentiates and divides to form the **bronchopulmonary segments** of the lung. The bronchial cartilages, smooth muscle, and other connective tissue elements are derived from the thoracic mesenchyme.

The air passages of the respiratory system consist of a conducting portion and a respiratory portion.

The **conducting portion of the respiratory system** consists of air passages that lead to the sites of respiration within the lung where gas exchange takes place. The conducting passages include those located outside as well as within the lungs.

The passages external to the lungs consist of the following:

- **Nasal cavities** that represent two large air-filled spaces in the uppermost part of the respiratory system (and, during forced breathing, the **oral cavity** residing inferior to the nasal cavities)
- **Nasopharynx** that lies behind the nasal cavities and above the level of the soft palate and communicates inferiorly with the **oropharynx** that is posterior to the oral cavity
- **Larynx** that is a hollow tubular organ containing the cartilaginous framework responsible for producing sounds
- **Trachea** that is a flexible air tube extending from the larynx to the thorax. It serves as a conduit for air, and in the mediastinum, it bifurcates into paired main bronchi.
- **Paired main (primary) bronchi** that enter the root of the right or left lung

Within the lungs, the **main bronchi** undergo extensive branching (~23 branch generations) to ultimately give rise to the **bronchioles**. The bronchioles represent the terminal part of the conducting passages. Collectively, the internal bronchi and the bronchioles constitute the **bronchial tree**.

The **respiratory portion of the respiratory system** is where gas exchange occurs. Sequentially, it includes the following structures:

- **Respiratory bronchioles** that are involved in both air conduction and gas exchange
- **Alveolar ducts** that are elongated airways that connect the respiratory bronchioles to the alveolar sacs
- **Alveolar sacs** that represent spaces surrounded by clusters of alveoli
- **Alveoli** that are the terminal respiratory units where gas exchange primarily occurs

Blood vessels enter the lung with the bronchi. The arteries branch into smaller vessels as they follow the bronchial tree into the substance of the lung. Capillaries come into intimate contact with the alveoli. This intimate relationship between the alveolar air spaces and the pulmonary capillaries is the structural basis for gas exchange within the lung parenchyma. The essential features of the lung blood supply are described on page 752.

Air passing through the respiratory passages must be conditioned before reaching the terminal respiratory units.

Conditioning or **climatization** of the air occurs in the **conducting portion of the respiratory system**, mainly in the nasal cavities. It includes warming and moistening of the inhaled air in addition to removal of particles. The temperature of inhaled air that passes into the nasopharynx reaches approximately 31° C - 34° C (88° F - 93° F) with a relative humidity of 90% - 95%. Lower parts of the respiratory system only minimally participate in climatization. During expiration, the nasal airways partially extract heat and humidity from the exhaled air, thus reducing the loss of heat and moisture during respiration.

Mucous and **serous secretions** play a major role in climatization. These secretions moisten the air and also trap particles that have managed to slip past the special short thick hairs, called **vibrissae**, in the nasal cavities. Almost 95% of particles with a diameter of more than 15 µm are eliminated from inspired air. Mucus, augmented by these serous secretions, also prevents the dehydration of the underlying epithelium by the moving air. Mucus covers almost the entire luminal surface of the conducting passages and is continuously produced by goblet cells and mucus-secreting glands in the walls of the passages. The mucus and other secretions are moved toward the **pharynx** by means of coordinated sweeping movements of cilia and are then normally swallowed.

■ NASAL CAVITIES

The **nasal cavities** are paired chambers separated by a bony and cartilaginous **nasal septum**. They are elongated spaces with a wide base that rest on the hard and soft palate and a narrow apex that points toward the anterior cranial fossa. The skeletal framework of the nasal cavities is formed by bones and cartilages; most are located centrally in the skull, except for the small anterior region that is enclosed within the **external nose**. Each cavity or chamber communicates anteriorly with the external environment through the **anterior nares** (nostrils); posteriorly with the nasopharynx through the **choanae**; and laterally with the **paranasal sinuses** and **nasolacrimal duct**, which drains tears from the eye into the nasal cavity (Fig. 19.2). The chambers are divided into three regions:

FIGURE 19.2. Diagram of the relationship of the pharynx to the respiratory and digestive systems. The pharynx is divided into three parts: nasopharynx, oropharynx, and laryngopharynx. It is

located posterior to the nasal and oral cavities and extends inferiorly past the larynx. The pharynx serves both the respiratory and digestive systems. This midsagittal section also transects the cartilages, forming the skeleton of the larynx (i.e., epiglottis, thyroid cartilage, and cricoid cartilage). Note the ventricular and vocal folds in the middle of the larynx, approximately at the level of the thyroid cartilage. This part of the larynx represents the narrowest portion of the respiratory system and is responsible for producing sound by audible vibration of the vocal folds.

- **Nasal vestibule**, a dilated space of the nasal cavity just inside the nostrils and is lined by skin
- **Respiratory region**, the largest part (inferior two-thirds) of the nasal cavities and is lined by respiratory mucosa
- **Olfactory region**, located at the apex (upper one-third) of each nasal cavity and is lined by specialized olfactory mucosa

Vestibule of the Nasal Cavity

The **nasal vestibule** forms a part of the external nose and communicates anteriorly with the external environment. It is lined with **stratified squamous epithelium**, a continuation of the skin of the face, and contains a variable number of **vibrissae** that entrap large particulate matter before it is carried in the air stream to the rest of the cavity. Sebaceous glands are also present, and their secretions assist in the entrapment of particulate matter. Posteriorly, where the vestibule ends, the stratified squamous epithelium becomes thinner and undergoes a transition to the pseudostratified epithelium that characterizes the respiratory region. At this site, sebaceous glands are absent.

Respiratory Region of the Nasal Cavity

The **respiratory region** constitutes most of the volume of the nasal cavities. It is lined by the **respiratory mucosa** that contains a ciliated, pseudostratified columnar epithelium on its surface. The surface area of the respiratory mucosa is about 100–200 cm². The underlying **lamina propria** is firmly

attached to the periosteum and perichondrium of the adjacent bone or cartilage.

The medial wall of the respiratory region, the **nasal septum**, is smooth, but the lateral walls are thrown into folds by the presence of three (rarely four) shelf-like, bony projections called **conchae** or turbinates. The conchae divide each nasal cavity into separate air chambers and play a dual role. They increase surface area and cause turbulence in airflow to allow more efficient conditioning of inspired air.

The **pseudostratified columnar ciliated epithelium** of the respiratory mucosa is composed of five cell types:

- **Ciliated cells**, tall columnar cells with cilia that project into the mucus covering the surface of the epithelium. They are the most abundant cells (up to 70%) in the epithelium.
- **Goblet cells** that synthesize and secrete mucus; they represent 5% - 15% of all cells in the epithelium.
- **Brush cells**, a general name for those cells in the respiratory tract that bear short, blunt microvilli; they represent **chemosensory receptor cells** and are intimately connected to sensory nerve fibers.
- **Small granule cells (Kulchitsky cells)** that resemble basal cells but contain secretory granules; they are **endocrine cells** of the diffuse neuroendocrine system (DNES) (see Folder 17.4).
- **Basal cells** that lie on the basement membrane and have no contact with the epithelial surface; they are **stem cells** from which the other cell types arise.

The epithelium of the respiratory region of the nasal cavity is essentially the same as the epithelium lining most of the parts that follow in the conducting system. Because the respiratory epithelium of the trachea is studied and examined in reference to that of the nasal cavity, the abovementioned cell types are discussed in the section on the trachea (page 739).

The mucosa of the respiratory region climatizes and filters inspired air; it also contains cells that provide a local

immune response to inhaled foreign antigens.

The **lamina propria** of the respiratory mucosa has a rich, vascular network that includes a complex set of capillary loops. The arrangement of the vessels allows the inhaled air to be warmed by blood flowing through the part of the loop closest to the surface. The capillaries that reside near the surface are arranged in rows; the blood flows perpendicular to the airflow, much as one would find in a mechanical heat exchange system. These same vessels may become engorged and leaky during allergic reactions or viral infections such as the common cold. The lamina propria then becomes distended with fluid, resulting in marked swelling of the mucous membrane with consequent restriction of the air passage, making breathing difficult.

The lamina propria also contains mucous glands, many exhibiting serous demilunes. These glands possess ducts opening into small crypts on the epithelial surface. The ducts are lined by a two-layered stratified cuboidal epithelium. Their secretions supplement that of the goblet cells in the respiratory epithelium.

By increasing surface area, the **conchae (turbinates)** increase the efficiency with which the inspired air is warmed. The turbinates also increase the efficiency of filtration of inspired air through the process of **turbulent precipitation**. The air stream is broken into eddies by the turbinates. Particles suspended in the air stream are thrown out of the stream and adhere to the mucus-covered wall of the nasal cavity. Particles trapped in this layer of mucus are transported to the **pharynx** by means of coordinated sweeping movements of cilia and are then swallowed. They may also be forcefully removed from the nasal cavity by sneezing. The **sneeze reflex** is usually provoked by foreign particles trapped in the mucus of nasal cavity. They stimulate sensory receptors that convey impulses to the sneezing center in the medulla. Initially, a rapid inspiration fills the lungs with air; the vocal cords, vestibular folds, and epiglottis of the larynx then close tightly to trap the inspired air in the lung. This is followed by a sudden forceful contraction of the diaphragm and other accessory respiratory muscles, which further

increases the pressure in the lungs. Once a sufficiently high pressure is reached, the vocal cords, the vestibular folds, and the epiglottis open suddenly, and the air is pushed out rapidly from the lungs through the nose. Liquid droplets and foreign particles exit the nose at a velocity approaching 50 m/s (180 km/h).

Respiratory mucosa of the nasal cavity also contains cells involved in **mucosal immunity**. These cells are represented by a variety of lymphocyte populations residing in both the respiratory epithelium and the lamina propria. The majority of cells found in these regions are **gamma/delta ($\gamma\delta$) T lymphocytes** expressing the T-cell receptor (TCR) that play an important role in local immunity to inhaled foreign antigens (page 488). Accumulations of other cell types such as helper T lymphocytes, regulatory (suppressor) T lymphocytes, B lymphocytes, neutrophils, macrophages, and mast cells are also found in the lamina propria.

Olfactory Region of the Nasal Cavity

The **olfactory region** is located on part of the dome of each nasal cavity and, to a variable extent, the contiguous lateral and medial nasal walls. It is lined with a specialized **olfactory mucosa**. In living tissue, this mucosa is distinguished by its slight yellowish brown color caused by pigment in the **olfactory epithelium** and the associated **olfactory glands**. In humans, the total surface area of the olfactory mucosa is only about 10 cm²; in animals with an acute sense of smell, the total surface area of the olfactory mucosa is considerably more extensive. For instance, the surface area of the olfactory mucosa in certain dog species is greater than 150 cm².

The lamina propria of the olfactory mucosa is directly contiguous with the periosteum of the underlying bone (Plate 19.1, page 758). This connective tissue contains numerous blood and lymphatic vessels, unmyelinated olfactory nerves, myelinated nerves, and olfactory glands.

The olfactory epithelium, like the epithelium of the respiratory region, is also pseudostratified, but it contains

very different cell types. In addition, it lacks goblet cells (Fig. 19.3 and Plate 19.1, page 758).

FIGURE 19.3. Olfactory mucosa of the nasal cavity. **a.** This diagram shows the three major cell types located within the olfactory epithelium: the olfactory cell, supporting (sustentacular) cell, and basal cell. The olfactory cell is the receptor cell; it has an apical expansion, the olfactory vesicle, from which long, nonmotile cilia extend. At its basal surface, it extends an axon into the connective tissue that joins with the axons of other olfactory cells to form an olfactory nerve. The basal cells are small and cuboidal. They are restricted to the basal part of the epithelium. The supporting cells, in contrast, are columnar and extend the full thickness of the epithelium; their nuclei are located in the upper portion of the cell. Note the olfactory (Bowman) gland and its duct that empties on the surface of the mucosa. **b.** Photomicrograph of the olfactory mucosa. The olfactory epithelium exhibits nuclei through much of its thickness, but the individual cell types to which they belong are not discernible. The underlying connective tissue is largely occupied by numerous olfactory (Bowman) glands, olfactory nerves, and blood vessels. Note that the ducts of the olfactory glands extend from the secretory portion of the gland to the epithelial surface. $\times 240$.

The **olfactory epithelium** is composed of the following cell types:

- **Olfactory receptor cells** are bipolar olfactory neurons that span the thickness of the epithelium and enter the central nervous system.
- **Supporting (sustentacular) cells** are columnar cells that are similar to neuroglia cells and provide mechanical and metabolic support to the olfactory receptor cells. They synthesize and secrete odorant-binding proteins.
- **Basal cells** are stem cells from which new olfactory receptor cells and supporting cells differentiate.
- **Brush cells** are the same cell type that occurs in the respiratory epithelium.

Olfactory receptor cells are bipolar neurons that possess an apical projection bearing cilia.

The apical domain of each **olfactory receptor cell** has a single **dendritic process** that projects above the epithelial surface as a knob-like structure called the **olfactory vesicle**. A number of long, thin cilia (10–23) with typical basal bodies arise from the olfactory vesicle and extend radially in a plane parallel to the epithelial surface (see Fig. 19.3). The cilia are usually up to 200 μm long and may overlap with cilia of the adjacent olfactory receptor cells. The cilia are regarded as nonmotile, although some research suggests that they may have limited motility. The basal domain of the cell gives rise to an unmyelinated axonal process that leaves the epithelial compartment. Collections of axons from olfactory receptor cells do not come together as a single nerve; instead, they are grouped into bundles that pass through a thin cribriform plate of the ethmoid bone, course through the dura and arachnoid matters, and finally are surrounded by pia matter, entering the olfactory bulb of the brain. The collections of axons from olfactory receptor cells form the **olfactory nerve (cranial nerve I)**. The olfactory axons are very fragile and can be harmed during traumatic head injury. They can be permanently severed, resulting in **anosmia** (loss of the sense of smell).

Autoradiographic studies show that olfactory receptor cells have a life span of about 1 month. If injured, they are quickly replaced. Olfactory receptor cells (and some neurons of the

enteric division of the autonomic nervous system) appear to be the only neurons in the nervous system that are readily replaced during postnatal life.

Entire olfactory transduction pathways occur within the cilia of the olfactory receptor cells.

Molecules involved in **olfactory transduction** are located within long cilia that arise from the olfactory bulb. First, incoming odorant chemicals are solubilized in the olfactory mucus. Next, the odorants selectively bind to **odorant-binding proteins (OBPs)** that are concentrated in the olfactory mucus (Fig. 19.4). The odorant-binding proteins are small (10–30 kDa), water-soluble proteins that are synthesized and secreted by supporting cells. They act as molecular carriers that transport odorants and deliver them to **olfactory receptors** located in the plasma membrane of the cilia.

FIGURE 19.4. Diagram of olfactory transduction pathway. This diagram shows interactions of the odorant molecules with proteins associated with olfactory receptor (*OR*) cell. Incoming inhaled air odorant molecules are solubilized in the olfactory mucus and bind to olfactory-binding proteins, which deliver them to the *olfactory receptors*. Note that different odorant molecules bind with different affinity to the olfactory receptors. Strong signal (see *green* G-protein-coupled olfactory receptor) is produced by high-affinity binding where odorant molecule (*green*) matches perfectly the binding site on the receptor. Other olfactory receptors (*yellow* and *pink*) show less affinity binding, thus producing weaker signals. Stimulated by odorant molecules, olfactory receptors activate the enzyme adenylyl cyclase and initiate the cyclic adenosine monophosphate (*cAMP*) cascade of events, leading to the opening of specific Na⁺ and Ca²⁺ channels. Influx of Na⁺ and Ca²⁺ is responsible for cell depolarization. Generated action potential travels on axons of olfactory receptor

cells from the nasal cavity, passing through the ethmoid bone and surrounding brain coverings to the olfactory bulb of the brain.

To date, more than 350 different olfactory receptors have been identified in humans. Olfactory receptors are specific for the olfactory receptor cells and belong to the family of **G-protein-coupled receptors** (known as G_{olf}). When stimulated by odorant molecules, G_{olf} olfactory receptors activate the enzyme adenylyl cyclase and initiate the cyclic adenosine monophosphate (cAMP) cascade of events (see Fig. 19.4). These include binding of cAMP to specific Na^+ and Ca^{2+} channel proteins and influx of Na^+ and Ca^{2+} into the cell, which is responsible for plasma membrane depolarization that generates an action potential.

These 350 different olfactory receptors in humans are able to accurately detect several thousands of known odor molecules by use of a special coding system for different impulses. This is achieved by a **population coding scheme**, in which each olfactory receptor protein binds to different odorants with different sensitivity. Thus, the olfactory system must decode olfactory impulses not from a single cell but from the entire population of cells within the olfactory epithelium.

Supporting cells provide mechanical and metabolic support for the olfactory receptor cells.

Supporting (sustentacular) cells are the most numerous cells in the olfactory epithelium. The nuclei of these tall columnar or sustentacular cells occupy a more apical position in the epithelium than do those of the other cell types, thus aiding in their identification in the light microscope (see Fig. 19.3 and Plate 19.1, page 758). They have numerous microvilli on their apical surface and abundant mitochondria. Numerous profiles of smooth-surfaced endoplasmic reticulum (sER) and, to a more limited extent, rough-surfaced endoplasmic reticulum (rER) are observed in the cytoplasm. They also possess lipofuscin granules. Adhering junctions are present between these cells and the olfactory receptor cells, but gap and tight junctions are absent. The supporting cells function in a manner

similar to that of neuroglial cells, providing both metabolic support (secretion of odorant-binding protein molecules) and physical support to the olfactory receptor cells. Damage to supporting cells is related to **transient anosmia** (temporary loss of the sense of smell) in individuals infected by the **SARS-CoV-2 virus**. Loss of smell with or without fever ($>37.5^{\circ}\text{C}$) is one of the most frequently, and perhaps the earliest and often the only, reported symptom in patients who are **COVID-19** positive. SARS-CoV-2 virus gains entry to human cells by binding to **angiotensin-converting enzyme 2 (ACE2)**, and viral uptake is further facilitated by a **transmembrane protease, serine 2 (TmPRSS2)**, which activates the viral spike protein. Cells that highly express these viral cell entry proteins have an increased affinity to binding the virus and are particularly susceptible to infection. A recent study reveals that olfactory receptor cells in the nasal mucosa express neither ACE2 nor TmPRSS2 and thus are not infected by the SARS-CoV-2 virus. However, both enzymes are highly expressed on the **supporting (sustentacular) cells** that provide mechanical and metabolic support to olfactory receptor cells. The virus binds to and subsequently depletes supporting cells in the olfactory epithelium. Although olfactory receptor cells are not directly infected, they do sustain significant damage from the infection of neighboring supporting cells. Depletion of supporting cells is followed by their regeneration about 10 days after infection, and in most cases, the sense of smell is restored.

Brush cells are involved in transduction of general sensation and chemosensation from the mucosa of the nasal cavity.

The olfactory epithelium also contains **brush cells**, which are present in much smaller numbers than ciliated cells. These columnar cells are also present in the epithelium of other parts of the conducting air passages. With the electron microscope (EM), brush cells exhibit large, blunt microvilli at their apical surface, a feature that gives them their name. In addition, the apical plasma membrane contains accumulations of **G-protein-coupled T2R taste receptors** for bitter taste

similar to those found in neuroepithelial cells of the taste buds of the tongue. The different T2R chemosensory receptors in brush cells respond to a variety of natural ligands (irritants) that are likely to enter the airways in the form of aerosols and dust particles. The basal surface of a brush cell is in synaptic contact with nerve fibers that penetrate the basal lamina. The nerve fibers are terminal branches of the **trigeminal nerve (cranial nerve V)** that function in general sensation and mediation of reflexes, such as sneezing or coughing in response to inhaled chemical or pathogenic irritants.

In addition, the presence of a microvillus border, vesicles near the apical cell membrane, and a well-defined Golgi apparatus suggests that brush cells might be involved in an absorptive as well as a secretory function.

Basal cells are progenitors to all other cell types in the olfactory mucosa.

Basal cells are small, rounded cells located close to the basal lamina. Their nuclei are frequently invaginated and lie at a level below those of the olfactory receptor cell nuclei. The cytoplasm contains few organelles, a feature consistent with their role as a reserve or **stem cell**. A feature consistent with their differentiation into supporting cells is the observation of processes in some basal cells that partially ensheath the first portion of the olfactory receptor cell axon. They thus maintain a relationship to the olfactory receptor cell even in their undifferentiated state.

Olfactory glands are a characteristic feature of the olfactory mucosa.

The olfactory epithelium is potentially vulnerable to dehydration by the air entering the nasal passages. The olfactory glands (Bowman glands) and their serous secretion prevent water evaporation and the subsequent increase in ion concentration on the olfactory surface. Maintaining the ion gradients is necessary for proper function (depolarization) of the cilia of the olfactory receptor cells.

The olfactory glands (Bowman glands), a characteristic feature of the olfactory mucosa, are branched tubuloalveolar serous glands that deliver their proteinaceous secretions via ducts onto the olfactory surface (see Fig. 19.3 and Plate 19.1, page 758). Lipofuscin granules are prevalent in the gland cells and, in combination with the lipofuscin granules in the supporting cells of the olfactory epithelium, give the mucosa its natural yellow-brown coloration. Short ducts composed of cuboidal cells lead from the glands and pass through the basal lamina into the olfactory epithelium, where they continue to the epithelial surface to discharge their contents.

Loss of water to evaporation leads to the formation of an osmotic gradient by the remaining ions. Restoring the equilibrium of the mucosa to protect olfactory function requires rapid water transport, which is achieved by the water channels of the **aquaporin pathway**. These channels rapidly transfer water from large superficial venules via the extracellular matrix to the lumen of the Bowman gland. Aquaporin molecules are found in the basolateral (AQP-3 and AQP-4) and apical (AQP-5) cell membrane of the gland's secretory cells. In addition, a similar distribution of aquaporins is present in supporting (sustentacular) and basal cells of the olfactory epithelium.

The serous secretion of the olfactory glands also serves as a trap and solvent for odoriferous substances. The constant flow from the glands rids the mucosa of remnants of detected odoriferous substances so that new odors can be continuously detected as they arise.

The identifying feature of the olfactory region of the nasal mucosa in a histologic preparation is the presence of the olfactory nerves in combination with olfactory glands in the lamina propria. The nerves are particularly conspicuous because of the relatively large diameter of the individual unmyelinated fibers that they contain (see Figs. 19.3 and 19.4).

Paranasal Sinuses

Paranasal sinuses are air-filled spaces in the bones of the walls of the nasal cavity.

The **paranasal sinuses** are extensions of the respiratory region of the nasal cavity and are lined by respiratory epithelium. The sinuses are named for the bone in which they are found (i.e., the ethmoid, frontal, sphenoid, and maxillary bones). The sinuses communicate with the nasal cavities via narrow openings onto the respiratory mucosa. Paranasal sinuses most likely function in voice resonance. The mucosal surface of the sinuses is a thin, ciliated, pseudostratified columnar epithelium with numerous goblet cells. The lamina propria is thin and continuous with the underlying periosteum. It contains only a few small glands. Mucus produced in the sinuses is swept into the nasal cavities by coordinated ciliary movements. The sinuses may become the site of a secondary bacterial infection (sinusitis) following viral infection of the upper respiratory tract. Severe infections may require physical drainage.

Paranasal sinuses are the main sites for nitric oxide (NO) production in the airways.

Research conducted in the past decade has shown that the respiratory epithelium of the paranasal sinuses contains large amounts of nitric oxide synthase, an enzyme responsible for **nitric oxide (NO) production**. NO is a potent neurotransmitter and chemical messenger. The concentration levels of NO produced continuously in the paranasal sinuses are several times higher than levels in other parts of the respiratory tract. Because air circulates between the paranasal sinuses and the nasal cavity, high levels of NO enter the nasal cavity and may play an important role in the nasal defense mechanism against invading microorganisms. In addition, NO from the paranasal sinuses reaches the lungs with each inhalation, where it facilitates gas exchange and reduces pulmonary vascular resistance by relaxing vascular smooth muscles.

■ PHARYNX

The **pharynx** connects the nasal and oral cavities to the larynx and esophagus. It serves as a passageway for air and food and acts as a resonating chamber for speech. The pharynx is located

posterior to the nasal and oral cavities and is divided regionally into the **nasopharynx** and **oropharynx**, respectively (see Fig. 19.2). The auditory (Eustachian) tubes connect the nasopharynx to each middle ear. Diffuse lymphatic tissue and lymphatic nodules are present in the wall of the nasopharynx. The group of lymphatic nodules concentrated at the junction between the superior and posterior walls of the pharynx is called the **pharyngeal tonsil**.

■ LARYNX

The passageway for air between the oropharynx and the trachea is the **larynx** (see Fig. 19.2). In addition to serving as a conduit for air, the larynx serves as the organ for producing sounds. This complex tubular region of the respiratory system is formed by irregularly shaped plates of **hyaline** and **elastic cartilages** (the epiglottis and the vocal processes of the arytenoid cartilages). Cartilages of the larynx are connected to one another by joints, membranes, and ligaments, and their movements in relation to each other are controlled by **intrinsic laryngeal muscles**. The mucosa of the larynx forms two pairs of shelf-like folds that project into the lumen of the larynx bilaterally. Both folds are oriented in an anteroposterior direction; thus, on the frontal section of the larynx, they are visible in cross section (cut perpendicularly to their length) separated by the invagination of the laryngeal mucosa called **ventricle** (Fig. 19.5). The upper pair of folds, the **vestibular folds**, are immobile, but the lower pair of folds, the **vocal folds**, are mobile and play an important role in producing sounds (phonation).

FIGURE 19.5. Topography of the larynx and trachea. **a.** The larynx is a hollow musculoligamentous structure reinforced by cartilaginous skeleton. It is located in the neck region, and its cavity is continuous inferiorly with the trachea and posteriorly with the oropharynx. The laryngeal cavity contains the vestibular and vocal folds oriented in an anteroposterior direction. The trachea extends from the larynx to the thorax and divides into the two main (primary) bronchi at the level of the T4-T5 thoracic vertebrae. Immediately posterior to the trachea is the esophagus, which continues into the abdomen. **b.** This specimen obtained from a frontal cut through the larynx shows both vocal and ventricular folds in cross section. Note that the vocal and ventricular folds are separated by the ventricle, an invagination of the laryngeal mucosa. $\times 15$. **c.** This photomicrograph shows a horizontal section of the fetal trachea and esophagus and its close relationships in the thorax. The trachealis muscle on the posterior wall of the trachea is adjacent to the anterior wall of the esophagus. The lumen of the trachea is round and remains open due to the arrangement of the cartilaginous rings $\times 10$.

Vocal folds control the flow of air through the larynx and vibrate to produce sound.

The **vocal folds**, also referred to as *vocal cords* (Fig. 19.6 and Plate 19.2, page 760), define the lateral boundaries of the opening of the larynx, the **rima glottidis**. A supporting ligament and skeletal muscle, the **vocalis muscle**, is contained within each vocal fold. Ligaments and the intrinsic laryngeal muscles join the adjacent cartilaginous plates and are responsible for generating tension in the vocal folds and for opening and closing the rima glottidis. The **extrinsic laryngeal muscles** insert on cartilages of the larynx but originate in extralaryngeal structures. These muscles move the larynx upward and forward during **deglutition** (swallowing).

FIGURE 19.6. Photomicrograph of a frontal section of the larynx. **a.** This photomicrograph shows three parts of the larynx: the vestibule above the ventricular folds, the ventricles between the vestibular folds and superior to the vocal folds, and the infraglottic cavity that extends from the vocal folds to the cricoid cartilage. Note that mucous glands are prominent in the ventricular folds and are covered by the typical pseudostratified ciliated epithelium. The vocal fold is composed of the epithelium, vocal ligament, and underlying vocalis muscle. Numerous lymph nodules are also present within the mucosa of the larynx (*arrows*). $\times 10$. **b.** High magnification of the area of the ventricular fold indicated by the *upper rectangle* in **a** shows on the *left* the pseudostratified ciliated epithelium that lines most of the larynx. Many nonsmoking adults and virtually all smokers exhibit patches of stratified squamous epithelium, as seen on the *right* of the micrograph. $\times 240$. **c.** High magnification of the area of the vocal fold indicated by the *lower rectangle* in **a** reveals normal stratified squamous epithelium at this site. Just beneath the epithelium is the connective tissue known as *Reinke space*. This clinically important site lacks lymphatic vessels and is poorly vascularized. The vocal ligament, inscribed by the *dashed line*, is seen at the *bottom* of the micrograph. $\times 240$.

Expelled air from lungs passing through the narrow space of the **rima glottidis** causes the vocal folds to vibrate against each other. The vibrations are altered by modulating the tension on the vocal folds and by changing the degree of glottal opening. This alteration of vibrations produces sounds of different **pitch**. Relaxed vocal cords produce a deeper pitch, whereas stretched and tense vocal cords produce a higher pitch. Sounds created in the larynx during the process of **phonation** are modified in the upper parts of the respiratory system (nasopharynx, nasal cavities, and paranasal sinuses) and the oral cavity (oropharynx, soft and hard palate, tongue, teeth, lips, etc.) to produce the individual speech sounds (different vowels and consonants).

The ventricular folds located above the vocal folds are the “false vocal cords.”

Above the vocal folds is an elongated recess in the larynx called the **ventricle**. Immediately above the ventricle is another pair of mucosal folds, the **ventricular folds** or false vocal cords (see Fig. 19.6 and Plate 19.2, page 760). These folds do not have the intrinsic muscular investment of the true

vocal cords and, therefore, do not modulate during phonation. Along with the ventricle, however, they are important in creating **sound resonance**. Inflammation and swelling of the larynx caused by viruses (such as the common cold virus) and other microbial agents is called *acute laryngitis*. Symptoms of *acute laryngitis* may include hoarseness or, in more severe cases, total loss of voice, coughing, and difficulty with swallowing and breathing. *Chronic laryngitis* is usually caused by prolonged exposure to irritating agents, such as tobacco smoke, dust, and/or polluted air.

Stratified squamous and ciliated pseudostratified columnar epithelium line the larynx.

The luminal surface of the **vocal cords** is covered with **stratified squamous epithelium**, as is most of the epiglottis (Plate 19.2, page 760). The epithelium serves to protect the mucosa from abrasion caused by the rapidly moving air stream. The rest of the larynx is lined with the ciliated, pseudostratified columnar epithelium that characterizes the respiratory tract (see Fig. 19.6 and Plate 19.2, page 760). The connective tissue of the larynx contains mixed mucoserous glands that secrete through ducts onto the laryngeal surface.

■ TRACHEA

The **trachea** is a short, flexible air tube approximately 2.5 cm in diameter and 10–12 cm long. It serves as a conduit for air; in addition, its wall assists in the climatization of inspired air. The trachea extends from the larynx to the middle of the thorax and is positioned in the front and adjacent to the esophagus (see Fig. 19.5). In the thorax, it divides into the two **main (primary) bronchi**, which enter the right and left lung. The lumen of the trachea remains open because of the arrangement of the series of cartilaginous rings (see later in this later).

The wall of the trachea consists of four definable layers:

- **Mucosa**, composed of a ciliated, pseudostratified epithelium and an elastic, fiber-rich lamina propria
- **Submucosa**, composed of a slightly denser connective tissue than the lamina propria
- **Cartilaginous layer**, composed of C-shaped hyaline cartilages
- **Adventitia**, composed of connective tissue that binds the trachea to adjacent structures

A unique feature of the trachea is the presence of a series of C-shaped hyaline cartilages that are stacked one on top of each other to form a supporting structure (Fig. 19.7). These cartilages, which might be described as a skeletal framework, prevent the collapse of the tracheal lumen, particularly during expiration. Fibroelastic tissue and smooth muscle, the trachealis muscle, bridge the gap between the free ends of the C-shaped cartilages at the posterior border of the trachea, adjacent to the esophagus.

FIGURE 19.7. Photomicrograph of a section of the trachea and esophagus. **a.** This specimen, obtained from an elderly individual, shows the relationship between the trachea and the esophagus at the base of the neck. The cartilaginous tracheal rings, which keep the trachea patent, have a C-shaped appearance. The cartilage gap, where

the trachea is adjacent to the esophageal wall, is spanned by a fibroelastic membrane. It contains the trachealis muscle and numerous seromucous glands. In this specimen, the tracheal ring has been transformed, in part, to bone, a process that occurs in aging. The darker staining material represents cartilage, whereas the lighter staining material has been replaced by bone tissue. The very light areas (*arrows*) are marrow spaces. $\times 3.25$. **b.** This high-magnification photomicrograph shows an area of the tracheal ring that has partially transformed into bone. The *top* of the micrograph shows the tracheal mucosa and submucosa. Below is part of the tracheal ring. In this particular region, however, a substantial portion of the cartilage has been replaced by bone tissue and marrow. The bone tissue exhibits typical lamellae and osteocytes. The cartilage tissue, in contrast, exhibits nests of chondrocytes. $\times 100$.

Tracheal Epithelium

Tracheal epithelium is similar to respiratory epithelium in other parts of the conducting airway.

Ciliated columnar cells, mucous (goblet) cells, and basal cells are the principal cell types in the tracheal **pseudostratified columnar ciliated epithelium** (Figs. 19.8 and 19.9). Brush cells are also present, but in small numbers, as are small granule cells.

FIGURE 19.8. Electron micrograph of human trachea. This electron micrograph shows the three main cell types of this respiratory epithelium. They are represented by ciliated epithelial cells extending to the surface, where they possess cilia; goblet cells with mucinogen granules; and basal cells, which are confined to the basal portion of the epithelial layer near the connective tissue. $\times 1,800$. (Courtesy of Dr. Johannes A. G. Rhodin.)

FIGURE 19.9. Scanning electron micrograph of the luminal surface of a bronchus. The nonciliated cells are the goblet cells (G). Their surface is characterized by small blunt microvilli that give a stippled appearance to the cell at this low magnification. The cilia of the many ciliated cells occupy the remainder of the micrograph. Note how all are “synchronously” arrayed (i.e., uniformly leaning in the same direction), appearing just as they were when fixed at a specific moment during their wave-like movement. $\times 1,200$.

- **Ciliated cells**, the most numerous of the tracheal cell types, extend through the full thickness of the epithelium. Cilia appear in histologic sections as short, hair-like profiles projecting from the apical surface (Plate 19.3, page 762). Each cell has approximately 250 cilia. Immediately below the cilia is a dark line formed by the aggregated ciliary basal bodies (Fig. 19.10). The cilia provide a coordinated sweeping motion of the mucous coat from the farthest reaches of the air passages toward the pharynx. In effect, the ciliated cells function as a “**mucociliary escalator**” that serves as an important protective mechanism for removing small inhaled particles from the lungs.

FIGURE 19.10. Photomicrograph of tracheal epithelium. Three major cell types are evident in the tracheal epithelium (*Ep*): ciliated columnar cells; mucus-secreting goblet cells (*G*) interspersed between the ciliated cells; and basal cells, which are close to the basement membrane (*BM*). The ciliated columnar cells extend from the basement membrane to the surface. At their free surface, they contain numerous cilia that, together, give the surface a brush-like appearance. At the base of the cilia is a dense eosinophilic line. This is owing to the linear aggregation of structures referred to as *basal bodies*, located at the proximal end of each cilium. Although basement membranes are not ordinarily seen in hematoxylin and eosin (H&E) preparations, a structure identified as such is seen regularly under the epithelium in the human trachea. The underlying lamina propria (*LP*) consists of loose connective tissue. The more deeply located submucosa (*SM*) contains dense irregular connective tissue with blood and lymphatic vessels, nerves, and numerous mucus-secreting tracheal glands. $\times 400$.

- **Mucous cells** are similar in appearance to intestinal goblet cells and are thus often referred to by the same name. They are interspersed among the ciliated cells and also extend through the full thickness of the epithelium (see Fig. 19.10). They are readily seen in the light microscope after they have accumulated mucinogen granules in their cytoplasm. Although the mucinogen is typically washed out in hematoxylin and eosin (H&E) preparations, the identity of the cell is made apparent by the remaining clear area in the cytoplasm and the lack of cilia at the apical surface. In contrast to ciliated cells, the number of mucous cells increases during chronic irritation of the air passages.
- **Brush cells** have the same general features as those described for the respiratory epithelium of the nasal cavity (Fig. 19.11). They are columnar cells that bear blunt microvilli. The basal surface of the cells is in synaptic contact with an afferent nerve ending (epitheli dendritic synapse). As discussed earlier, brush cells are regarded as general sensory and chemoreceptor cells.

FIGURE 19.11. Diagram of a terminal bronchiolar epithelium. This diagram shows several cells found in the respiratory epithelium. The club cell, as illustrated here, is interposed between the brush cell and the small granule cell. The club cell is a nonciliated cell that has rounded apical surface, well-developed basal rough-surfaced endoplasmic reticulum (*rER*), and Golgi apparatus and contains secretory vesicles filled with a surface-active agent. Adjacent is the brush cell that contains blunt microvilli and makes synaptic contact (epitheliiodendritic synapse) with an afferent nerve fiber, which are distinctive features of this cell. Cytoplasm of the brush cell shows a Golgi apparatus, lysosomes, mitochondria, and glycogen inclusions. A small granule cell is shown located between the club cell and the ciliated cell. This cell contains small secretory vesicles, most of which are in the basal portion of the cell. In addition to the vesicles, the most conspicuous organelles of this cell are *rER*, a Golgi apparatus, and mitochondria. A nerve terminal is shown within the epithelium.

- **Small granule cells (Kulchitsky cells)** are respiratory representatives of the general class of **enteroendocrine cells** of the gut and gut derivatives (see Fig. 19.11). Their presence is explained by the development of the respiratory tract and lungs from an evagination of the primitive foregut. Small granule cells usually occur singly in the trachea and are sparsely dispersed among the other cell types. They are difficult to distinguish from basal cells in the light microscope without special techniques such as silver

staining, which reacts with the granules. The nucleus is located near the basement membrane; the cytoplasm is somewhat more extensive than that of the smaller basal cells. With the transmission electron microscope (TEM), a thin, tapering cytoplasmic process is sometimes observed extending to the lumen. Also, with the TEM, the cytoplasm exhibits numerous, membrane-bound, dense-core granules. In one type of small granule cell, the secretion is a **catecholamine**. A second cell type produces polypeptide hormones, such as **serotonin**, **calcitonin**, and **gastrin-releasing peptide (bombesin)**. Some small granule cells appear to be innervated. The function of these cells is not well understood. Some are present in groups in association with nerve fibers, forming neuroepithelial bodies, which are thought to function in reflexes regulating the airway or vascular caliber.

- **Basal cells** represent a stem cell population that maintains individual cell replacement in the epithelium. Basal cells tend to be prominent because their nuclei form a row in close proximity to the basal lamina. Although nuclei of other cells reside at this same general level within the epithelium, they are relatively sparse. Thus, most of the nuclei near the basement membrane belong to basal cells.

Basement Membrane, Lamina Propria, and Submucosa

A thick “basement membrane” is a characteristic feature of the tracheal epithelium.

Located beneath the tracheal epithelium is a distinctive layer typically referred to as a **basement membrane** (see Fig. 19.10). It usually appears as a glassy or homogeneous light-staining layer approximately 25–40 μm thick. EM reveals that it consists of densely packed collagenous fibers that lie immediately under the epithelial basal lamina. Structurally, it can be regarded as an unusually thick and dense reticular lamina and, as such, is part of the lamina propria. **In smokers, particularly those who experience chronic coughing, this layer may be considerably thicker, a response to mucosal irritation.**

In individuals with asthma, the basement membrane is also thicker and more pronounced, especially at the level of the bronchioles.

The boundary between mucosa and submucosa is defined by an elastic membrane.

The lamina propria, excluding that part just designated as basement membrane, appears as a typical loose connective tissue. It is very cellular, containing numerous lymphocytes, many of which infiltrate the epithelium. Plasma cells, mast cells, eosinophils, and fibroblasts are the other cell types readily observed in this layer. Lymphatic tissue, in both diffuse and nodular forms, is consistently present in the lamina propria and submucosa of the tracheal wall. It is also present in other parts of the respiratory system involved primarily with air conduction. This lymphatic tissue is the developmental and functional equivalent of the bronchus-associated lymphatic tissue (BALT). Interspersed among the collagenous fibers are numerous elastic fibers. Where the lamina propria ends, the elastic material is more extensive, and in specimens stained for these fibers, a distinct band of elastic material is seen. This band or elastic membrane marks the boundary between the lamina propria and submucosa. In H&E preparations, however, the boundary is not obvious.

The submucosa is unlike that of most other organs, which is typically a dense connective tissue. In the trachea, the submucosa is a relatively loose connective tissue similar in appearance to the lamina propria, which makes it difficult to determine where it begins. Diffuse lymphatic tissue and lymphatic nodules characteristically extend into this layer from the lamina propria. The submucosa contains the larger distributing vessels and lymphatics of the tracheal wall. Submucosal glands composed of mucus-secreting acini with serous demilunes are also present in the submucosa. Their ducts consist of a simple cuboidal epithelium and extend through the lamina propria to deliver their product, largely glycoproteins, on the epithelial surface. The glands are especially numerous in the cartilage-free gap on the posterior portion of the

trachea. Some penetrate the muscle layer at this site and, therefore, also lie in the adventitia. The submucosal layer ends where its connective tissue fibers blend with the perichondrium of the cartilage layer.

The tracheal cartilages and trachealis muscle separate submucosa from adventitia.

The **tracheal cartilages**, which number approximately 16–20 in humans, represent the next layer of the tracheal wall. As noted, the cartilages are C shaped. They sometimes anastomose with adjacent cartilages, but their arrangement provides flexibility to the trachea and also maintains patency of the lumen. With age, the hyaline cartilage may be partially replaced by bone tissue (see Fig. 19.7), causing it to lose much of its flexibility.

FOLDER 19.1

CLINICAL CORRELATION: COMMON CONDITIONS AFFECTING THE NASAL MUCOSA

Inflammation of the nasal mucosa is referred to as **rhinitis**. This inflammatory process may also spread into the paranasal sinuses (**rhinosinusitis**) because of their proximity to and connections with the nasal cavity. Viruses, including rhinoviruses, myxoviruses, coronaviruses, and adenoviruses, are the most common cause of nasal mucosa inflammation, referred to as **viral rhinitis** or the “**common cold**.” Viral rhinitis occurs more commonly in children than in adults. Swelling of the nasal mucosa, often called **mucosal inflammation**, may lead to nasal congestion or obstruction, resulting in reduced nasal airflow and increased nasal secretion with simultaneous narrowing of the openings to the paranasal sinuses. Microscopic findings in mucosal inflammation include marked tissue swelling and edema of the respiratory mucosa with significantly increased infiltration of the lamina propria by inflammatory cells, including eosinophils, neutrophils, basophils, mast cells, plasma cells, and lymphocytes (Fig. F19.1.1). Viral infection may lead to secondary bacterial infection (**acute bacterial rhinosinusitis** or **chronic bacterial rhinosinusitis**). The microscopic findings would reveal heavily infiltrated lamina propria and respiratory epithelium with inflammatory cells, including neutrophils and T cells. Acute

bacterial rhinosinusitis is usually treated with antibiotic therapy.

FIGURE F19.1.1. Photomicrograph of a biopsy specimen of the maxillary sinus mucosa from a patient with rhinosinusitis. Microscopic findings in rhinosinusitis include inflammation of the respiratory mucosa of the nasal passages and paranasal sinuses. Note that the respiratory epithelium is separated from the bone of the maxillary sinus by the inflamed lamina propria. In this photomicrograph, the lamina propria is noticeably thickened (edematous) with enlarged blood vessels and is heavily infiltrated by immune cells, mainly lymphocytes, eosinophils, and plasma cells. $\times 480$. (Courtesy of Dr. Joaquin J. Garcia.)

Allergic rhinitis, frequently referred to as “hay fever,” is caused by allergic reactions to airborne particles, such as grass pollens, dust, molds, or animal allergens that are deposited on the nasal mucosa. These particles trigger acute or chronic immune reactions. Allergens in combination with **IgE antibodies** (secreted by the plasma cells in the lamina propria) bind to high-affinity F_c receptors expressed on the surface of mast cells. This triggers activation of **mast cells** with the release of vasoactive agents and inflammatory mediators (e.g., histamine and leukotrienes) from the cell granules (see pages 200–204). Degranulation of mast cells causes rhinorrhea or “runny nose” and nasal congestion. The characteristic microscopic features of allergic rhinitis include infiltration of the nasal mucosa by numerous eosinophils, plasma cells, and mast cells. In chronic allergic rhinitis, an increased number of mast cells and thickening of the basement membrane are often observed. Treatment for allergic rhinitis includes antihistamine agents to suppress immune reactions and anti-inflammatory corticosteroids to control symptoms.

The **adventitia**, the outer layer, lies peripheral to the cartilage rings and trachealis muscle. It binds the trachea to adjacent structures in the neck and mediastinum and contains the largest blood vessels and nerves that supply the tracheal wall as well as the larger lymphatics that drain the wall.

■ BRONCHI

The trachea divides into two branches forming the **main (primary) bronchi**. Anatomically, these divisions are more frequently described as simply the **right and left main bronchi**, terms that are more useful because of the physical difference between the two. The right bronchus is wider and significantly shorter than the left. On entering the hilum of the lung, each main bronchus divides into the **lobar bronchi (secondary bronchi)**. The left lung is divided into two lobes; the right lung is divided into three lobes. Thus, the right bronchus divides into three lobar bronchial branches and the left into two lobar bronchial branches, with each branch supplying one lobe. The left lung is further divided into 8 **bronchopulmonary segments** and the right lung into 10 such segments. Thus, in the right lung, the lobar bronchi give rise to 10 **segmental bronchi (tertiary bronchi)**; the lobar bronchi of the left lung give rise to 8 segmental bronchi.

A **segmental bronchus** and the lung parenchyma that it supplies constitute a bronchopulmonary segment. The significance of the bronchopulmonary segment in the human lung becomes apparent when considering the need for surgical resection, which may be required in certain disease states. The segments, each with their own blood supply and connective tissue septa, are convenient subunits that facilitate surgical resection.

Initially, the bronchi have the same general histologic structure as the trachea. At the point where the bronchi enter the lungs to become intrapulmonary bronchi, the structure of the bronchial wall changes. The cartilage rings are replaced by cartilage plates of irregular shape. The plates are distributed in a linear array around the entire circumference of the wall,

giving the bronchi a circular or cylindrical shape in contrast to the ovoid shape with a flattened posterior wall of the trachea. As the bronchi decrease in size because of branching, the cartilage plates become smaller and less numerous. The plates ultimately disappear at the point where the airway reaches a diameter of approximately 1 mm, whereupon the branch is designated a **bronchiole**.

Bronchi can be identified by their cartilage plates and a circular layer of smooth muscle.

The second change observed in the wall of the intrapulmonary bronchus is the addition of **smooth muscle** to form a complete circumferential layer. The smooth muscle becomes an increasingly conspicuous layer as the amount of cartilage diminishes. Initially, the smooth muscle is arranged in interlacing bundles, forming a continuous layer. In the smaller bronchi, the smooth muscle may appear discontinuous.

Because the smooth muscle forms a separate layer, namely, a muscularis, the wall of the bronchus can be regarded as having five layers:

- **Mucosa**, composed of a pseudostratified epithelium with the same cellular composition as the trachea. The height of the cells decreases as the bronchi decrease in diameter. In H&E specimens, the “basement membrane” is conspicuous in the primary bronchi but quickly diminishes in thickness and disappears as a discrete structure in the secondary bronchi. The lamina propria is similar to that of the trachea but is reduced in amount in proportion to the diameter of the bronchi.
- **Muscularis**, a continuous layer of smooth muscle in the larger bronchi. It is more attenuated and loosely organized in smaller bronchi, where it may appear discontinuous because of its spiral course. Contraction of the muscle regulates the appropriate diameter of the airway.
- **Submucosa** remains as a relatively loose connective tissue. Glands are present as well as adipose tissue in the larger bronchi.

- **Cartilage layer** consists of discontinuous cartilage plates that become smaller as the bronchial diameter diminishes.
- **Adventitia** is moderately dense connective tissue that is continuous with that of adjacent structures, such as pulmonary artery and lung parenchyma.

■ BRONCHIOLES

The **bronchopulmonary segments** are further subdivided into **pulmonary lobules**; each lobule is supplied by a bronchiole. Delicate connective tissue septa that partially separate adjacent lobules may be represented on the surface of the lung as faintly outlined polygonal areas. **Pulmonary acini** are smaller units of structure that make up the lobules. Each acinus consists of a **terminal bronchiole** and the **respiratory bronchioles** and **alveoli** that it aerates (Fig. 19.12 and Plate 19.4, page 764). The smallest functional unit of pulmonary structure is thus the **respiratory bronchiolar unit**. It consists of a single respiratory bronchiole and the alveoli that it supplies.

FIGURE 19.12. Photomicrograph showing the respiratory portion of the bronchial tree. In this photomicrograph, a terminal bronchiole (*TB*) is shown longitudinally sectioned as it branches into two respiratory bronchioles (*RB*). The terminal bronchiole is the most distal part of the conducting portion of the respiratory system and is not engaged in gas exchange. The respiratory bronchiole engages in gas exchange and is the beginning of the respiratory portion of the bronchial tree. Respiratory bronchioles give rise to alveolar ducts

(AD), which are elongated airways that have almost no walls, only alveoli surrounding the duct space. Alveolar sacs (AS) are spaces at the termination of the alveolar ducts that, likewise, are surrounded by alveoli. $\times 120$.

Bronchiolar Structure

Bronchioles are air-conducting ducts that measure 1 mm or less in diameter. The larger bronchioles represent branches of the segmental bronchi. These ducts branch repeatedly, giving rise to the smaller **terminal bronchioles** that also branch. The terminal bronchioles finally give rise to the **respiratory bronchioles**.

Cartilage plates and glands are not present in bronchioles.

The larger diameter bronchioles initially have a ciliated, pseudostratified columnar epithelium that gradually transforms into a simple ciliated columnar epithelium as the duct narrows. Goblet cells are still present in the largest bronchioles, but not in the terminal bronchioles that follow. An exception is in smokers and others exposed to irritants in the air. There are no subepithelial glands in bronchioles. Cartilage plates, characteristic of bronchi, are absent in bronchioles. Instead, small elements of cartilage may be present, particularly at branching points. A relatively thick layer of smooth muscle is present in the wall of all bronchioles.

Small bronchioles have a simple cuboidal epithelium. The smallest conducting bronchioles, the **terminal bronchioles**, are lined with a simple cuboidal epithelium in which **club cells** are interspersed among the ciliated cells (Fig. 19.13 and Plate 19.5, page 766). Club cells increase in number as the ciliated cells decrease along the length of the bronchiole. Occasional brush cells and small granule cells are also present. A small amount of connective tissue underlies the epithelium, and a circumferential layer of smooth muscle underlies the connective tissue in the conducting portions.

FIGURE 19.13. Scanning electron micrograph of a terminal bronchiole. This scanning photomicrograph shows a longitudinal

section throughout the terminal bronchiole and surrounding alveoli (A). Note that the apical surfaces of the club cells possess no cilia and have a characteristic dome-shaped appearance. $\times 150$. The *inset* shows some of the club cells at a higher magnification and the cilia of a neighboring ciliated cell, which are present in very small numbers at this level. Note the relatively few cilia present on these small cells. $\times 1,200$.

Club cells are nonciliated cells that have a characteristic rounded or dome-shaped apical surface projection. They display TEM characteristics of protein-secreting cells (Fig. 19.14 and Plate 19.5, page 766). They have a well-developed basal rER, a lateral or supranuclear Golgi apparatus, secretory granules that stain for protein, and numerous cisternae of sER in the apical cytoplasm. Club cells secrete a **surface-active agent**, a lipoprotein that prevents luminal adhesion should the wall of the airway collapse on itself, particularly during expiration. In addition, club cells produce a 16-kDa protein known as **club cell secretory protein (CC16)**, which is an abundant component of airway secretion. **Chronic lung diseases, such as chronic obstructive pulmonary disease (COPD) and asthma,** are associated with changes in the levels of CC16 in airway fluid and serum. Secretion of CC16 into the bronchial tree decreases because of the damage to club cells that occurs during lung injury, whereas serum levels of CC16 may increase because of leakage across the air-blood barrier. CC16 can thus be used as a measurable pulmonary marker in bronchoalveolar lavage fluid and serum.

FIGURE 19.14. Diagram of a club cell between bronchiolar ciliated epithelial cells. The nucleus is in a basal location. Rough-surfaced endoplasmic reticulum (*rER*), a Golgi apparatus, and mitochondria are chiefly in basal and paranuclear locations of the cell. Smooth-surfaced endoplasmic reticulum (*sER*) and secretory vesicles are chiefly in the apical cytoplasm. Two of the secretory vesicles are shown discharging its contents onto the surface of the cell.

FOLDER 19.2

CLINICAL CORRELATION: SQUAMOUS METAPLASIA IN THE RESPIRATORY TRACT

In human **respiratory mucosa**, ciliated pseudostratified columnar epithelium may change to stratified squamous epithelium. This change from columnar to squamous epithelium is referred to as **columnar-to-squamous metaplasia** or simply **squamous metaplasia**. Epithelial alterations of this kind are reversible

and are characterized by a change from one type of fully differentiated adult cell to a different type of adult cell. A given mature cell does not change to another type of mature cell; rather, basal cell proliferation gives rise to the new differentiated cell type. These cellular changes are considered to be controlled and adaptive.

Squamous metaplasia is a normal occurrence on the rounded, more exposed portions of the turbinates, on the vocal folds, and in certain other regions.

Changes in the character of the respiratory epithelium may, however, occur in other ciliated epithelial sites when the pattern of airflow is altered or when forceful airflow occurs, as in chronic coughing. Typically, in **chronic bronchitis** and **bronchiectasis**, the respiratory epithelium changes in certain regions to a stratified squamous form. The altered epithelium is more resistant to physical stress and insult, but it is less effective functionally. In smokers, a similar epithelial change occurs. Initially, the cilia on ciliated cells lose their synchronous beating pattern as a result of noxious elements in smoke. As a result, removal of mucus is impaired. To compensate, the individual begins to cough, thereby facilitating the expulsion of accumulated mucus in the airway, particularly in the trachea. With time, the number of ciliated cells decreases because of chronic coughing. This reduction in ciliated cells further impairs the normal epithelium and results in its replacement with stratified squamous epithelium at affected sites in the airway. If the factors (i.e., tobacco smoking) that predispose to squamous metaplasia are not eliminated, the metaplastic epithelium may undergo malignant transformation. In this way, one of the two most common forms of cancer of the respiratory tract, **squamous cell carcinoma**, originates from squamous metaplastic cells.

FOLDER 19.3

CLINICAL CORRELATION: ASTHMA

Asthma is a chronic inflammatory disease involving the airways of the lungs and is caused by a combination of genetic and environmental factors. The disease affects people of all ages, races, and ethnic groups worldwide. It is characterized by recurrent **obstruction of airflow** that results from **inflammation** of the bronchioles and **constriction** of their smooth muscles (**bronchospasm**). Obstruction of airways makes it difficult for air to move in and out of the lung alveoli, causing symptoms such as wheezing, coughing, shortness of breath, and chest tightness. Inflammation of the respiratory mucosa, underlying connective tissue, and smooth muscles of bronchioles is found in

patients with asthma. It is characterized by infiltration of the bronchiolar wall by eosinophils (in some cases, neutrophils), lymphocytes (mostly activated helper T cells), and mast cells. In individuals with asthma, the bronchiolar epithelium is thick, contains an increased number of goblet cells (thus producing more mucus), and has a thick basement membrane owing to an increased deposition of collagen fibers in the reticular lamina (Fig. F19.3.1). The smooth muscle layer is also more pronounced and contains several layers of hyperplastic smooth muscle cells.

FIGURE F19.3.1. Photomicrograph of the lung from a patient with bronchial asthma. **a.** This section of the lung from a patient with asthma shows a bronchiole in the *center* with surrounding alveoli. The bronchiolar wall is thick, inflamed, and has enlarged blood vessels. $\times 100$. **b.** This high-magnification photomicrograph shows the structure of a bronchiolar pseudostratified columnar epithelium containing a large number of goblet cells. The mucus in the lumen is a product of the goblet cells. Note the presence of a large number of eosinophils (cells with *red* cytoplasm), lymphocytes, and other connective tissue cells that infiltrated the lamina propria and submucosa of the bronchiole. The basement membrane is thick and well defined. The smooth muscle layer is also thick, and the underlying adventitia contains enlarged blood vessels (*BV*). $\times 680$. (Courtesy of Dr. Joseph P. Grande.)

Medications used to treat patients with asthma include **bronchodilators** that cause relaxation of smooth muscle; **anti-inflammatory** medications that suppress inflammatory reactions; and leukotriene modifiers that inhibit the production of leukotrienes, which are lipid mediators linked to increased activity of smooth muscle and mucus secretion. Asthma medications

are classified into two general categories according to their time of action in the overall management of this disease: (1) **quick-relief medications**, such as β -adrenergic agonist bronchodilators to reverse smooth muscle constriction, or (2) **long-term control medications**, such as inhaled corticosteroids, long-acting β -agonist bronchodilators, and leukotriene modifiers.

Bronchiolar Function

Respiratory bronchioles are the first part of the bronchial tree that allows gas exchange.

Respiratory bronchioles constitute a transitional zone in the respiratory system; they are involved in both air conduction and gas exchange. They have a narrow diameter and are lined by cuboidal epithelium. The epithelium of the initial segments of the respiratory bronchioles contains both **ciliated cells** and **club cells** (see Fig. 19.13). Distally, club cells predominate. Occasional brush cells and dense-core granule cells are also present along the length of the respiratory bronchiole. Scattered, thin-walled outpocketings, **alveoli**, extend from the lumen of the respiratory bronchioles (see Fig. 19.12). Alveoli are the sites at which air leaves and enters the bronchiole to allow gas exchange.

■ ALVEOLI

Alveoli are the site of gas exchange.

The surface area available for gas exchange is increased by the lung alveoli. **Alveoli** are the terminal air spaces of the respiratory system and are the actual sites of gas exchange between the air and the blood. Each alveolus is surrounded by a network of capillaries that brings blood in close proximity to inhaled air inside the alveolus. About 150–250 million alveoli are found in each adult lung; their combined internal surface area is approximately 75 m², roughly the size of a tennis court. Each alveolus is a thin-walled polyhedral chamber approximately

0.2 mm in diameter that is confluent with an alveolar sac (Fig. 19.15 and Plate 19.5, page 766).

FIGURE 19.15. Photomicrograph showing an alveolar sac with adjacent alveoli. This photomicrograph shows the terminal components of the respiratory system, namely, the alveolar sac (AS) and the surrounding alveoli (A). The A are surrounded and separated from one another by a thin connective tissue layer, the interalveolar septa, containing blood capillaries. On the *right* is the lung surface, which is covered by visceral pleura containing simple squamous epithelium and an underlying layer of connective tissue. $\times 360$.

- **Alveolar ducts** are elongated airways that have almost no walls, only alveoli, as their peripheral boundary. Rings of

smooth muscle are present in the knob-like interalveolar septa (see the next paragraph).

- **Alveolar sacs** are spaces surrounded by clusters of alveoli. The surrounding alveoli open into these spaces.

Alveolar sacs usually occur at the termination of an alveolar duct but may occur anywhere along its length. Alveoli are surrounded and separated from one another by an exceedingly thin connective tissue layer that contains blood capillaries. The tissue between adjacent alveolar air spaces is called the **interalveolar septum** or **septal wall** (Fig. 19.16).

FIGURE 19.16. Electron micrograph of lung alveoli. This electron micrograph shows two alveolar spaces separated by an interalveolar septum containing capillaries, some of which contain red blood cells. Note the areas of thin and thick portions of the interalveolar septum. These are shown at a higher magnification in Figure 19.21. $\times 5,800$. Inset. Photomicrograph of an alveolus for comparison with the alveolar wall as seen in an electron micrograph. Arrows indicate alveolar capillaries containing red blood cells. $\times 480$.

Alveolar epithelium is composed of type I and II alveolar cells and occasional brush cells.

The **alveolar surface** forms a vulnerable biological interface that is subject to many destabilizing surface forces and to continuous exposure to inhaled particles, pathogens, and toxins. The alveolar epithelium is composed of several specialized cells and their products, some of which play defensive and protective roles:

- **Type I alveolar cells**, also known as *type I pneumocytes*, comprise only 40% of the alveolar-lining cells. They are extremely thin squamous cells; they line most (95%) of the surface of the alveoli (see Fig. 19.16). These cells are joined to one another and to the other cells of the alveolar epithelium by occluding junctions (Fig. 19.17). The junctions form an effective barrier between the air space and the components of the septal wall. Type I alveolar cells are not capable of cell division.

FIGURE 19.17. Electron micrograph of a type II alveolar cell. The type II alveolar cell has a dome-shaped apical surface with a number of short microvilli at its periphery and a relatively smooth-contoured apical center. The lateral cell margins are overlain to a variable degree by the type I alveolar cells that are joined to the type II cell by occluding junctions. Both cell types rest on the basal lamina (BL). The secretory vesicles (G) in this specimen are largely dissolved, but their lamellar character is shown to advantage in Figure 19.18b. $\times 24,000$.

- **Type II alveolar cells**, also called *type II pneumocytes* or **septal cells**, are secretory cells. These cuboidal cells are interspersed among the type I cells but tend to congregate at septal junctions. Type II cells account for 60% of the alveolar-lining cells, but because of their different shape, they cover only about 5% of the alveolar air surface. Like club cells, type II cells tend to bulge into the air space (see Fig. 19.17). Their apical cytoplasm is filled with granules that are resolved with the TEM (Fig. 19.18) as stacks of parallel membrane lamellae, the **lamellar bodies**.

They are rich in a mixture of phospholipids, neutral lipids, and proteins that are secreted by exocytosis to form an alveolar-lining, surface-active agent called **surfactant**. In addition to secretion of surfactant, type II alveolar cells are progenitor cells for type I alveolar cells. Striking differences in the distribution of both types of alveolar cells can be easily visualized using immunofluorescence techniques (Fig 19.19). Following lung injury, they proliferate and restore both types of alveolar cells within the alveolus. Hyperplasia of type II alveolar cells is an indicator of alveolar injury and repair.

FIGURE 19.18. Diagram of a type II alveolar cell and electron micrograph of lamellar bodies. **a.** Surfactant is an oily mixture of proteins, phospholipids, and neutral lipids that are synthesized in the rough-surfaced endoplasmic reticulum (*rER*) from precursors in the blood. These precursors are glucose, fatty acids, choline, and amino acids. The protein constituents of surfactant are produced in the *rER* and stored in the cytoplasm within lamellar bodies, which are discharged into the lumen of the alveolus. With the aid of surfactant protein, surfactant is distributed on the surface of epithelial cells lining the alveolus as a thin film that reduces the surface tension. **b.** Higher magnification electron micrograph showing the typical lamellar pattern of the secretory vesicles of type II

alveolar cells. These vesicles contain the pulmonary surfactant precursor proteins. $\times 38,000$.

FIGURE 19.19. Immunofluorescent-stained image of the formalin-fixed frozen section of the adult pig lung. This high-magnification image shows the distribution of type I and type II alveolar cells within the alveolar wall. Type I alveolar cells (*green*) are visualized using an indirect immunofluorescence technique that utilizes primary polyclonal goat (IgG) antibodies against the cell membrane receptor for advanced glycation end products (RAGE), followed by secondary anti-goat antibodies conjugated with Alexa Fluor 488 fluorescent stain. The RAGE receptor is a transmembrane protein used as a molecular marker for type I alveolar cells and is localized in their apical cell membrane. Type

II alveolar cells (*red*) are visualized using primary polyclonal rabbit (IgG) antibodies against prosurfactant protein C, followed by secondary anti-rabbit antibodies conjugated with Alexa Fluor 555 fluorescent stain. Prosurfactant protein C is synthesized by type II alveolar cells and further processed into mature secreted protein C (SP-C). Note that 95% of the alveolar surface is covered by type I alveolar cells. Nuclei were stained blue by the DAPI stain that reacts with nuclear DNA and exhibits *blue* fluorescence over the nucleus. The nuclei within thin portions of the interalveolar septa belong to both type I and type II alveolar cells and endothelial cells of blood capillaries. Accumulation of septal macrophages and other connective tissue cells is reflected by the accumulation of nuclear stains in thick portions of the interalveolar septa. × 840. (Courtesy Dr. Atta Behfar and Skylar A. Rizzo, Van Cleve Center for Regenerative Medicine, Mayo Clinic.)

- **Brush cells** are also present in the alveolar wall, but they are few in number. They serve as chemoreceptors that monitor air quality in the lung.

Surfactant decreases the alveolar surface tension and actively participates in the clearance of foreign materials.

The **surfactant** layer produced by type II alveolar cells reduces the surface tension at the air-epithelium interface. The most critical agent for air space stability is a specific phospholipid called **dipalmitoylphosphatidylcholine (DPPC)**, which accounts for almost all surface tension-reducing properties of surfactant. Surfactant synthesis in the fetus occurs after the 35th week of gestation and is modulated by a variety of hormones, including cortisol, insulin, prolactin, and thyroxine. **Without adequate secretion of surfactant, the alveoli would collapse on each successive exhalation. Such collapse occurs in preterm infants whose lungs have not developed sufficiently to produce surfactant, which can lead to neonatal respiratory distress syndrome (RDS). Administration of exogenous surfactant at birth to preterm infants reduces the incidence of RDS. In addition, antenatal administration of corticosteroids to women with threatened preterm delivery decreases neonatal mortality.**

Surfactant proteins help organize the surfactant layer and modulate alveolar immune responses.

In addition to phospholipids, hydrophobic proteins are necessary for the structure and function of surfactant. These proteins are listed as follows:

- **Surfactant protein A (SP-A)**, the most abundant surfactant protein. SP-A is responsible for surfactant homeostasis (regulating synthesis and secretion of surfactant by type II alveolar cells). It also modulates immune responses to viruses, bacteria, and fungi.
- **Surfactant protein B (SP-B)**, an important protein for the transformation of the lamellar body into the thin surface film of surfactant. SP-B is a critical surfactant-organizing protein responsible for adsorption and spreading of surfactant onto the surface of the alveolar epithelium.
- **Surfactant protein C (SP-C)**, which represents only 1% of the total mass of surfactant protein. Along with SP-B, SP-C aids in orientation of DPPC within the surfactant and maintenance of the thin film layer within the alveoli.
- **Surfactant protein D (SP-D)**, a primary protein involved in host defense. It binds to various microorganisms (e.g., Gram-negative bacteria) and lymphocytes. SP-D participates in a local inflammatory response to acute lung injury and, with SP-A, modulates an immune response to various inhaled antigens.

The interalveolar septum is the site of the air-blood barrier.

The **air-blood barrier** refers to the cells and cell products across which gases must diffuse between the alveolar and capillary compartments. The thinnest air-blood barrier consists of a thin layer of surfactant, a type I epithelial cell and its basal lamina, and a capillary endothelial cell and its basal lamina. Often, these two basal laminae are fused (Fig. 19.20). Connective tissue cells and fibers that may be present between the two basal laminae widen the air-blood barrier. These two arrangements produce a **thin portion** and a **thick portion** of the barrier (Fig. 19.21). It is thought that most gas exchange occurs across the thin portion of the

barrier. The thick portion is thought to be a site in which tissue fluid can accumulate and even cross into the alveolus. Lymphatic vessels in the connective tissue of the terminal bronchioles drain fluid that accumulates in the thick portion of the septum. In acute interstitial pneumonia, disruption of the blood-air barrier caused by the injury of type I pneumonocytes or the endothelial epithelium leads to the exudation of plasma proteins into the alveolar space. In diffuse alveolar damage, exuded plasma proteins mix with lipids and components of pulmonary surfactant to form hyaline membranes, an elongated, homogeneous, amorphous, and eosinophilic structure that lines the alveolar wall and prevents normal gas exchange.

FIGURE 19.20. Diagram of the interalveolar septum. This diagram shows the thick and thin portions of the interalveolar septum. The thin portion forms the air-blood barrier and is responsible for most of the gas exchange that occurs in the lung. *Arrows* indicate the direction of CO₂ and O₂ exchange between the alveolar air space and the blood. The thick portion of the interalveolar septum plays an important role in fluid distribution and its dynamics. It contains connective tissue cells. Note the macrophage in the thick portion that extends its processes into the lumen of the alveolus.

FIGURE 19.21. Electron micrograph of the interalveolar septum. This high-magnification micrograph shows the thin portion of the air-blood barrier where it consists of type I alveolar cells, capillary endothelium, and the fused basal lamina shared by both cells. In the thick portion, the type I alveolar cell (*arrows*) rests on a basal lamina, and on the opposite side is connective tissue in which collagen fibrils and elastic fibers are evident. $\times 33,000$.

Alveolar macrophages remove inhaled particulate matter from the air spaces and red blood cells from the septum.

Alveolar macrophages are unusual in that they function in the air space of the alveolus (Fig. 19.22). In air spaces, they scavenge the surface to remove inhaled particulate matter (e.g., dust and pollen), thus giving them one of their alternative names, **dust cells**. Alveolar macrophages are derived from blood monocytes and belong to the mononuclear phagocyte system (see page 203). They phagocytize red blood cells that may enter the alveoli in heart failure (see Fig. 19.22). Some engorged macrophages pass up the bronchial tree in the mucus and are disposed of by swallowing or excretion when they reach the pharynx. **Septal macrophages** reside in the connective tissue of the interalveolar septa. They represent a population of alveolar macrophages that returned from air spaces of the alveoli or remained stationary in the connective tissue of interalveolar septa. They are filled with accumulated phagocytized material, and they may remain in the septa for much of an individual's life (Fig. 19.23). *At autopsy, the lungs of urban dwellers and smokers usually show many alveolar macrophages and septal macrophages filled with carbon particles, anthracotic pigment, and birefringent needle-like particles of silica. Alveolar macrophages also phagocytose infectious organisms such as *Mycobacterium tuberculosis*, which can be recognized in cells in appropriately stained specimens. These bacilli are not digested by macrophages; however, other infections or conditions that damage alveolar macrophages can cause the release of the bacteria and recurrent tuberculosis. In addition, recent evidence suggests that apoptosis of septal macrophages contributes to the development of emphysema.*

FIGURE 19.22. Photomicrograph of alveoli and alveolar macrophages. This high-magnification photomicrograph shows the structure of the interalveolar septum and the lumen of an alveolus

containing alveolar macrophages and red blood cells. The cytoplasm of the alveolar macrophages, when they are present in significant numbers, often contains the brown pigment hemosiderin from phagocytosed red blood cells. These hemosiderin-laden macrophages (often called "heart failure cells") are typically found in heart disease, mostly left ventricular failures that cause pulmonary congestion and edema. This results in enlargement of the alveolar capillaries and small hemorrhages into the alveoli. ×560.

FIGURE 19.23. Photomicrograph of alveolar and septal macrophages. This high-magnification photomicrograph shows interalveolar septa surrounding alveolar air spaces (*A*). The septum in the *middle* contains a larger blood vessel (*BV*). Macrophages that have phagocytosed cellular debris and inhaled environmental pollutants (e.g., dust particles, silica, cigarette tar, and microorganisms) in the alveolar lumen migrate back to the interalveolar septa, where they remain throughout life. These septal macrophages are seen here as large, irregularly shaped cells loaded with black cytoplasmic inclusions that obscure the view of the nucleus. Note that the septal macrophages are surrounded by lymphocytes, a sign of inflammatory response. Alveolar macrophages containing the brown pigment hemosiderin from phagocytosed red blood cells are also present in the lumen of the alveoli. $\times 560$.

Collateral air circulation through alveolar pores allows air to pass between alveoli.

Scanning electron microscopic studies of alveolar structure show openings in the **interalveolar septa** that allow circulation of air from one alveolus to another. These **alveolar pores (of Kohn)** can be of great significance in some pathologic conditions in which obstructive lung disease blocks the normal pathway of air to the alveoli. The alveoli distal to the blockage may continue to be aerated, via the pores, from an adjacent lobule or acinus.

A basic summary of information related to the respiratory system is included in Figure 19.24.

FIGURE 19.24. Divisions of the bronchial tree and summary of its histologic features.

■ BLOOD SUPPLY

The lung has both pulmonary and bronchial circulations.

The **pulmonary circulation** supplies the capillaries of the interalveolar septum and is derived from the pulmonary artery that leaves the right ventricle of the heart. The branches of the pulmonary artery travel with those of the bronchi and bronchioles and carry blood down to the capillary level at the alveoli. This blood is oxygenated and collected by pulmonary venous capillaries that join to form venules. They ultimately form the four pulmonary veins that return blood to the left atrium of the heart. The pulmonary venous system is located at a distance from the respiratory passages at the periphery of the bronchopulmonary segments.

The **bronchial circulation**, via bronchial arteries that branch from the aorta, supplies all of the lung tissue other than the alveoli (i.e., the walls of the bronchi and

bronchioles and the connective tissue of the lung other than that of the interalveolar septum). The finest branches of the bronchial arterial tree also open into the pulmonary capillaries. Therefore, the bronchial and pulmonary circulations anastomose at about the level of the junction between the conducting and respiratory passages. Bronchial veins drain only the connective tissue of the hilar region of the lungs. Most of the blood reaching the lungs via the bronchial arteries leaves the lungs via the pulmonary veins.

■ LYMPHATIC VESSELS

A dual **lymphatic drainage** of the lungs parallels the dual blood supply. One set of lymphatic vessels drains the parenchyma of the lung and follows the air passages to the hilum. Lymph nodes are found along the route of the larger lymphatic vessels. A second set of lymphatic vessels drains the surface of the lung and travels in the connective tissue of the **visceral pleura**, a serous membrane consisting of a surface mesothelium and the underlying connective tissue. Both of these systems converge in the hilum. Lymph passes through several groups of lymph nodes, including bronchopulmonary, tracheobronchial, and paratracheal, before draining into the venous system via either the thoracic duct on the left side or right lymphatic trunk on the right side of the body.

■ NERVES

Most of the nerves that serve the lung are not visible at the level of the light microscope. They are components of the sympathetic and parasympathetic divisions of the autonomic nervous system and mediate reflexes that modify the dimensions of the air passages (and blood vessels) by contraction of the smooth muscle in their walls. In addition, the autonomic nervous system controls glandular secretion of the respiratory mucosa.

CLINICAL CORRELATION: CYSTIC FIBROSIS

Cystic fibrosis (CF, mucoviscidosis) is a chronic obstructive pulmonary disease of children and young adults. It is an autosomal recessive disorder caused by a mutation in a gene called the **cystic fibrosis transmembrane conductance regulator (CFTR)** located on chromosome 7. The product of this gene, the **Cl⁻ channel protein**, is involved in the final alteration of mucus and digestive secretions, sweat, and tears. All mutations of CFTR gene result in abnormal epithelial transport of Cl⁻ that affects the viscosity of the secretion of the exocrine glands. Almost all exocrine glands secrete abnormally viscid mucus that obstructs the glands and their excretory ducts.

The course of the disease is largely determined by the degree of pulmonary involvement. At birth, the lungs are normal. However, the defective Cl⁻ channel protein in the bronchial epithelium causes decreased Cl⁻ secretion and increased Na⁺ and water reabsorption from the lumen (Fig. F19.4.1). As a result, the “mucociliary escalator” malfunctions, with consequent accumulation of an unusually thick, viscous mucous secretion. The pulmonary lesion is probably initiated by obstruction of the bronchioles. Bronchiolar obstruction blocks the airways and leads to thickening of the bronchiole walls and other degenerative changes in the alveoli. Because fluids remain trapped in the lungs, individuals with CF have frequent respiratory tract infections.

FIGURE F19.4.1. Schematic diagram of pathology in cystic fibrosis. In cystic fibrosis, secretion of Cl^- anions into the lumen of the bronchial tree is markedly decreased because of a defective or nonexistent chloride channel protein. Na^+ resorption from the lumen of the bronchial tree is then increased, causing movement of water into the cell. As a result, the mucous layer within the bronchial tree becomes dehydrated and viscous. This thick mucus is difficult to move by the mucociliary escalator mechanism, and it clogs the lumen of the bronchial tree, obstructing airflow.

FOLDER 19.5

CLINICAL CORRELATION: CHRONIC OBSTRUCTIVE PULMONARY DISEASE AND PNEUMONIA

Chronic obstructive pulmonary disease (COPD) is a pulmonary condition characterized by chronic obstruction of airflow. Several subtypes of COPD have been recognized, including **chronic bronchitis**, **chronic obstructive asthma**, and **emphysema**. The severity of COPD is clinically more important, however, than recognition of the specific subtype.

Emphysema is a condition of the lung characterized by permanent enlargement of the air spaces distal to the terminal bronchiole. This enlargement is accompanied by destruction of the alveolar wall (Fig. F19.5.1a). Thus, significant surface area for gas exchange is lost in this disease. Emphysema is relatively common; it is seen in about half of all autopsies and is easily recognized. Emphysema is often caused by chronic inhalations of foreign particulate material, such as coal dust, textile fibers, and construction dust. The most common cause, however, is cigarette smoking.

FIGURE F19.5.1. Photomicrographs of emphysema and pneumonia. **a.** This photomicrograph from the lung of an individual with emphysema shows the partial destruction of interalveolar septa, resulting in permanent enlargement of the air spaces. Note that the changes in the lung parenchyma are accompanied by thickening of the wall of the pulmonary vessels (*arrows*) and the presence of numerous cells within the air spaces. These cells are alveolar macrophages and are shown at higher magnification in Figure 19.22. $\times 240$. **b.** This photomicrograph is from the lung of an individual in the early

stages of acute pneumonia (inflammation of the lung). Note that the air spaces are filled with exudate containing white blood cells (mainly neutrophils), red blood cells, and fibrin. The capillaries in the interalveolar septum are enlarged and congested with red blood cells. Pathologists recognize this stage as the red hepatization stage of pneumonia. At this stage, the affected portion of the lung on gross examination appears red (because of enlarged capillaries), firm (because of the lack of air spaces), and heavy (because of the presence of exudate within the alveoli); the term *hepatization* stems from the tissue's resemblance to the liver. $\times 240$. Inset. Part of an alveolus at a higher magnification. Note the enlarged, congested capillary within the interalveolar septum. The air space is filled with neutrophils and red blood cells. The *lower right* corner shows early organization of the intra-alveolar exudate; observe that the developing fibrin network contains entrapped neutrophils and several red blood cells. $\times 420$.

The destruction of the alveolar wall may be associated with excess lysis of elastin and other structural proteins in the interalveolar septa. Elastase and other proteases are derived from lung neutrophils, macrophages, and monocytes. A specific genetic disease, α_1 -antitrypsin deficiency, causes a particularly severe form of emphysema in both heterozygous and homozygous individuals. It is usually fatal in homozygotes if untreated, but its severity can be reduced by supplying the enzyme inhibitor exogenously.

Pneumonia is a generic term that describes inflammation of the lung parenchyma. It is often caused by infection with viruses or bacteria and less often by other microorganisms. Certain drugs (immunosuppressive agents) and autoimmune diseases increase the risk of certain types of pneumonia. Despite the impact of antibiotics, pneumonia caused by *Streptococcus pneumoniae* is quite common (~50% of cases), especially in young and middle-aged adults. Other common bacteria causing pneumonia include *Haemophilus influenzae*, *Chlamydophila pneumoniae*, *Mycoplasma pneumoniae*, *Staphylococcus aureus*, and various Gram-negative microorganisms.

Pneumonia is most commonly acquired by individuals with no primary disorders of the immune system in a community setting (**community-acquired pneumonia**). However, it may be acquired by the infection spread by an organism in the hospital environment (**nosocomial pneumonia**) or as an **opportunistic pneumonia** in individuals with compromised immune systems.

In the earliest stage of **bacterial pneumonia**, protein-rich fluid containing numerous microorganisms fills the lung alveoli. Marked enlargement of the capillaries surrounding the alveoli is followed by a massive migration of neutrophils and erythrocytes into the alveolar air space (Fig. F19.5.1b). At this stage, the

lung is firm and red and resembles the liver; for this reason, it is often referred to as the **red hepatization stage** of pneumonia. In the next stage, macrophages phagocytose the fragmented neutrophils and other cellular and tissue debris. This stage is called the **gray hepatization stage**; congestion is diminished, but the lung remains firm. The alveolar exudate is then removed, the alveolar spaces gradually become refilled with air, and the lungs return to their normal function.

Respiratory infections caused by **coronavirus 2 (SARS-CoV-2)** range in severity from mild (resembling the common cold) to severe (severe acute respiratory syndrome). The SARS-CoV-2 virus targets cells in the nasal mucosa, bronchial epithelium, and alveolar pneumocytes. Lung examinations from autopsies of individuals who died from SARS-CoV-2 (COVID-19) infection reveal the presence of **diffuse alveolar damage** (characterized by interstitial and alveolar edema, the presence of hyaline membranes composed of condensed plasma proteins that line alveolar walls, proliferation of type II pneumocytes, and progressive interstitial fibrosis), accompanied by extensive **vascular damage** with thrombosis.

The molecular mechanism of SARS-CoV-2 infection is initiated by the virus spike protein (S), which binds to the angiotensin-converting enzyme 2 (ACE2) receptor expressed mainly on type II pneumocytes. This binding activates the virus spike S protein, mediating the entry of the virus into the pneumocyte. In the later stages of lung infection, the virus spreads into the endothelial cells of pulmonary capillaries and pericytes. In response, an inflammatory reaction involving infiltration by monocytes and neutrophils occurs that eventually leads to diffuse alveolar damage. Accompanied fulminant activation of the coagulation cascade leads to thrombosis, pulmonary emboli, and lung infarcts.

RESPIRATORY SYSTEM

OVERVIEW OF THE RESPIRATORY SYSTEM

- The **respiratory system** consists of the paired lungs and a series of air passages that lead to and from the lungs.

- Three principal functions of the respiratory system are air conduction, air filtration, and gas exchange (respiration).
- The upper part of the respiratory system (nasal cavities, paranasal sinuses, nasopharynx, and oropharynx) develops from the primitive oral cavity.
- The lower part of the respiratory system (larynx, trachea, bronchi with their divisions, and lungs) develops from the ventral evagination of the foregut endoderm.
- The conducting portion of the respiratory system includes the upper part of the respiratory system, larynx, trachea, bronchi, and most of the bronchioles (up to the terminal bronchioles).
- The respiratory portion contains the respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli.

NASAL CAVITIES

- The paired chambers of the nasal cavities are divided into vestibules (entrance to nasal cavities), respiratory regions, and olfactory regions.
- The respiratory region is lined by the respiratory mucosa that contains ciliated, pseudostratified columnar epithelium.
- Respiratory epithelium is composed of tall columnar cells with cilia (for movement of secretion and other particles on the mucosal surface), goblet cells (to secrete mucus), brush cells (for sensory innervation), small granule cells (enteroendocrine cells for secreting hormones and cytokines), and basal cells (stem cells).
- The respiratory mucosa warms, moistens, and filters inspired air. It possesses a rich vascular network in the lamina propria, as well as numerous mucus- and serous-secreting glands.
- The olfactory region located at the roof of the nasal cavity is lined by a pseudostratified olfactory

epithelium without goblet cells.

- **Olfactory epithelium** is composed of **olfactory receptor cells** (bipolar neurons), **supporting cells**, **brush cells**, and **basal cells**.
- **Olfactory receptor cells** possess apical immotile cilia, which contain G-protein-coupled receptors involved in the olfactory transduction pathway.
- **Olfactory (Bowman) glands** are a characteristic feature of the olfactory mucosa.

PHARYNX AND LARYNX

- The **pharynx** is a posterior continuation of the oral and nasal cavities. It passes food into the esophagus and air into the larynx.
- The **larynx** is a connection between the pharynx and the trachea. It contains **vocal folds** that control the flow of air through the larynx and vibrate to produce sound.
- The larynx is lined by the **respiratory mucosa**, except for the luminal surface of the vocal cords, which is covered by a **stratified squamous epithelium**.

TRACHEA

- The **trachea** extends from the larynx into the mediastinum, where it divides into the two main (primary) bronchi.
- The wall of the trachea consists of four layers: **mucosa** (composed of a ciliated, pseudostratified epithelium resting on a thick basement membrane), **submucosa** (dense irregular connective tissue), **cartilaginous layer** (composed of C-shaped hyaline cartilages), and **adventitia** (binds the trachea to adjacent structures).

BRONCHI AND BRONCHIOLES

- The trachea divides into **right and left main (primary) bronchi** that enter the lungs and undergo repeated divisions ending with the bronchioles.
- Bronchi are lined by **respiratory mucosa** with the same cellular composition as the trachea. They possess **cartilage plates** and a circular layer of **smooth muscle**.
- **Bronchioles** are branches of segmental bronchi that are 1 mm or less in diameter and do not possess cartilage plates or glands.
- The smallest conducting **terminal bronchioles** are lined with a simple cuboidal epithelium containing **club cells**. These cells produce a surface-acting agent that prevents airway collapse.
- **Respiratory bronchioles** are the first part of the bronchial tree that allows gas exchange.

ALVEOLI

- The **respiratory bronchiole** divides into the alveolar ducts that lead into alveolar sacs surrounded by clusters of alveoli.
- **Alveoli** are the terminal air spaces of the respiratory system. Their septa are the locations for gas exchange between the air and the blood.
- **Alveolar epithelium** is composed of type I and II alveolar cells (pneumocytes) with occasional brush cells.
- **Type I alveolar cells** are extremely thin squamous cells that line 95% of the alveolar surface and form the barrier between the air space and the septal wall.
- **Type II alveolar cells** are secretory cells that produce and secrete surfactant, which lowers surface tension in the alveoli. They have characteristic lamellar bodies visible with EM.

- The **interalveolar septum** is the site of the **air-blood barrier**. It consists of a thin layer of surfactant, a type I epithelial cell with its basal lamina, and a capillary endothelial cell with its basal lamina. Often, these two basal laminae are fused together.
- **Alveolar and septal macrophages** are present in alveolar air spaces and septal connective tissue, respectively.

BLOOD SUPPLY, INNERVATION, AND LYMPHATIC DRAINAGE

- The lung has both pulmonary and bronchial circulations.
- **Pulmonary circulation** delivers blood via branches of the pulmonary artery to the capillary network surrounding the alveoli for oxygenation. Blood is collected by pulmonary venous capillaries that eventually form the pulmonary veins.
- **Bronchial circulation**, via bronchial arteries, supplies the walls of the bronchi, bronchioles, and the remaining connective tissue of the lung.
- **Autonomic nerves** follow the branches of pulmonary arteries and innervate the smooth muscle of blood vessels, the bronchial tree, and the respiratory mucosa.
- A dual **lymphatic drainage** of the lungs parallels the dual blood supply. Accumulation of the bronchus-associated lymphatic tissue (**BALT**) and lymph nodes is frequently found near large bronchi.

PLATE 19.1 ■ OLFACTORY MUCOSA

Olfactory mucosa is located in the roof and part of the walls of the nasal cavity. Its pseudostratified epithelium is thicker than that of nonsensory epithelium, and it serves as the receptor for smell. Olfactory epithelium consists of olfactory cells, supporting (sustentacular) cells, basal cells, and brush cells.

Olfactory cells are bipolar neurons. The apex of the cell is expanded into the olfactory vesicle from which nonmotile cilia, the actual receptors, extend into surface secretions. The base of the cell tapers into an axonal process that enters the lamina propria and joins axons from other receptor cells to form the olfactory nerve. Large, cuboidal Schwann cells are a prominent feature of these axons, giving the nerve an unusual appearance.

Supporting cells are columnar cells with apical microvilli. They attach to the receptor cells through adhering junctions and provide mechanical and metabolic support to the olfactory cells. Basal cells are stem cells from which olfactory and supporting cells differentiate. Brush cells are the same cell type that occurs in nonsensory respiratory epithelium.

The lamina propria is directly contiguous with periosteum. It contains numerous blood and lymphatic vessels, unmyelinated and myelinated nerves, and olfactory (Bowman) glands. These are tubuloalveolar serous glands whose watery secretion serves as a trap and solvent for odorant substances and continuously washes the olfactory surface.

Olfactory mucosa, nasal cavity, human, Azan ×75.

This low-magnification orientation micrograph shows part of the wall of the nasal cavity. The **olfactory mucosa** (*OM*), adjacent ethmoid bone (*EB*), and ethmoid sinus (*ES*) are indicated. The olfactory mucosa is directly attached to the bone tissue; no submucosa is present. In this specimen, however, the mucosa is separated from the bone tissue because of shrinkage, a frequently encountered artifact. The **olfactory epithelium** (*OEp*) is pseudostratified, like respiratory epithelium; however, it is typically thicker. Note the **respiratory epithelium** (*REp*) included in the *lower right* of the micrograph. The feature that is most useful in identifying olfactory mucosa is the presence of numerous large, unmyelinated nerves (*N*) and extensive **olfactory (Bowman) glands** (*BG*) in the connective tissue of the mucosa. Occasional blood vessels (i.e., arteries [*A*] and veins) are also visible. Note that the adjacent respiratory mucosa lacks nerves and exhibits a relative paucity of glands.

Olfactory mucosa, nasal cavity, human, Azan ×375.

At this higher magnification, it is possible to distinguish in a general way the three principal cell types of the olfactory epithelium on the basis of nuclear location and appearance as well as by certain cytoplasmic characteristics. For example, the nuclei of the **supporting cells** (*SC*) are relatively dense and are located closest to the epithelial surface. They are arranged in an almost discrete single layer. The supporting cell has a cylindrical shape and extends from the basement membrane through the full thickness of the epithelium. Immediately beneath this layer are the cell bodies of the **olfactory receptor cells** (*OC*). They lie at different levels within the thickness of the epithelium. Careful examination of the nuclei of these bipolar neuronal cells reveals that they contain more euchromatin than the nuclei of the supporting cells and often exhibit several nucleoli. In this preparation, the nucleoli appear as small round red bodies. In some cases, particularly when there is shrinkage, the thin tapering dendritic process that extends to the olfactory surface may be observed. Similarly, an axonal process may sometimes be observed extending basally. The **basal cells** (*BC*), the least numerous of the principal cell types, are characterized by their small round nuclei and scant cytoplasm. They are irregularly spaced and lie in proximity to the basement membrane. Note that the olfactory mucosa in contrast to respiratory mucosa lacks goblet cells.

The **lamina propria** contains numerous blood vessels (capillaries [*C*], veins [*V*]), lymphatics, olfactory nerves (*N*), and olfactory (Bowman) glands (*BG*). The **Bowman glands** are branched tubuloalveolar structures. They exhibit a very small lumen (*arrows*). The duct elements extend from the secretory portion of the gland beginning in close proximity to the overlying epithelium (*arrowhead*) and pass directly through the epithelium to deliver their secretions at the surface. The ducts are very short, making it difficult to identify them. The very thin axonal processes (*AP*) of the olfactory cells are sometimes evident within the lamina propria before being ensheathed by Schwann cells to form the prominent olfactory nerves. The nuclei present within the olfactory nerves represent Schwann cell nuclei (*ScC*).

A, artery
 AP, axonal process
 BC, basal cells
 BG, Bowman glands
 C, capillary
 EB, ethmoid bone
 ES, ethmoid sinus

N, olfactory nerves
OC, olfactory cells
OEp, olfactory epithelium
OM, olfactory mucosa
REp, respiratory epithelium
SC, supporting cell nuclei
ScC, Schwann cell nuclei
V, vein
arrows, lumina of Bowman glands
arrowhead, duct of a Bowman gland entering epithelium

PLATE 19.2 ■ LARYNX

The larynx is the passageway for air between the oropharynx and the trachea that functions in the production of sound. It consists of a cartilaginous framework to which both extrinsic and intrinsic muscles are attached and a mucosal surface that varies in character from pseudostratified to stratified squamous in regions subject to abrasion by the air stream. The muscles move certain cartilages with respect to others, thus increasing or decreasing the opening of the rima glottis and increasing or decreasing the tension on the vocal folds (cords). In this way, vibrations of different wavelengths are generated in the passing air, and sound is produced.

Larynx, monkey, hematoxylin and eosin (H&E)
×15.

The **vocal folds** are ridge-like structures that are oriented in an anteroposterior (ventral-dorsal) direction. In frontal sections, the vocal folds (*VF*) are cross-sectioned, giving the appearance seen here. The two vocal folds and the space between them constitute the glottis. Just above each vocal fold is an elongated recess called the **ventricle** (*V*), and above the ventricle is another ridge called the **ventricular fold** (*VnF*) or, sometimes, the false vocal fold. Below and lateral to the vocal folds are the vocalis muscles (*VM*). Within the vocal fold is a considerable amount of elastic material, although it is usually not evident in routine H&E preparations. This elastic material is part of the vocal ligament. It lies in an anteroposterior direction within the substance of the vocal fold and plays an important role in phonation.

Ventricular and vocal folds, larynx, monkey, H&E ×160.

The surfaces of a **vocal fold** and the facing ventricular fold within *rectangle 1* in the *top figure* are turned 90 degree clockwise and shown at higher magnification in this figure. Medially, both are lined by **stratified squamous epithelium** (*SSE*). Here, the contact between surfaces is considerable. Laterally, the surfaces consist of **stratified columnar epithelium** (*SCE*). The contact between these

surfaces is less wearing. Small glands (*GI*) are in the lamina propria of the laryngeal mucosa.

Infraglottic cavity, larynx, monkey, H&E ×160.

Rectangle 2 in the *top figure* is shown at higher magnification in this figure. This area of the larynx below the ventricles and rima glottidis communicates with the trachea and is called the *infraglottic cavity*.

It shows the junction between the **stratified squamous epithelium** (*SSE*), with its flat surface cells, and the **stratified columnar epithelium** (*SCE*), with its columnar surface cells. The lamina propria consists of loose connective tissue in which glands (*GI*) are present.

Infraglottic cavity, larynx, monkey, H&E ×160.

Epithelium of the infraglottic cavity of the larynx just below the portion shown in the *top figure* changes again, giving way, below, to the **ciliated pseudostratified columnar epithelium** (*PSE*) shown here.

Note the cylinders of cytoplasm that clearly indicate the columnar nature of the surface cells. In the *upper part* of the figure, the epithelium is stratified columnar; in the *lower part* of the figure, it is pseudostratified columnar. This distinction is difficult to make from the examination of a single sample such as that shown here, and other information is needed to make the assessment. The additional information is the presence of cilia on the pseudostratified columnar epithelium; this epithelium is typically ciliated. Although not evident in the photomicrographs, note that stratified columnar epithelium has a very limited distribution, usually occurring between stratified squamous epithelium and some other epithelial types (e.g., pseudostratified columnar here or simple columnar at the anorectal junction; Plate 17.11, page 690). The lamina propria is a loose cellular connective tissue, and it also shows some glands (*GI*).

GI, glands
PSE, pseudostratified columnar epithelium
SCE, stratified columnar epithelium
SSE, stratified squamous epithelium
V, ventricles

VF, vocal folds
VM, vocalis muscles
VnF, ventricular folds

PLATE 19.3 ■ TRACHEA

The **trachea** is a short tube about 2.5 cm in diameter and about 10 cm long. It extends from the larynx to about the middle of the thorax, where it divides into the two main bronchi (**primary bronchi**). Its major function is to serve as a conduit for air. The lumen of the trachea is held open by a series of C-shaped hyaline cartilages that are stacked on one another to form a supporting structure. Fibroelastic tissue and smooth muscle (the **trachealis muscle**) bridge the gap between the free ends of the cartilages at the posterior border of the trachea, adjacent to the esophagus. Typical respiratory (ciliated pseudostratified columnar) epithelium lines the trachea and primary bronchi.

On entering the lungs, the primary bronchi branch immediately to give rise to the **lobar bronchi** (**secondary bronchi**) that supply the two lobes of the left lung and the three lobes of the right lung. Within the lung, the C-shaped cartilages are replaced by an investment of (sometimes overlapping) cartilaginous plates that completely surround the bronchi.

Trachea, human, hematoxylin and eosin (H&E)
×90.

This low-magnification micrograph of the posterior wall of the human trachea shows the **pseudostratified ciliated columnar epithelium** (*EP*) subtended by a well-developed **basement membrane** (*Bm*). The basement membrane, which consists of tightly packed, fine collagen fibers, is actually an unusually thick and dense reticular layer and is thus part of the lamina propria. It is particularly distinct in the human trachea and may thicken with chronic irritation, as in smokers. Numerous goblet cells (*GC*) are evident as clear ovoid spaces in the respiratory epithelium. A thin **lamina propria** (*LP*) and a dense thick submucosa (*SM*) underlie the respiratory epithelium. Seromucous glands (*GI*) are seen on both sides of the **trachealis muscle** (*TM*), a band of smooth muscle that fills the gap between the posterior ends of the C-shaped tracheal cartilages (not shown) and serves to separate the trachea from the esophagus. Adipose tissue (*Ad*) is also present in the submucosa between the esophagus and the trachea.

Trachea, human, H&E $\times 65$.

This micrograph shows the wall of the trachea at the level of one end of the C-shaped tracheal cartilage (*TC*). The portion of the **pseudostratified ciliated columnar epithelium** (*EP*) does not exhibit as many goblet cells as are seen in the previous figure. However, the **basement membrane** (*Bm*) is clear, as are the cellular **lamina propria** (*LP*) and the **submucosa** (*SM*) of the trachea. Again, seromucous glands (*GI*) are evident beneath the submucosa. The ends of the bundles of the trachealis muscle (*TM*) are located toward the posterior midline from the glands. A small lymphatic nodule (*LN*) is located adjacent to the end of one of the bundles. A significant amount of adipose tissue (*Ad*) is found in the connective tissue between the trachealis muscle and the wall of the esophagus (not shown in this figure).

Trachea, human, H&E $\times 250$; inset $\times 500$.

In this higher magnification micrograph of the tracheal wall and in the *inset*, the cilia of the **pseudostratified ciliated columnar epithelium** (*EP*) are particularly well demonstrated, as is the dense line (*BB*) formed by the basal bodies of the cilia (*C*) in the apical cytoplasm of the epithelial cells. **Goblet cells** (*GC*) are easily recognized, and the displacement of the flattened nucleus (*N*) toward the base of the cell is well demonstrated. The thickness and density of the **basement membrane** (*Bm*) are more easily seen here than in the lower magnification views in the other figures. A venule (*V*) containing red cell ghosts is seen in the middle of the submucosa, and some inflammatory cells (*IC*), probably lymphocytes, are seen adjacent to the vein as well as distributed lightly through the submucosa and more densely in the lamina propria. Portions of the seromucous glands (*GI*) are just visible at the *bottom edge* of the figure.

Ad, adipose tissue
BB, basal bodies
Bm, basement membrane
C, cilia
EP, epithelium
GC, goblet cells

G1, glands
IC, inflammatory cells
LN, lymphatic nodule
LP, lamina propria
N, nuclei of goblet cells
SM, submucosa
TC, tracheal cartilage
TM, trachealis muscle
V, vein

PLATE 19.4 ■ BRONCHIOLES AND END RESPIRATORY PASSAGES

The primary bronchus that enters each lung divides into smaller secondary and tertiary bronchi. As the bronchi become smaller, some components of the wall are lost or reduced in amount. Ultimately, the respiratory passage has distinctly different features than those of a bronchus, and it is called a bronchiole. The features that characterize the bronchiole are the absence of cartilage, loss of submucosal glands, and gradual disappearance of goblet cells. The epithelium changes from pseudostratified columnar to simple ciliated columnar, and some columnar cells even lack cilia. Smooth muscle occupies a relatively larger portion of the bronchiolar wall than the bronchial wall.

The smallest diameter conducting bronchioles, the **terminal bronchioles**, are lined with simple ciliated cuboidal epithelium in which club cells, cells that secrete a surface-active agent that prevents luminal adhesion of bronchiolar walls during expiration, are found among the ciliated cells. **Respiratory bronchioles** are the first part of the bronchial tree that allows gas exchange to occur. Respiratory bronchioles constitute a transition zone in which both air conduction and gas exchange occur. Scattered, thin-walled evaginations of the lumen of the respiratory bronchiole are called **alveoli**; these are the structures in which gas exchange between the air passages and the blood capillaries occurs.

Bronchiole, lungs, human, hematoxylin and eosin (H&E) $\times 75$.

A typical **bronchiole** (*B*) is shown here. Characteristically, blood vessels (*BV*) are adjacent to the bronchiole. The main features of the bronchiolar wall that are evident in the figure are bundles of smooth muscle (*SM*) and the lining epithelium (shown at higher magnification in Plate 19.5, page 766). Higher magnification would reveal that the epithelium is ciliated. The connective tissue is minimal and, at this low magnification, not conspicuous. Nevertheless, it is present and separates the muscle into bundles (i.e., the muscle layer is not a single continuous layer). The connective tissue contains collagenous and some elastic fibers. Glands are not present in the wall of the bronchiole. Surrounding the bronchiole, comprising most of the lung substance, are the air spaces or alveoli of the lung.

Bronchiole and respiratory bronchioles, lungs, human, H&E $\times 75$.

In this figure, a short length of a bronchiole (*B*) is shown longitudinally sectioned as it branches into two **respiratory bronchioles** (*RB*). The last portion of a bronchiole that leads into respiratory bronchioles is called a **terminal bronchiole**. It is not engaged in exchange of air with the blood; the respiratory bronchiole does engage in air exchange. *Arrows* mark the place where the terminal bronchiole ends. Not uncommonly, as shown here, cartilage (*C*) is found in the bronchiolar wall where branching occurs. Blood vessels (*BV*) and a nodule of lymphocytes (*L*) are adjacent to the bronchiole.

The respiratory bronchiole has a wall composed of two components: One consists of recesses that have a wall similar to that of the alveoli and are thus capable of gas exchange; the other has a wall formed by small cuboidal cells that appear to rest on a small bundle of eosinophilic material. This is smooth muscle surrounded by a thin investment of connective tissue. Both of these components are shown at higher magnification in Plate 19.5 (page 766).

Alveoli, lungs, human, H&E $\times 75$.

The most distal component of the respiratory passage is the alveolus. Groups of alveoli clustered together and sharing a common opening are referred to as an **alveolar sac** (*AS*). Alveoli that form a tube are referred to as **alveolar ducts** (*AD*). The outer surface of lung tissue is the serosa (*S*); it consists of a lining of mesothelial cells resting on a small amount of connective tissue. This is the layer that gross anatomists refer to as the **visceral pleura**.

AD, alveolar ducts
AS, alveolar sacs
B, bronchiole
BV, blood vessels
C, cartilage
L, nodule of lymphocytes
RB, respiratory bronchiole
S, serosa
SM, smooth muscle

arrows, end of terminal bronchiole

PLATE 19.5 ■ TERMINAL BRONCHIOLE, RESPIRATORY BRONCHIOLE, AND ALVEOLUS

Respiratory bronchioles continue to divide to form alveolar ducts, passages lined solely with rows of alveoli that have rings of smooth muscle in knob-like interalveolar septa. The alveolar ducts terminate in alveolar sacs, enlarged spaces surrounded by clusters of alveoli that open into the spaces. The alveoli are lined with type I alveolar cells, extremely thin squamous cells that cover about 95% of the alveolar surface, and with type II alveolar cells, cuboidal cells that secrete surfactant, a surface-active agent that reduces surface tension at the air-epithelium surface. The tissue between adjacent alveoli is called the interalveolar septum. This consists of the alveolar epithelial cells and their basal lamina, the basal lamina of the underlying capillary endothelium and the endothelial cells, themselves, and any other connective tissue elements that may lie between the two basal laminae. The interalveolar septum is the site of the air-blood barrier.

Terminal bronchiole, lungs, human, hematoxylin and eosin (H&E) $\times 550$.

The histologic features of the terminal bronchiolar wall are shown here. Ciliated epithelium extends from the *top* of the figure to the *diamond*. This is **ciliated pseudostratified columnar epithelium** (*PsEp*). Some basal cells are still present, thus the designation pseudostratified columnar. Elsewhere, the epithelium might be ciliated simple columnar, and just before it becomes a respiratory bronchiole, the epithelium may include cuboidal or low columnar nonciliated cells. These nonciliated cells are **club cells** (*CC*, beyond the *diamond*). Club cells produce a surface-active agent that is instrumental in the expansion of the lungs. The smooth muscle (*SM*) in the bronchiolar wall is organized in bundles; other cells under the epithelium and around the smooth muscle belong to the connective tissue.

Respiratory bronchiole, lungs, human, H&E $\times 550$.

The wall of a **respiratory bronchiole** is shown here and in the *lower left* figure. The alveoli (*A*) are terminal air spaces on the *left* in each of the two figures. The lumen of the respiratory bronchiole is

wall similar to the alveolar wall; this is considered in the next figure.

on the *right*. Characteristically, the wall of the respiratory bronchiole consists of alternating thick and thin regions. The thick regions are similar to the wall of the bronchiole, except that cuboidal club cells, instead of columnar epithelium, form the surface. Thus, as seen here, **club cells** (*CC*) are the surface-lining cells of the thick regions, and **smooth muscle bundles** (*SM*) are under the club cells, with a small amount of intervening connective tissue. The thin regions have a

Respiratory bronchiole, lungs, human, H&E ×550.

The **respiratory bronchiole** shown in this figure is slightly more distal than the area seen in the *top right* figure. Structurally, the wall of respiratory bronchiole is surrounded by alveoli (*A*), and it shows essentially the same features as those seen in the *upper right* figure, except that there are fewer club cells and the smooth muscle bundles (*SM*) are somewhat thinner.

Alveolus, lungs, human, H&E × 800.

The central component of the alveolar wall is the **capillary** (*C*) and, in certain locations, associated connective tissue. On each side, where it faces the alveolus (*A*), a flat squamous cell is interposed between the capillary and the air spaces. This is a **pneumocyte type I cell**. In some places, the type I cell is separated from the capillary endothelial cell by a single basal lamina shared by the two cells. This is the thin portion of the alveolar-capillary complex, readily seen in the *upper part* of the figure (*arrows*). Gas exchange occurs through the thin portion of the alveolar-capillary complex. Elsewhere, connective tissue is interposed between the pneumocyte type I cell and the endothelial cell of the capillary; each of these epithelial cells retains its own basal lamina.

A second cell type, the **pneumocyte type II cell** or septal cell (*SC*), also lines the alveolar air space. This cell typically displays a rounded (rather than flattened) shape, and the nucleus is surrounded by a noticeable amount of cytoplasm, some of which may appear clear.

The septal cell produces a surface-active agent different from that of the club cell, which also acts in permitting the lung to expand.

HISTOLOGY

■ OVERVIEW OF THE URINARY SYSTEM

The urinary system consists of the paired **kidneys**; paired **ureters**, which lead from the kidneys to the **urinary bladder**; and the **urethra**, which leads from the bladder to the exterior of the body.

The kidneys play an important role in body homeostasis by conserving fluids and electrolytes and disposing metabolic waste.

Like the lungs and liver, the **kidneys** retrieve essential materials and dispose of wastes. To maintain **homeostasis**, kidneys conserve water, electrolytes, and certain metabolites. The kidneys are essential in maintaining constant plasma pH by regulating acid-base balance, which is achieved by excreting hydrogen ions when body fluids become too acidic or excreting bicarbonates when body fluids become too basic. The kidneys play an important role in regulating and maintaining the composition and volume of extracellular fluid. Metabolic waste products are discharged from cells into the circulation; within the kidneys, these wastes are removed from the blood by filtration and **excretion** into the urine.

The kidneys are highly vascular organs; they receive approximately 25% of the cardiac output. Both excretory and homeostatic functions of the kidney begin when blood arrives at the **filtration apparatus** in the **glomerulus**. Initially, plasma is separated from the cells and large proteins to produce a

glomerular ultrafiltrate of the blood or primary urine, which is then modified by selective resorption and specific secretion by the cells of the kidney. The final **urine** is conveyed by the ureters to the urinary bladder, where it is stored until discharged via the urethra.

The final urine contains water and electrolytes as well as waste products, such as urea, uric acid, and creatinine, and breakdown products of various substances.

The kidney also functions as an endocrine organ.

Endocrine activities of the kidneys include the following:

- Synthesis and secretion of the glycoprotein hormone **erythropoietin (EPO)**, which acts on the bone marrow and regulates red blood cell formation in response to decreased blood oxygen concentration. EPO is synthesized by endothelial cells of the peritubular capillaries in the renal cortex and acts on specific receptors expressed on the surface of erythrocyte progenitor (ErP) cells in the bone marrow. **Recombinant human erythropoietin (rhEPO)** is used for the treatment of **anemia** in patients with **end-stage renal disease**. It is also used to treat anemia resulting from **bone marrow suppression** that develops in individuals with AIDS undergoing treatment with antiretroviral drugs, such as azidothymidine (AZT).
- Synthesis and secretion of the acid protease **renin**, an enzyme involved in the control of blood pressure and blood volume. Renin is produced by juxtaglomerular cells and cleaves circulating angiotensinogen to release angiotensin I (see pages 781–784).
- Hydroxylation of **25-OH vitamin D₃**, a steroid precursor produced in the liver, to hormonally active 1,25-(OH)₂ vitamin D₃. This step is regulated primarily by parathyroid hormone (PTH), which stimulates the activity of the enzyme **1 α -hydroxylase** and increases the production of the active hormone (Folder 20.1).

Despite its name, **vitamin D** is actually an inactive precursor that undergoes a series of transformations to become the fully active hormone that regulates plasma calcium levels. In the human body, vitamin D is derived from two sources:

- **Skin**, in which **vitamin D₃ (cholecalciferol)** is rapidly produced by the action of ultraviolet light on the precursor 7-dehydrocholesterol. The skin is the major source of vitamin D₃, especially in regions where food is not supplemented with vitamin D. Typically, 30 minutes to 2 hours of sunlight exposure per day can provide enough vitamin D to fulfill daily body requirements for this vitamin.
- **Diet**, from which vitamin D₃ is absorbed by the small intestine in association with chylomicrons

In the blood, vitamin D₃ is bound to **vitamin D-binding protein** and transported to the liver. The first transformation occurs in the liver and involves hydroxylation of vitamin D₃ to form **25-OH vitamin D₃**. This compound is released into the bloodstream and undergoes a second hydroxylation in the proximal tubules of the kidney to produce the highly active **1,25-(OH)₂ vitamin D₃ (calcitriol)**. The process is regulated indirectly by a decrease in plasma Ca²⁺ concentration, which triggers the secretion of parathyroid hormone (PTH), or directly by a decrease in circulating phosphates, which, in turn, stimulates the activity of 1 α -hydroxylase responsible for conversion of 25-OH vitamin D₃ into active 1,25-(OH)₂ vitamin D₃. Active 1,25-(OH)₂ vitamin D₃ is released into the circulation and stimulates intestinal absorption of Ca²⁺ and phosphate and mobilization of Ca²⁺ from bones. It is, therefore, necessary for the normal development and growth of bones and teeth. The related compound **vitamin D₂ (ergocalciferol)** undergoes the same conversion steps as vitamin D₃ and produces the same biological effects.

Patients with end-stage **chronic kidney disease** have inadequate conversion of vitamin D into active metabolites, resulting in vitamin D₃ deficiency. In adults, vitamin D₃ deficiency is manifested by impaired bone mineralization and reduced bone density. Patients with chronic kidney disease, especially those on prolonged renal hemodialysis, often need vitamin D₃ and calcium supplements to prevent the severe disturbance of calcium homeostasis that results from secondary hyperparathyroidism, a common complication in these patients. Vitamin D₃ deficiency in childhood results in **rickets**, a disease that causes abnormal bone ossification.

■ GENERAL STRUCTURE OF THE KIDNEY

The **kidneys** are large, reddish, bean-shaped organs located on either side of the spinal column in the retroperitoneal space of the posterior abdominal cavity. They extend from the 12th thoracic to the 3rd lumbar vertebrae, with the right kidney positioned slightly lower. Each kidney measures approximately 10 cm long $\times$ 6.5 cm wide (from concave to convex border) $\times$ 3 cm thick. On the **upper pole** of each kidney, embedded within the renal fascia and a thick protective layer of perirenal adipose tissue, lies an **adrenal gland**. The **medial border** of the kidney is concave and contains a deep vertical fissure, called the **hilum**, through which the renal vessels and nerves pass and the expanded, funnel-shaped origin of the ureter, called the **renal pelvis**, exits. A section through the kidney shows the relationship of these structures as they lie just within the hilum of the kidney in a space called the **renal sinus** (Fig. 20.1). Although not shown in the illustration, the space between and around these structures is filled largely with loose connective tissue and adipose tissue.

FIGURE 20.1. Diagram of kidney structure. The diagram represents a hemisection of a kidney, revealing its structural organization.

Capsule

The kidney surface is covered by a connective tissue **capsule**. The capsule consists of two distinct layers: an outer layer of fibroblasts and collagen fibers and an inner layer with a cellular component of myofibroblasts (Fig. 20.2). The contractility of the myofibroblasts may aid in resisting volume and pressure variations that can accompany variations in kidney function. Its specific role, however, is unknown. The capsule

passes inward at the hilum, where it forms the connective tissue covering the sinus and becomes continuous with the connective tissue, forming the walls of the calyces and renal pelvis (see Fig. 20.1).

FIGURE 20.2. Photomicrograph of human kidney capsule. This photomicrograph of a Mallory-Azan-stained section shows the capsule (*cap*) and part of the underlying cortex. The outer layer of the capsule (*OLC*) is composed of dense connective tissue. The fibroblasts in this part of the capsule are relatively few in number; their nuclei appear as narrow, elongated, red-staining profiles against a blue background representing the stained collagen fibers. The inner layer of the capsule (*ILC*) consists of large numbers of myofibroblasts whose nuclei appear as

round or elongated, red-staining profiles, depending on their orientation within the section. Note that the collagen fibers in this layer are relatively sparse and that the myofibroblast nuclei are more abundant than those of the fibroblasts in the outer layer of the capsule. $\times 180$.

Cortex and Medulla

Examination with the naked eye of the cut face of a fresh, hemisected kidney reveals that its substance can be divided into two distinct regions:

- **Cortex**, the outer reddish brown part
- **Medulla**, the much lighter colored inner part

The color seen on the cut surface of the unfixed kidney reflects the distribution of blood in the organ. Approximately 90%–95% of the blood passing through the kidney is in the cortex; 5%–10% is in the medulla.

The cortex is characterized by renal corpuscles and their associated tubules.

The **cortex** consists of **renal corpuscles** along with the **convoluted tubules** and **straight tubules** of the **nephron**, **connecting tubules**, **collecting ducts**, and an extensive vascular supply. The **nephron** is the basic functional unit of the kidney and is described later in this chapter. The renal corpuscles are spherical structures, barely visible with the naked eye. They constitute the beginning segment of the nephron and contain a unique capillary network called a **glomerulus**.

Examination of a section cut through the cortex at an angle perpendicular to the surface of the kidney reveals a series of vertical striations that appear to emanate from the medulla (see Fig. 20.1). These striations are the **medullary rays** (of Ferrein). Their name reflects their appearance, as the striations seem to radiate from the medulla. Approximately 400–500 medullary rays project into the cortex from the medulla.

Each medullary ray is an aggregation of straight tubules and collecting ducts.

Each medullary ray contains **straight tubules** of nephrons and **collecting ducts**. The regions between medullary rays contain the renal corpuscles, the convoluted tubules of the nephrons, and the connecting tubules. These areas are referred to as **cortical labyrinths**. Each nephron and its **connecting tubule** (which connects to a collecting duct in the medullary ray) form the **uriniferous tubule**.

The medulla is characterized by straight tubules, collecting ducts, and a special capillary network, the vasa recta.

The **straight tubules** of the nephrons and the **collecting ducts** continue from the cortex into the medulla. They are accompanied by a capillary network, the **vasa recta**, that runs in parallel with the various tubules. These vessels represent the vascular part of the **countercurrent exchange system** that regulates the concentration of urine.

The **tubules in the medulla**, because of their arrangement and differences in length, collectively form a number of conical structures called **pyramids** (Fig. 20.3). Usually 8-12 but as many as 18 pyramids may be present in the human kidney. The bases of the pyramids face the cortex, and the apices face the renal sinus. The apical portion of each pyramid, which is known as the **papilla**, projects into a minor calyx, a cup-shaped structure that represents an extension of the renal pelvis. The tip of the papilla, also known as the **area cribrosa**, is perforated by the openings of the collecting ducts (Fig. 20.4). The minor calyces are branches of the two or three **major calyces** that, in turn, are major divisions of the renal pelvis (see Fig. 20.1).

FIGURE 20.3. Diagram showing standard nomenclature for structures in the kidney. The two types of nephrons in the kidney are shown with

their associated duct systems. A long-looped nephron is shown on the *left*, and a short-looped nephron is shown on the *right*. The relative position of the cortex, medulla, papilla, and capsule is indicated (not drawn to scale). The inverted cone-shaped area in the cortex represents a medullary ray. The parts of the nephron are indicated by number: 1, renal corpuscle including the glomerulus and Bowman capsule; 2, proximal convoluted tubule; 3, proximal straight tubule (thick descending limb); 4, descending thin limb; 5, ascending thin limb; 6, distal straight tubule (thick ascending limb); 7, macula densa located in the final portion of the thick ascending limb; 8, distal convoluted tubule; 9, connecting tubule; 9*, connecting tubule of the juxtamedullary nephron that forms an arch (arched connecting tubule); 10, cortical collecting duct; 11, outer medullary collecting duct; and 12, inner medullary collecting duct. (Modified from Kriz W, Bankir L. A standard nomenclature for structures of the kidney. The Renal Commission of the International Union of Physiological Sciences. *Kidney Int.* 1988;33:1-7.)

FIGURE 20.4. Renal papilla and calyx. a. This scanning electron micrograph shows the conical structure that represents the renal papilla, projecting into the renal calyx. The apex of the papilla contains openings (*arrows*) of the collecting ducts (of Bellini). These ducts deliver urine from the pyramids to the minor calyx. The surface of the papilla containing the openings is designated the area cribrosa. $\times 24$. b. Photomicrograph of a hematoxylin and eosin (H&E)-stained specimen of the papilla showing the distal portion of the collecting

ducts opening into the minor calyx. $\times 120$. (Courtesy of Dr. C. Craig Tisher.)

Each pyramid is divided into an **outer medulla** (adjacent to the cortex) and an **inner medulla**. The outer medulla is further subdivided into an **inner stripe** and an **outer stripe**. The zonation and stripes are readily recognized in a sagittal section through the pyramid of a fresh specimen. They reflect the location of distinct parts of the nephron at specific levels within the pyramid (see Fig. 20.3).

The renal columns represent cortical tissue contained within the medulla.

The caps of cortical tissue that lie over the pyramids are sufficiently extensive that they extend peripherally around the lateral portion of the pyramid, forming the **renal columns** (of Bertin). Although renal columns contain the same components as the rest of the cortical tissue, they are regarded as part of the medulla. In effect, the amount of cortical tissue is so extensive that it “spills” over the side of the pyramid much as a large scoop of ice cream extends beyond and overlaps the sides of an ice cream cone.

Kidney Lobes and Lobules

The number of lobes in a kidney equals the number of medullary pyramids.

Each **medullary pyramid** and the associated cortical tissue at its base and sides (one half of each adjacent renal column) constitute a **lobe** of the kidney. The lobar organization of the kidney is conspicuous in the developing fetal kidney (Fig. 20.5). Each lobe is reflected as a convexity on the outer surface of the organ, but they usually disappear after birth. The surface convexities typical of the fetal kidney may persist, however, until the teenage years and, in some cases, into adulthood. Each human kidney contains 8–18 lobes. Kidneys of some animals possess only one pyramid; these kidneys are classified as unilobar, in contrast to the multilobar kidney of the human.

FIGURE 20.5. Photomicrograph of fetal kidney. This photomicrograph of a hematoxylin and eosin (H&E)-stained human fetal kidney shows the cortex, the medulla, and two associated pyramids. Note that each surface convexity corresponds to a kidney lobe. During postnatal life, the lobar convexities disappear, and the kidney then exhibits a smooth surface. $\times 30$.

A lobule consists of a collecting duct and all the nephrons that it drains.

The lobes of the kidney are further subdivided into lobules consisting of a central medullary ray and surrounding cortical material (Fig. 20.6 and Plate 20.2, page 804). Although the center or axis of a lobule is readily identifiable, the boundaries between adjacent lobules are not obviously demarcated from one another by connective tissue septa. The concept of the lobule has an important physiologic basis; the medullary ray containing the collecting duct for a group of nephrons that drain into that duct constitutes the renal secretory unit. It is the equivalent of a glandular secretory unit or lobule.

FIGURE 20.6. Diagrams and photomicrograph of an adult human kidney. The *diagram* in the *upper left* is a hemisection of the adult human kidney included for orientation. The *diagram* on the *right* of an enlarged portion of the kidney emphasizes the relationship between two nephrons and their tubules and ducts to the cortex and medulla. The upper nephron, a midcortical nephron, extends only a short distance into the medulla and possesses a short thin segment in the loop of Henle. The lower nephron, a juxtamedullary nephron, has a long loop of Henle that extends deep into the medulla. Both nephrons drain into the cortical collecting ducts in the medullary ray. The photomicrograph shows a section of the cortex. It is organized into a series of medullary rays containing straight tubules and cortical collecting ducts; between the rays are cortical labyrinths containing the renal corpuscles and their associated proximal and distal convoluted tubules. A kidney lobule consists of a medullary ray at its center and half of the adjacent cortical labyrinth on either side. $\times 60$.

The Nephron

The nephron is the structural and functional unit of the kidney.

The **nephron** is the fundamental unit of the kidney (see Fig. 20.3). Both human kidneys contain approximately 2 million nephrons. Nephrons are responsible for the production of urine and correspond to the secretory part of glands. The collecting ducts are responsible for the final concentration of the urine and are analogous to the ducts of exocrine glands that modify the concentration of the secretory product. Unlike the typical exocrine gland in which the secretory and duct portions arise from a single epithelial outgrowth, nephrons and their collecting ducts arise from separate primordia and only later become connected.

General organization of the nephron

The nephron consists of the renal corpuscle and a tubule system.

As stated previously, the **renal corpuscle** represents the beginning of the nephron. It consists of the **glomerulus**, a tuft of capillaries composed of 10-20 capillary loops, surrounded by a double-layered epithelial cup, the renal or **Bowman capsule**. The Bowman capsule is the initial portion of the nephron, where blood flowing through the glomerular capillaries undergoes filtration to produce the **glomerular ultrafiltrate**. The glomerular capillaries are supplied by an **afferent arteriole** and are drained by an **efferent arteriole** that then branches, forming a new capillary network to supply the kidney tubules. The site where the afferent and efferent arterioles penetrate and exit from the parietal layer of the Bowman capsule is called the **vascular pole**. Opposite this site is the **urinary pole** of the renal corpuscle, where the proximal convoluted tubule begins (Fig. 20.7).

FIGURE 20.7. Structure of the renal corpuscle. **a.** This schematic diagram shows the organization of the renal corpuscle and associated structures at the vascular and urinary poles. Mesangial cells are associated with the capillary endothelium of the glomerulus and the glomerular basement membrane. The macula densa cells of the distal tubule are shown intimately associated with the juxtaglomerular cells of the afferent arteriole and the extraglomerular mesangial cells. **b.** Photomicrograph of a hematoxylin and eosin (H&E)-stained specimen showing a renal corpuscle. The macula densa is seen in close proximity to the vascular pole. $\times 160$. (Modified from Kriz W, Sakai T. Morphological aspects of glomerular function. In: *Nephrology: Proceedings of the Tenth International Congress of Nephrology*. Bailliere-Tindall; 1987.)

Continuing from the Bowman capsule, the remaining parts of the nephron (the tubular parts) are as follows:

- **Proximal thick segment**, consisting of the proximal convoluted tubule (pars convoluta) and the proximal straight tubule (pars recta)
- **Thin segment**, which constitutes the thin part of the loop of Henle

- **Distal thick segment**, consisting of the distal straight tubule (pars recta) and the distal convoluted tubule (pars convoluta)

The **distal convoluted tubule** connects to the **cortical collecting duct**, often through a connecting tubule, thus forming the uriniferous tubule (i.e., the nephron plus collecting duct; see Fig. 20.3). The cortical collecting duct continues into the medulla as the **medullary collecting duct** and empties in the papilla of the renal pyramid. In clinical nomenclature, the cortical collecting duct, medullary collecting duct, and, sometimes, the connecting tubule are collectively referred to as the **collecting tubule**, emphasizing the fact that this segment emerges from the confluence of many nephrons. For clarity, the term “collecting tubule” is not used in this chapter because it is easily confused with “connecting tubule” and does not precisely define the cortical versus medullary location of the described segment.

Tubules of the nephron

The tubular segments of the nephron are named according to the course that they take (convoluted or straight), location (proximal or distal), and wall thickness (thick or thin).

Beginning from the Bowman capsule, the sequential parts of the **nephron** consist of the following tubules:

- **Proximal convoluted tubule** originates from the urinary pole of the Bowman capsule. It follows a very tortuous or convoluted course and then enters the medullary ray to continue as the proximal straight tubule.
- **Proximal straight tubule**, commonly referred to as the *thick descending limb of the loop of Henle*, descends into the medulla.
- **Thin descending limb** is the continuation of the proximal straight tubule within the medulla. It makes a hairpin turn and returns toward the cortex.
- **Thin ascending limb** is the continuation of the thin descending limb after its hairpin turn.
- **Distal straight tubule**, which is also referred to as the *thick ascending limb of the loop of Henle*, is the continuation of the

thin ascending limb. The distal straight tubule ascends through the medulla and enters the cortex in the medullary ray to reach the vicinity of its renal corpuscle of origin. The distal straight tubule then leaves the medullary ray and makes contact with the vascular pole of its parent renal corpuscle. At this point, the epithelial cells of the tubule adjacent to the afferent arteriole of the glomerulus are modified to form the **macula densa**. The distal tubule then leaves the region of the corpuscle and becomes the distal convoluted tubule.

- **Distal convoluted tubule** is less tortuous than the proximal convoluted tubule; thus, in a section showing the cortical labyrinth, there are fewer distal tubule profiles than proximal tubule profiles. At its termination, the distal convoluted tubule empties into a cortical collecting duct that lies in the medullary ray via either an **arched connecting tubule** or a shorter tubule simply called the **connecting tubule**.

The loop of Henle forms the entire U-shaped portion of a nephron.

The proximal straight tubule, the thin descending limb with its hairpin turn, the thin ascending limb, and the distal straight tubule are collectively called the **loop of Henle**. In some nephrons, the thin descending and ascending segments are extremely short; therefore, the hairpin turn may be made by the distal straight tubule.

Types of nephrons

Several types of nephrons are identified based on the location of their renal corpuscles in the cortex (see Fig. 20.3):

- **Subcapsular nephrons** or **cortical nephrons** have their renal corpuscles located in the outer part of the cortex. They have short loops of Henle, extending only into the outer medulla. They are typical of the nephrons described previously, wherein the hairpin turn occurs in the distal straight tubule.
- **Juxtamedullary nephrons** make up about one-eighth of the total nephron count. Their renal corpuscles occur in proximity to the base of a medullary pyramid. They have long loops of Henle and long ascending thin segments that extend well into the inner

region of the pyramid. These structural features are essential to the urine-concentrating mechanism, which is described in a further section.

- **Intermediate nephrons** or **midcortical nephrons** have their renal corpuscles in the midregion of the cortex. Their loops of Henle are of intermediate length.

Collecting Ducts

The **cortical collecting ducts** begin in the cortex from the merger of either **connecting tubules** or **arched connecting tubules** of many nephrons and proceed within the medullary rays toward the medulla. When the cortical collecting ducts reach the medulla, they are referred to as outer or inner **medullary collecting ducts**. These ducts travel to the apex of the pyramid, where they merge into larger collecting ducts (up to 200 μm), the **papillary ducts** (ducts of Bellini), that open into the minor calyx (see Fig. 20.4). The area on the papilla that contains the openings of these collecting ducts is called the **area cribrosa**.

In summary, the gross appearance of the functional tissue of the kidney reflects the structure of the nephron. The renal corpuscle and the proximal and distal convoluted tubules are located in and comprise the substance of the cortical labyrinths. The portions of the straight proximal and straight distal tubules with accompanying cortical collecting ducts in the cortex are located in and comprise the major portion of the medullary rays. The thin descending and thin ascending limbs of the loop of Henle are always located in the medulla and are accompanied by medullary collecting ducts. Thus, the arrangement of the nephrons (and collecting ducts) accounts for the characteristic appearance of the cut surface of the kidney, as seen in Figure 20.6.

Filtration Apparatus of the Kidney

The renal corpuscle contains the filtration apparatus of the kidney, which consists of the glomerular endothelium, underlying glomerular basement membrane, and the visceral layer of the Bowman capsule.

The **renal corpuscle** is spherical and has an average diameter of 200 μm . It consists of the glomerular capillary tuft and the surrounding visceral and parietal epithelial layers of the Bowman capsule (Fig. 20.8). The filtration apparatus, also called **glomerular filtration barrier**, enclosed by the parietal layer of the Bowman capsule, consists of three different components:

FIGURE 20.8. Schematic diagram of filtration barrier. The *arrow* indicates movement of plasma fluid across the glomerular filtration barrier, forming the glomerular ultrafiltrate (primary urine) that accumulates in the urinary space of the Bowman capsule. Note the layers of the filtration barrier that include fenestrated glomerular endothelial cells, glomerular basement membrane, and podocytes with filtration slit diaphragms spanned between their foot processes. In addition, the endothelial surface layer of glycoproteins and subpodocyte spaces are shown in this diagram.

- **Endothelium of the glomerular capillaries**, which possesses numerous fenestrations (Fig. 20.9). These fenestrations are

larger (70–90 nm in diameter), more numerous, and more irregular in outline than fenestrations in other capillaries. Moreover, the diaphragm that spans the fenestrations in other capillaries is absent in the glomerular capillaries. Endothelial cells of glomerular capillaries possess a large number of aquaporin-1 (AQP-1) water channels that allow the fast movement of water through the epithelium. Secretory products of endothelial cells, such as nitric oxide (NO) or prostaglandins (PGE₂), play an important role in the pathogenesis of several thrombotic glomerular diseases.

FIGURE 20.9. Scanning electron micrograph of the interior surface of a glomerular capillary. The wall of the capillary shows horizontal ridges formed by the cytoplasm of the endothelial cell. Elsewhere, fenestrations are seen as numerous dark oval and circular profiles. $\times 5,600$. (Courtesy of Dr. C. Craig Tisher.)

- **Glomerular basement membrane (GBM)**, a thick (300–370 nm) basal lamina that is the joint product of the endothelium and the podocytes, the cells of the visceral layer of the Bowman

capsule. Because of its thickness, it is prominent in histologic sections stained with the periodic acid-Schiff (PAS) procedure (see Fig. 1.2, page 6). The GBM is composed of a network consisting of **type IV collagen** (mainly $\alpha 3$ -, $\alpha 4$ -, and $\alpha 5$ -chains), **laminin**, **nidogen**, and **entactin**, together with **heparan sulfate proteoglycans**, such as agrin and perlecan, as well as **multiadhesive glycoproteins** (see pages 195-197). GBM can also be visualized with immunofluorescence techniques using antibodies directed to a specific α -chain of type IV collagen (Fig. 20.10). **Mutation in genes encoding the $\alpha 3$ -, $\alpha 4$ -, and $\alpha 5$ -chains of type IV collagen gives rise to Alport syndrome (hereditary glomerulonephritis), manifested by hematuria (presence of the red blood cells in the urine), proteinuria (presence of significant amount of protein in the urine), and progressive renal failure. In Alport syndrome, the GBM becomes irregularly thickened with laminated lamina densa and fails to serve as an effective filtration barrier. Collagen type IV is also the target in autoimmune diseases, such as Goodpasture syndrome and Alport post-transplantation disease. Both diseases are characterized by autoantibodies attacking the GBM and causing rapidly progressive glomerulonephritis (see Folder 20.2).**

FIGURE 20.10. Immunofluorescent-stained glomerular basement membrane in a human kidney. The glomerular basement membrane (GBM) is composed of five ($\alpha 1 - \alpha 5$) of the six chains of type IV collagen. This high-magnification micrograph of the GBM within the kidney glomerulus was obtained using primary monoclonal antibodies against the $\alpha 1$ -chain of type IV collagen molecules that were visualized by a secondary antibody conjugated with fluorescein dye. $\times 1,200$. FOLDER 20.2

CLINICAL CORRELATION: ANTIGLOMERULAR BASEMENT MEMBRANE ANTIBODY - INDUCED GLOMERULONEPHRITIS; GOODPASTURE SYNDROME

As discussed earlier in the section on the basal lamina assembly (see Chapter 5, Epithelial Tissue), the major building block of any basement membrane, including the **glomerular basement membrane (GBM)**, is the **type IV collagen** molecule. Its core structure is composed of three α -chain monomers, each representing one or more of six types of α -chains (see Table 6.2, page 182). Each molecule has three domains: an amino-terminus 7S domain, a middle collagenous helical domain, and a carboxy-terminus noncollagenous NC1 domain. The molecular architecture of type IV collagen is a key to understanding the pathophysiology of glomerular kidney diseases. For instance, an autoimmune response to the noncollagenous NC1 domain of the $\alpha 3$ -chain of type IV collagen ($\alpha 3[\text{IV}]$) in the glomerular basement membrane (GBM) is responsible for the development of **anti-GBM antibody - induced glomerulonephritis**. This condition is characterized by a linear deposition of immunoglobulin G (IgG) antibodies in the GBM.

In some individuals, anti-GBM antibodies may cross-react with the alveolar basement membrane in the lungs, producing **Goodpasture syndrome**. A characteristic clinical feature of Goodpasture syndrome is rapidly progressive glomerulonephritis (inflammation in the glomeruli) and pulmonary hemorrhage due to disruption of the air-blood barrier. In response to deposition of IgG in the glomerulus, the complement system is activated and circulating leukocytes elaborate a variety of proteases, leading to disruption of the GBM and deposition of fibrin. Fibrin, in turn, stimulates the proliferation of parietal cells lining the Bowman capsule and causes influx of monocytes from the circulation. The product of these reactions is often seen within the glomerulus as a **crescent**, a characteristic microscopic feature of glomerulonephritis (Fig. F20.2.1). Most patients affected by Goodpasture syndrome have a severe crescentic glomerulonephritis with transiently elevated levels of circulating anti-GBM antibodies. Formation of anti-GBM antibodies is most likely triggered by viruses, cancer, pharmacologic agents, and chemical compounds found in a variety of paints, solvents, and dyes.

FIGURE F20.2.1. Photomicrograph of a glomerulus in Goodpasture syndrome. **a.** In this Mallory trichrome-stained specimen obtained from a kidney biopsy, the collagen molecules in the mesangial matrix and glomerular capillaries are stained *dark blue*. The *bright red* stain within the renal corpuscle represents fibrin, which leaked out of the glomerular capillary loops into the urinary space. A cellular crescent (outlined in *dashed line*) is formed by deposition of fibrin infiltrated by macrophages and proliferated parietal cells of the Bowman capsule. The *light blue* color surrounding the glomerulus is reflective of edematous reaction containing cells mediating inflammatory reactions. Note the basal lamina of a parietal layer of the Bowman capsule. $\times 320$. **b.** This immunofluorescence image of the renal corpuscle shows the glomerular basement membrane (GBM) labeled with antibodies directed against human IgG and visualized with secondary antibodies conjugated with fluorescent dye. In Goodpasture syndrome, IgGs bind to the NC1 domain of type IV collagen ($\alpha 3$ -chain) found in the GBM. Note the irregular thickness pattern of the GBM surrounding capillary loops. The remaining space is occupied by the cellular crescent. $\times 360$. *IgG*, immunoglobulin G. (Courtesy of Dr. Joseph P. Grande.)

Individuals with Goodpasture syndrome present with both respiratory and urinary symptoms, including shortness of breath, cough, and bloody sputum as well as hematuria (blood in urine), proteinuria (proteins in the urine), and other symptoms of progressive kidney failure.

The main therapeutic goal in treating Goodpasture syndrome is to remove the circulating pathogenic antibodies from the blood. This is achieved by plasmapheresis, in which blood plasma is removed from the circulation and replaced by fluid, protein, or donated plasma. In addition, treatment with immunosuppressive drugs and corticosteroids is beneficial to keep the immune system from producing pathogenic autoantibodies.

- **Visceral layer of the Bowman capsule**, which contains specialized cells called **podocytes** or **visceral epithelial cells**. These cells extend processes around the glomerular capillaries (Fig. 20.11 and Plate 20.3, page 806). The podocytes arise during embryonic development from one of the blind ends of the developing nephron through invagination of the end of the tubule to form a double-layered epithelial cup. The inner cell layer (i.e., the visceral cell layer) lies in apposition to a capillary network, the glomerulus, which forms at this site. The outer layer of these cells, the parietal layer, forms the squamous cells of the Bowman capsule. The cup eventually closes to form the spherical structure containing the glomerulus. As they differentiate, the podocytes extend processes around the capillaries and develop numerous primary and secondary processes, giving rise to **pedicels** called **foot processes**. The foot processes interdigitate with foot processes of neighboring podocytes, a feature that can be clearly seen with the scanning electron microscope (SEM; Fig. 20.12). The elongated spaces between the interdigitating foot processes, called **filtration slits**, are about 40 nm wide and covered by an ultrathin **filtration slit diaphragm** that spans the filtration slit slightly above the GBM (Fig. 20.13, *inset*).

FIGURE 20.11. Transmission electron micrograph of a glomerulus in the region of the urinary pole. The nuclear and perinuclear regions of the endothelial cells (*EC*) that line the glomerular capillaries (*C*) bulge into the vascular lumen. On the outer surface of the capillaries are the processes of the podocytes (*P*). External to the podocytes is the urinary space (*U*). The Bowman capsule (*BC*) is shown on the *left*; it is continuous at the *dashed line* (marked by *arrowheads*) with the tubule cells of the proximal tubule (*PTC*). Note the numerous mitochondria (*M*) in the base of these cells and the brush border (*BB*) at the apex that projects into the urinary space. The nuclei of three adjacent mesangial cells (*MC*) can be seen in the *upper right* of the micrograph. $\times 4,700$.

FIGURE 20.12. Scanning electron micrograph of a glomerulus. **a.** Low-magnification image revealing the tortuous course of the podocyte-covered glomerular capillaries. $\times 700$. **b.** A higher magnification of the area in the *rectangle* in **a**. Note the podocyte and its processes embracing the capillary wall. The primary processes (1°) of the

podocyte give rise to secondary processes (2°), which, in turn, give rise to the pedicels (foot processes). The space between the interdigitating pedicels creates the filtration slits. $\times 6,000$. Inset. This higher magnification of the area in the *rectangle* reveals the filtration slits and clearly shows that alternating pedicels belong to the secondary process of one cell; the intervening pedicels belong to the adjacent cell. $\times 14,000$.

FIGURE 20.13. Transmission electron micrograph of a glomerular capillary and adjacent podocyte. The pedicels of the podocytes rest on the basal lamina adjacent to the capillary endothelium, and together, the three components—capillary endothelium, basal lamina, and podocyte—form a filtration apparatus. $\times 5,600$. Inset. The *large arrows* point to the fenestrations in the endothelium. On the other side of the basal lamina are the pedicels of the podocytes. Note the slit diaphragm (*small arrows*) spanning the gap between adjacent pedicels. $\times 12,000$.

Nephrin is an important structural protein of the filtration slit diaphragm.

Studies of the **filtration slit diaphragm** reveal its complex protein structure as a zipper-like sheet configuration with a central density. **Nephrin**, a 185 kDa transmembrane protein, is a

key structural and functional component of the slit diaphragm. Nephrin molecules emerging from opposite foot processes interact in the center of the slit (homophilic interactions), forming a central density with pores on both sides (Fig. 20.14). This intercellular protein sheet also contains other adhesion molecules, such as **Neph-1**, **Neph-2**, **P-cadherin**, **FAT1**, and **FAT2**. The filtration slit diaphragm is firmly anchored to numerous actin filaments within the foot processes of podocytes. Regulation and maintenance of the actin cytoskeleton of podocytes has emerged as a critical process for regulating the size, patency, and selectivity of the filtration slits. **Mutations in the nephrin gene (NPHS1) are associated with congenital nephrotic syndrome, a disease characterized by massive proteinuria and edema.**

FIGURE 20.14. Diagram of the filtration slit diaphragm. The filtration slit diaphragm is a complex, zipper-like sheet structure formed by the transmembrane protein nephrin. The extracellular domains of the nephrin molecules emerge from the opposite foot processes of neighboring podocytes and interdigitate in the center of the slit, forming a central density with pores on both sides. The intracellular domains of nephrins interact with the actin cytoskeleton within the cytoplasm of foot processes. The sheet of nephrin molecules is reinforced near its attachment to the foot processes by Neph1 and Neph2 proteins that interact with each other and with nephrin. Other adhesion molecules, including P-cadherin, FAT1, and FAT2, are also found in this region. The apical cell membrane of podocytes' foot processes that face the urinary space is covered by the glycocalyx. It contains podocalyxin, a negatively charged membrane-bound sialoglycoprotein that acts as an antiadhesive molecule. The negatively charged podocalyxin keeps adjacent foot processes apart and maintains open filtration slits. Note that the foot processes of the podocytes are separated by the glomerular basement membrane (GBM) from the fenestrated endothelial cells lining the

glomerular capillaries. (Redrawn from Tryggvason K, Patrakka J, Wartiovaara J. Hereditary proteinuria syndromes and mechanisms of proteinuria. *N Engl J Med*. 2006;354:1387 - 1401.)

The negative charge of podocalyxin repels the plasma membranes of the neighboring foot processes and maintains open access to the filtration slit diaphragm.

Podocalyxin is a negatively charged transmembrane sialoglycoprotein (55 kDa) that plays a key role in maintaining the structural integrity of the kidney's filtration apparatus. It is synthesized by podocytes and expressed within the glycocalyx covering the apical cell membrane of their foot processes that face the urinary space. Owing to its highly negative charges and location near the filtration slits, podocalyxin acts as an antiadhesive molecule keeping adjacent foot processes separated from each other, thereby maintaining open filtration slits. Podocalyxin acts on actin filaments via actin-associated proteins (i.e., ezrin that links integral membrane proteins with actin filaments), which changes the cytoskeletal architecture of the foot processes. In addition, the negative charges appear to be important in maintaining the urinary space between podocytes and the parietal layer of Bowman capsule. [Experimental podocalyxin-deficient mice die within the first 24 hours of life. Their kidneys exhibit severe podocyte malformations characterized by impaired glomerular development and fail to develop podocyte foot processes and slit diaphragms. These changes block the passage of urine, resulting in renal failure.](#)

The endothelial surface layer of glomerular capillaries and the subpodocyte space also make important contributions to overall glomerular function.

The filtration apparatus is a complex semipermeable barrier, with properties that allow for a high rate of water filtration, nonrestricted passage of small- and middle-sized molecules, and almost total exclusion of serum albumins and other larger proteins. The filtration apparatus may thus be described as a barrier having two discontinuous cellular layers, the **endothelium of glomerular capillaries** and **visceral layer of the**

Bowman capsule applied to either side of a continuous extracellular layer of the **glomerular basement membrane**. These three layers have traditionally been considered the glomerular filtration barrier. However, two additional physiologically important layers, the endothelial surface layer of glomerular capillaries and subpodocyte space, are included as part of the filtration apparatus:

- **The endothelial surface layer** of the glomerular capillaries consists of a thick carbohydrate-rich meshwork (200–400 nm) attached to the luminal surface of glomerular endothelial cells. It contains a **glycocalyx**, which refers to plasma membrane-bound negatively charged proteoglycans (such as perlecan, syndecan, and versican) associated with glycosaminoglycan side chains (such as heparan sulfate and chondroitin sulfate) and peripheral membrane proteins. **Plasma proteins** (e.g., albumins) adsorbed from the blood coat the luminal surface of glycocalyx.
- **Subpodocyte space** represents a narrow space between the foot processes with their filtration slit diaphragms on one side and a cell body of the podocyte on the other side (see Fig. 20.13). Recent three-dimensional reconstruction of these spaces revealed their interconnected but structurally restrictive character. They cover approximately 60% of the entire surface area of the glomerular filtration barrier and may function in regulating glomerular fluid flux across the filtration apparatus.

The glomerular basement membrane (GBM) acts as a physical barrier and an ion-selective filter.

As discussed earlier, the **GBM** contains type IV and XVIII collagens, sialoglycoproteins, and other noncollagenous glycoproteins (e.g., laminin, fibronectin, entactin) as well as proteoglycans (e.g., perlecan, agrin) and glycosaminoglycans, particularly heparan sulfate (Fig. 20.15). These components are localized in particular portions of the GBM:

FIGURE 20.15. Immunofluorescent-stained glomerulus. This triple-exposure micrograph of a normal adult rat glomerulus is immunostained with two different antibodies. One antibody recognizes specific extracellular components, namely, basement membrane heparan sulfate proteoglycan (BM-HSPG, rhodamine label). The other antibody recognizes basement membrane chondroitin sulfate proteoglycan (BM-CSPG, fluorescein

label). Because it is a triple-exposure micrograph, a yellow color occurs where the two fluorescent labels exactly co-distribute. The blue fluorescence is nuclear counterstaining with Hoechst nuclear stain. The micrograph shows that compartmentalization occurs with respect to glomerular proteoglycan populations. The glomerular capillary basement membrane is composed exclusively of BM-HSPG, whereas the mesangial matrix (*yellow*) contains both BM-HSPG and BM-CSPG. The Bowman capsule appears to be strongly stained by only BM-CSPG antibodies. $\times 360$. (Courtesy of Dr. Kevin J. McCarthy.)

- The **lamina rara externa**, adjacent to the podocyte processes. It is particularly rich in polyanions, such as heparan sulfate, that specifically impede the passage of negatively charged molecules.
- The **lamina rara interna**, adjacent to the capillary endothelium. Its molecular features are similar to those of the lamina rara externa.
- The **lamina densa**, the overlapping portion of the two basal laminae, sandwiched between the laminae rarae. It contains type IV collagen, which is organized into a network that acts as a physical filter. Type XVIII collagen, perlecan, and agrin are responsible for the bulk of anionic charges found in GBM. The laminin and other proteins present in the laminae rarae interna and externa are involved in the attachment of the endothelial cells and podocytes to the GBM.

The GBM restricts the movement of particles, usually proteins, larger than approximately **70 kDa** or with a 3.6-nm radius (e.g., albumin or hemoglobin). Although albumin is not a usual constituent, it may sometimes be found in urine, indicating that the size of albumin is close to the effective pore size of the filtration barrier. The polyanionic glycosaminoglycans of the laminae rarae have strong negative charges and restrict the movement of anionic particles and molecules across the GBM, even those smaller than 70 kDa. Despite the ability of the filtration barrier to restrict protein, several grams of protein do pass through the barrier each day. This protein is reabsorbed by endocytosis in the proximal convoluted tubule. **Albuminuria** (presence of significant amounts of albumin in the urine) or **hematuria** (presence of significant amounts of red blood cells in the urine) indicates physical or functional damage to the GBM. In such cases (e.g., **diabetic nephropathy**), the number of anionic

sites, especially in the lamina rara externa, is significantly reduced.

The filtration slit diaphragm acts as a size-selective filter.

The narrow **filtration slits** formed by the foot processes of podocytes and the filtration slit diaphragms act as physical barriers to restrict the movement of solutes and solvents across the filtration barrier. The discovery of specific proteins that form the **slit diaphragm** has led to new insights into the function of the filtration apparatus in the kidney. Most of the proteins found in the diaphragm are crucial for the normal development and function of the kidney. The slit diaphragm architecture accounts for true size-selective filter properties, which determine the molecular sieving characteristics of the glomerulus. Several mechanisms prevent clogging of the filtration slit diaphragms. These include the negative charge of glycosaminoglycans in the GBM, negative charge of the podocyte cell membrane (due to sialoglycoproteins such as podocalyxin), and the phagocytic function of mesangial cells in the renal corpuscle.

Changes in individual components of the filtration apparatus influence the functions of other components.

The molecular structure and composition of each component of the glomerular filtration barrier has important consequences for adjacent components of the barrier. For instance, molecular changes in the GBM modify not only the contribution of this layer but also the rate at which solutes and solvents pass through the endothelium of glomerular capillaries on one side and the visceral layer of the Bowman capsule on the other. In addition, it is important to understand that the glomerular filtration barrier is not a passive but an active structure that can remodel itself and modify its own permeability.

Simple squamous epithelium constitutes the parietal layer of the Bowman capsule.

The **parietal layer of the Bowman capsule** contains **parietal epithelial cells** and forms a simple squamous epithelium. At the urinary pole of the renal corpuscle, the parietal layer is

continuous with the cuboidal epithelium of the proximal convoluted tubule (see Figs. 20.7 and 20.11). Proliferation of parietal epithelial cells is a typical diagnostic feature in certain types of **glomerulonephritis** (inflammation of the glomerulus). For an example of such a disease, see Folder 20.2.

The space between the visceral and parietal layers of the Bowman capsule is called the **urinary space** or **Bowman space** (see Fig. 20.11). It is the receptacle for the glomerular ultrafiltrate (primary urine) produced by the filtration apparatus of the renal corpuscle. At the urinary pole of the renal corpuscle, the urinary space is continuous with the lumen of the proximal convoluted tubule.

Mesangium

In the renal corpuscle, the GBM is shared among several capillaries to create a space containing an additional group of cells called **mesangial cells**. Mesangial cells are thus enclosed by the GBM (Fig. 20.16). These cells and their extracellular matrix constitute the **mesangium**. The mesangium is most obvious at the vascular stalk of the glomerulus and at the interstices of adjoining glomerular capillaries. The mesangial cells are not confined entirely to the renal corpuscle; some are located outside the corpuscle along the vascular pole, where they are also designated as **lacis cells** and form part of what is called the **juxtaglomerular apparatus** (see Fig. 20.7).

FIGURE 20.16. Diagram and photomicrograph showing the relationship between intraglomerular mesangial cells and glomerular capillaries. a. The mesangial cell and its surrounding matrix are enclosed by the glomerular basement membrane (GBM) of the glomerular capillaries. The mesangial cells are located in the same compartment as the endothelial cells and can be intimately associated with the GBM as well as with the endothelial cells without the intervening GBM. Note that a mesangial cell produces extracellular mesangial matrix, which provides support for the glomerular capillaries. b. Photomicrograph of a glomerulus stained by the periodic acid-Schiff (PAS) method. Note that the GBM is well visualized within the glomerulus and surrounds the glomerular capillaries. The GBM reflects at the vascular pole to become the basal lamina of the epithelial cells that form the parietal layer of the Bowman capsule. The nuclei of the PAS-positive mesangial cells are positioned between the loops of capillaries more toward the center of the glomerulus. Specimen was counterstained with hematoxylin. $\times 360$.

Important functions of the mesangial cells are as follows:

- **Phagocytosis and endocytosis.** Mesangial cells remove trapped residues and aggregated proteins from the GBM and filtration slit diaphragm, thus keeping the glomerular filter free of debris. They also endocytose and process a variety of plasma proteins, including immune complexes. Maintaining the structure and function of the glomerular barrier is the primary function of the mesangial cells.
- **Structural support.** Mesangial cells produce components of the extracellular mesangial matrix that provide support for the podocytes in the areas where the epithelial basement membrane is absent or incomplete (see Fig. 20.16). Mesangial matrix differs in composition substantially from the GBM and allows larger molecules to pass from the lumen of capillaries into the mesangium.
- **Secretion.** Mesangial cells synthesize and secrete a variety of molecules such as interleukin-1 (IL-1), PGE_2 , and platelet-derived growth factor (PDGF), which play a central role in response to glomerular injury.
- **Modulation of glomerular distension.** Mesangial cells have contractile properties. In the past, it was suggested that contraction of mesangial cells could increase the intraglomerular blood volume and filtration pressure. More recent studies have revealed that mesangial contribution to

glomerular filtration rate is minimal and that the mesangial cells may function in regulating glomerular distension in response to increased blood pressure.

Clinically, it has been observed that mesangial cells proliferate in certain kidney diseases in which abnormal amounts of protein and protein complexes are trapped in the GBM. Proliferation of mesangial cells is a prominent feature in the immunoglobulin A (IgA) nephropathy (Berger disease), membranoproliferative glomerulonephritis, lupus nephritis, and diabetic nephropathy.

Embryologically, mesangial and juxtaglomerular cells (discussed in the following paragraph) are derived from smooth muscle cell precursors from the metanephric mesenchyme. During development, these cells are characterized by expressing platelet-derived growth factor receptors (PDGFRs). Their migration into the developing glomeruli is guided by chemotactic effects of the platelet-derived growth factor- β (PDGF β) expressed on the developing podocytes. Although mesangial cells are clearly phagocytotic, they are unusual in the sense that they are not derived from blood-borne monocytes, the usual precursor cells of the mononuclear phagocytotic system.

Juxtaglomerular Apparatus

The juxtaglomerular apparatus includes the macula densa, the juxtaglomerular cells, and the extraglomerular mesangial cells.

Lying directly adjacent to the afferent and efferent arterioles and adjacent to some extraglomerular mesangial cells at the vascular pole of the renal corpuscle is the terminal portion of the distal straight tubule of the nephron. At this site, the wall of the tubule contains cells that are referred to collectively as the macula densa. When viewed in the light microscope, the cells of the macula densa are distinctive in that they are narrower and usually taller than other distal tubule cells (see Fig. 20.7). The nuclei of these cells appear crowded, even to the extent that they appear partially superimposed over one another, thus the name macula densa.

In this same region, the smooth muscle cells of the adjacent afferent arteriole (and, sometimes, the efferent arteriole) are modified. They contain secretory granules, and their nuclei are spherical, as opposed to the typical elongated smooth muscle cell nucleus. These **juxtaglomerular cells** (see Fig. 20.7) require special stains to reveal the secretory vesicles in the light microscope.

The juxtaglomerular apparatus regulates blood pressure by activating the renin-angiotensin-aldosterone system.

In certain physiologic (low sodium intake) or pathologic conditions (decrease in volume of circulating blood because of hemorrhage or reduction in renal perfusion owing to compression of the renal arteries), juxtaglomerular cells are responsible for activating the **renin-angiotensin-aldosterone system (RAAS)**. This system plays an important role in maintaining sodium homeostasis and renal hemodynamics (see Folder 20.3). The granules of the juxtaglomerular cells contain an aspartyl protease called **renin**, which is synthesized, stored, and released into the bloodstream from the modified smooth muscle cells. In the blood, renin catalyzes the hydrolysis of a circulating α_2 -globulin, angiotensinogen, to produce the decapeptide angiotensin I. Production of angiotensin I prompts the following sequence of events:

FOLDER 20.3

CLINICAL CORRELATION: RENIN - ANGIOTENSIN - ALDOSTERONE SYSTEM AND HYPERTENSION

The **renin-angiotensin-aldosterone system (RAAS)** plays a key role in Na^+ and blood volume homeostasis as well as in long-term regulation of arterial blood pressure. Renin secreted by the juxtaglomerular apparatus of the kidney converts angiotensinogen to angiotensin I, which is then converted in the lungs by the angiotensin-converting enzyme (ACE) to **angiotensin II**, one of the most potent vasoconstrictors in the human body. Angiotensin II has an important function in stimulating **aldosterone** secretion from the adrenal cortex. Aldosterone reabsorbs Na^+ and excretes K^+ ; thus, it has an effect on retention of extracellular water volume (Fig. F20.3.1).

FIGURE F20.3.1. Renin - angiotensin - aldosterone system (RAAS) and sites for potential pharmacologic influence. The RAAS is a multisystem endocrine cascade that regulates electrolyte homeostasis, fluid balance, and blood pressure through action on the kidney and cardiovascular system. Decreased perfusion pressure in the kidney triggers the juxtaglomerular cells to release renin into the bloodstream and begin the cascade. *Blue arrows* indicate stimulatory action on the system; *red arrows* indicate inhibitory feedback and action of pharmaceutical agents. Examples of frequently used pharmaceutical agents that influence RAAS include mineralocorticoid (MC) receptor blockers (e.g., spironolactone, eplerenone), ACE inhibitors (e.g., captopril, enalapril), renin inhibitors (e.g., aliskiren), and angiotensin II receptor blockers (e.g., valsartan, losartan). Aldosterone synthase inhibitors are still in the experimental phase.

For years, cardiologists and nephrologists believed that **chronic essential hypertension**, the most common form of hypertension, was somehow related to an abnormality in the RAAS. However, 24-hour urine renin levels in such patients were usually normal. Not until a factor in the venom of a South American snake (Brazilian pit viper, *Bothrops jararaca*) was shown to be a potent inhibitor of ACE in the lung did investigators have both a clue to the cause of chronic

essential hypertension and a new series of drugs with which to treat this common disease.

The “lesion” in chronic essential hypertension is now believed to be excessive production of **angiotensin II** in the lung.

Development of the so-called **ACE inhibitors**—captopril, enalapril, and related derivatives of the original snake venom factor—has revolutionized the treatment of chronic essential hypertension.

These antihypertensive drugs do not cause the often-dangerous side effects of the diuretics and β -blockers that were previously the most commonly used drugs for the control of this condition.

- **Angiotensin I** is converted to the active octapeptide **angiotensin II** by **angiotensin-converting enzyme (ACE)** present in the endothelial cells of lung capillaries.
- Angiotensin II stimulates the synthesis and release of the hormone **aldosterone** from the **zona glomerulosa of the adrenal gland** (see pages 843–844).
- **Aldosterone**, in turn, acts on principal cells of connecting tubules and collecting ducts to increase reabsorption of Na^+ and water, as well as K^+ secretion, thereby raising blood volume and pressure.
- **Angiotensin II** is also a potent vasoconstrictor that has a regulatory role in the control of renal and systemic vascular resistance.

The **juxtaglomerular apparatus** functions not only as an endocrine organ that secretes **renin** but also as a sensor of blood volume and tubular fluid composition. The cells of the macula densa **monitor the Na^+ concentration** in the tubular fluid and regulate both the glomerular filtration rate and the release of renin from the juxtaglomerular cells. The decreased Na^+ concentration in the distal convoluted tubule is believed to be a stimulus for unique ion-transporting molecules expressed on the apical membrane of macula densa cells. These molecules include $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporters, Na^+/H^+ exchangers, and pH^- and calcium-regulated K^+ channels. Activation of membrane transport pathways changes the intracellular ion concentration within the macula densa cells and initiates signaling mechanisms by releasing various mediators, such as adenosine triphosphate (ATP), adenosine, nitric oxide (NO), and prostaglandins (PGE_2). These molecules act in a paracrine manner and signal both the

underlying juxtaglomerular cells of the afferent arteriole to secrete renin and the vascular smooth muscle cells to contract. An increase in blood volume sufficient to cause stretching of the juxtaglomerular cells in the afferent arteriole may be the stimulus that closes the feedback loop and stops the secretion of renin.

■ KIDNEY TUBULE FUNCTION

As the **glomerular ultrafiltrate** passes through the uriniferous tubule and collecting ducts of the kidney, it undergoes changes that involve both active and passive absorption and secretion:

- Certain substances within the ultrafiltrate are reabsorbed, some partially (e.g., water, sodium, and bicarbonate) and some completely (e.g., glucose).
- Other substances (e.g., creatinine and organic acids and bases) are added to the ultrafiltrate (i.e., the primary urine) by secretory activity of the tubule cells.

Thus, the volume of the ultrafiltrate is reduced substantially, and the urine is made hyperosmotic. The long loop of Henle and the connecting tubules and collecting ducts that pass parallel to similarly arranged blood vessels, the vasa recta, serve as the basis for the countercurrent multiplier mechanism that is instrumental in concentrating the urine, thereby making it hyperosmotic.

Proximal Convoluted Tubule

The proximal convoluted tubule is the initial and major site of reabsorption.

The **proximal convoluted tubule** receives the ultrafiltrate from the urinary space of the Bowman capsule. The cuboidal cells of the proximal convoluted tubule have elaborate surface specializations associated with cells engaged in absorption and fluid transport. They exhibit the following features:

- A **brush border**, composed of relatively long, closely packed, and straight microvilli (Fig. 20.17)

FIGURE 20.17. Diagram of proximal convoluted tubule cells. This diagram is drawn at the electron microscopic level and shows the sectioned face on the *right* and a three-dimensional view of the basolateral surface of a proximal convoluted tubule cell with a partial cut face on the *left*. Here, the interdigitating parts of the adjoining cell have been removed to show the basolateral interdigitations. Some of the interdigitating processes extend the full height of the cell. The processes are long in the basal region and create an elaborate extracellular compartment adjacent to the basal lamina. Apically, the microvilli constitute the brush border. In some locations, the microvilli have been omitted, thereby revealing the convoluted character of the apical cell boundary. (Based on Bulger RE. The shape of rat kidney tubular cells. *Am J Anat.* 1965;116:253.)

- A **junctional complex**, consisting of a narrow, tight junction that seals off the intercellular space from the lumen of the tubule and a zonula adherens that maintains the adhesion between neighboring cells
- **Plicae** or **folds** located on the lateral surfaces of the cells, which are large flattened processes, alternating with similar processes of adjacent cells (see Fig. 20.16)

- Extensive **interdigitation of basal processes** of adjacent cells (Figs. 20.18 and 20.19)

FIGURE 20.18. Electron micrograph of a proximal tubule cell. The apical surface of the cell shows the closely packed microvilli (*Mv*) that collectively are recognized as the brush border in the light

microscope. Many vesicles (*V*) are evident in the apical cytoplasm. Also present in the apical region of the cell are lysosomes (*L*). The nucleus has not been included in the plane of section. Extensive numbers of longitudinally oriented mitochondria (*M*) are present in the cell within the interdigitating processes. The mitochondria are responsible for the appearance of the basal striations seen in the light microscope, particularly if the extracellular space is enlarged. The electron micrograph also reveals a basal lamina (*BL*) and a small amount of connective tissue and the fenestrated endothelium (*En*) of an adjacent peritubular capillary. $\times 15,000$. **Upper inset.** This higher magnification of the microvilli shows the small endocytotic vesicles that have pinched off from the plasma membrane at the base of the microvilli. $\times 32,000$. **Lower inset.** A higher magnification of the basal portion of the interdigitating processes (*IP*) below the reach of the mitochondria. The extreme basal aspect of these processes reveals a dense material (*arrows*) that represents bundles of actin filaments (see Fig. 20.16). $\times 30,000$.

FIGURE 20.19. Electron micrograph of a proximal convoluted tubule cell. This section is almost tangential and slightly oblique

to the base of a proximal convoluted tubule cell and the subjacent basal lamina and capillary. In the *left part* of the micrograph is the capillary endothelium (*En*). Characteristically, the endothelium possesses numerous fenestrations (*EnF*), and in this plane of section, the fenestrations are seen en face, displaying circular profiles. The plane of section also makes the basal lamina (*BL*) appear as a broad band of homogeneous material. To the *right* of the basal lamina are the interdigitating basal processes of the proximal tubule cells. The long, straight processes contain longitudinally oriented actin filaments (*arrows*). In this plane of section, the basal extracellular space appears as a maze between the cellular processes. $\times 32,000$.

- **Basal striations**, consisting of elongated mitochondria concentrated in the basal processes and oriented vertically to the basal surface (see Fig. 20.18)

In well-fixed histologic preparations, the basal striations and the apical brush border help distinguish the cells of the proximal convoluted tubule from those of the other tubules.

At the base of the proximal convoluted tubule cell, in the interdigitating processes, bundles of 6-nm microfilaments are present (see *arrows*, Figs. 20.18 and 20.19). These actin filaments may play a role in regulating the movement of fluid from the basolateral extracellular space across the tubule basal lamina toward the adjacent peritubular capillary.

The proximal convoluted tubule recovers most of the fluid from the ultrafiltrate. Of the 180 L/d of ultrafiltrate entering the nephrons, approximately 120 L/d, or 65% of the ultrafiltrate, is reabsorbed by the proximal convoluted tubule. Two major proteins are responsible for fluid reabsorption in the proximal convoluted tubules:

- **Na^+/K^+ -ATPase pumps**, transmembrane proteins that are localized in the lateral folds of the plasma membrane. They are responsible for the *reabsorption of Na^+* , which is the major driving force for reabsorption of water in the proximal convoluted tubule. As in the intestinal and gallbladder epithelia, this process is driven by active transport of Na^+ into the lateral intercellular space. Active transport of Na^+ is followed by passive diffusion of Cl^- to maintain electrochemical neutrality. The accumulation of NaCl in the lateral intercellular spaces creates an osmotic gradient that

draws water from the lumen into the intercellular compartment. This compartment distends as the amount of fluid in it increases; the lateral folds separate to allow this distension.

- **Aquaporin-1 (AQP-1)**, a small (~30 kDa) transmembrane protein that functions as a molecular water channel in the cell membrane of proximal convoluted tubules. Movement of water through these membrane channels does not require the high energy generated by Na^+/K^+ -ATPase pumps. Immunocytochemical methods can be used to demonstrate the presence of these proteins.

The hydrostatic pressure that builds up in the distended intercellular compartment, presumably aided by contractile activity of the actin filaments in the base of the tubule cells, drives an essentially isosmotic fluid across the tubule basement membrane into the renal connective tissue. Here, the fluid is reabsorbed into the vessels of the peritubular capillary network.

The proximal convoluted tubule also reabsorbs nearly all glucose, amino acids, and small polypeptides.

As in the intestine, the microvilli of the proximal convoluted tubule cells are covered with a well-developed glycocalyx that contains several ATPases, peptidases, and high concentrations of disaccharidases. The proximal convoluted tubule recovers almost 100% of **glucose** using Na^+ glucose cotransporters (SGLT2) that simultaneously absorb Na^+ and glucose from the lumen of the tubule. Glucose uptake by epithelial cells generates a high intracellular concentration of glucose, which activates the family of glucose transporters (GLUT2). GLUT2 transports glucose through the basolateral membrane into the connective tissue, where it enters the lumen of blood vessels. The proximal convoluted tubule also recovers approximately 98% of the filtered **amino acids**. These amino acids are absorbed by several amino acid transporters that either exchange Na^+ , H^+ , and K^+ ions (acidic amino acid transporters) or Na^+ and H^+ ions (basic and neutral amino acid transporters). The brush border in the proximal convoluted tubule resembles that of a striated border in the small intestine in that it possesses many peptidases that degrade large proteins into smaller proteins and polypeptides.

Similar to glucose, **small polypeptides** are recovered in a process that employs apical surface H^+ peptide cotransporters (PepT1 and PepT2). Once inside the cell, polypeptides are rapidly degraded and transported across the basolateral membrane as free amino acids.

Proteins and large peptides are endocytosed in the proximal convoluted tubule.

Deep tubular invaginations are present between the microvilli of the proximal convoluted tubule cells. Proteins in the ultrafiltrate, on reaching the tubule lumen, bind to endocytotic receptors expressed on the plasma membrane. When proteins bind to receptors, the process of endocytosis is initiated and endocytotic vesicles containing the bound protein form large protein-containing early endosomes (see Fig. 20.18). These early endosomes are destined to become lysosomes, and the endocytosed proteins are degraded by acid hydrolases. The amino acids produced in the lysosomal degradation are recycled into the circulation via the intercellular compartment and the interstitial connective tissue.

In addition, the pH of the ultrafiltrate is modified in the proximal convoluted tubule by the reabsorption of bicarbonate and the specific secretion into the lumen of exogenous organic acids and organic bases derived from the peritubular capillary circulation.

Proximal Straight Tubule

The cells of the **proximal straight tubule** (i.e., the thick descending limb of the loop of Henle) are not as specialized for absorption as are those of the proximal convoluted tubule. They are shorter, with a less well-developed brush border and fewer and less complex lateral and basolateral processes. The mitochondria are smaller than those of the cells of the convoluted segment and are randomly distributed in the cytoplasm. There are fewer apical invaginations and endocytotic vesicles as well as fewer lysosomes. Cells in the proximal straight tubule are designed to recover the remaining glucose that escaped recovery in the proximal convoluted tubules before it enters the

thin segment of the loop of Henle. They are equipped with high-affinity Na^+ glucose cotransporters (SGLT1) that simultaneously absorb Na^+ and glucose from the lumen of the tubule. These cells also possess complementary GLUT1 glucose transporters in their basolateral membrane to transport glucose out of the cell and into the extracellular matrix.

Thin Segment of Loop of Henle

As noted earlier, the length of the **thin segment** varies with the location of the nephron in the cortex. Juxtamedullary nephrons have the longest limbs; cortical nephrons have the shortest. Furthermore, various cell types are present in the thin segment. In the light microscope, it is possible to detect at least two kinds of thin segment tubules, one with a more squamous epithelium than the other. Electron microscopic examination of the thin segments of various nephrons reveals further differences, namely, the existence of four types of epithelial cells (Fig. 20.20):

FIGURE 20.20. Schematic diagram of loop of Henle thin limb epithelial cells. This diagram shows the various types of epithelia and the region where they are found in the thin limb of the short and long loops of Henle. The diagrams of the epithelium do not include

nuclear regions of the epithelial cells. (Modified from Madsen KM, Tisher CC. Physiologic anatomy of the kidney. In: Fisher JW, ed. *Kidney Hormones*. Academic Press; 1986;3:45-100.)

- **Type I epithelium** is found in the thin descending and ascending limbs of the loop of Henle of short-looped nephrons. It consists of a thin, simple epithelium. The cells have almost no interdigitations with neighboring cells and few organelles.
- **Type II epithelium**, found in the thin descending limb of long-looped nephrons in the cortical labyrinth, consists of taller epithelium. These cells possess abundant organelles and have many small, blunt microvilli. The extent of lateral interdigitation with neighboring cells varies by species.
- **Type III epithelium**, found in the thin descending limb in the inner medulla, consists of a thinner epithelium. The cells have a simpler structure and fewer microvilli than type II epithelial cells. Lateral interdigitations are absent.
- **Type IV epithelium**, found at the bend of long-looped nephrons and through the entire thin ascending limb, consists of a low, flattened epithelium without microvilli. The cells possess few organelles.

The specific functional roles of the four cell types are related to their role in the countercurrent exchange system that functions in concentrating tubular fluid. Morphologic differences, such as microvilli, mitochondria, and the degree of cellular interdigitation, probably reflect specific active or passive roles in this process.

The thin descending and ascending limbs of the loop of Henle differ in structural and functional properties.

Studies of the ultrafiltrate that enters the thin descending limb and leaves the thin ascending limb of the loop of Henle reveal dramatic changes in ultrafiltrate osmolality. The ultrafiltrate that enters the **thin descending limb** is **isosmotic**, whereas the ultrafiltrate leaving the **thin ascending limb** is **hyposmotic** to plasma. This change is achieved by reabsorbing more salts than water. The two limbs of the loop of Henle have different permeabilities and thus different functions:

- The **thin descending limb** of the loop of Henle is **highly permeable to water** because of the presence of AQP_s that allow for free passage of water. This limb is much less permeable to Na⁺ and urea; however, it does permit small amounts to enter the nephron at this site. Urea enters this segment of the nephron via urea transporter A2 (UT-A2). Because the interstitial fluid in the medulla is hyperosmotic, water exits this nephron segment by osmosis, causing the luminal content of Na⁺ and Cl⁻ to become progressively more concentrated. The cells of this limb do not actively transport ions; thus, the *increased tubular fluid osmolality* that occurs in this nephron segment is caused in large part by the passive movement of water into the peritubular connective tissue.
- The **thin ascending limb** of the loop of Henle is **highly permeable to Na⁺ and Cl⁻** because of the presence of Na⁺/K⁺/2Cl⁻ cotransporters in the apical plasma cell membranes. Na⁺ is then pumped out of the cells by Na⁺/K⁺-ATPase, whereas K⁺ and Cl⁻ passively diffuse through their respective channels into the medulla following their concentration gradients. Although the energy from ATP is required to open these channels, the movement of Cl⁻ is not an example of active transport and does not require Cl⁻-stimulated ATPase activity. Counter ions, in this case, Na⁺ (the majority) and K⁺, follow passively to maintain electrochemical neutrality. The hyperosmolarity of the interstitium is directly related to the transport activity of the cells in this nephron segment. Furthermore, the thin ascending limb is largely **impermeable to water**; therefore, Na⁺ and Cl⁻ concentration increases in the interstitium, causing it to become hyperosmotic and the fluid in the lumen of the nephron to become hyposmotic. For this reason, the thin ascending limb is sometimes referred to as the **diluting segment of the nephron**.

In addition, epithelial cells lining the thick ascending limb produce an 85-kDa protein called **uromodulin (Tamm-Horsfall protein)** that influences NaCl reabsorption and urinary concentration ability. **Uromodulin also modulates cell adhesion and signal transduction by interacting with various cytokines.** It also **inhibits the aggregation of calcium oxalate crystals**

(preventing kidney stone formation) and provides a defense against urinary tract infection. In individuals with inflammatory kidney diseases, a precipitated uromodulin is detected in urine in the form of urinary casts (see Folder 20.4).

FOLDER 20.4

CLINICAL CORRELATION: EXAMINATION OF THE URINE—URINALYSIS

Urinalysis is an important part of the examination of patients with suspected renal disease. It typically includes several measurements of physical, biochemical, and microscopic urine characteristics, such as pH, specific gravity (indirect measurement of ion concentration), bilirubin, concentration of intermediate compounds derived from the fatty acid metabolism known as *ketone bodies*, hemoglobin, and concentration of the proteins. The excretion of excessive amounts of protein in the urine (**proteinuria** or **albuminuria**) is an important diagnostic sign of renal disease and is a key part of urinalysis. Normally, less than 150 mg of protein is excreted in the urine each day. Although excessive excretion of protein almost always indicates renal disease, extreme exercise, such as jogging, or severe dehydration may produce increased proteinuria in individuals without renal disease. Microscopic examination of the urine may reveal the presence of red and white blood cells, mineral crystals, and pathogenic agents, such as bacteria or fungi. Often, these elements are enclosed within cylindrical structures called **urinary casts**. The matrix of a urinary cast is formed by an 85-kDa protein, **uromodulin (Tamm-Horsfall protein)**, that precipitates in the lumen of distal convoluted tubules and collecting ducts during a disease process.

Distal Straight Tubule

The distal straight tubule is part of the ascending limb of the loop of Henle.

The **distal straight tubule (thick ascending limb)**, as previously noted, is part of the ascending limb of the loop of Henle and includes both medullary and cortical portions, with the latter located in the medullary rays. The distal straight tubule, like the ascending thin limb, transports ions from the tubular lumen to the interstitium. The apical cell membrane in this segment has electroneutral transporters (synporters) that allow

Cl^- , Na^+ , and K^+ to enter the cell from the lumen. Na^+ is actively transported across the extensive basolateral plications by the Na^+/K^+ -ATPase pumps; Cl^- and K^+ diffuse out from the intracellular space by the Cl^- and K^+ channels. Some K^+ ions leak back into the tubular fluid through K^+ channels, causing the tubular lumen to be positively charged with respect to the interstitium. This positive gradient provides the driving force for the reabsorption of many other ions, such as Ca^{2+} and Mg^{2+} . Note that this significant movement of ions occurs without the movement of water through the wall of the distal straight tubule, resulting in the separation of water from its solutes.

In routine histologic preparations, the large cuboidal cells of the distal straight tubule stain lightly with eosin, and the lateral margins of the cells are indistinct (Plate 20.4, page 808). The nucleus is located in the apical portion of the cell and sometimes, especially in the straight segment, causes the cell to bulge into the lumen. As noted earlier, these cells have extensive basolateral plications, and there are numerous mitochondria associated with these basal folds (Fig. 20.21). They also have considerably fewer and less well-developed microvilli than proximal straight tubule cells (compare Figs. 20.18 and 20.19).

FIGURE 20.21. Electron micrograph of a distal convoluted tubule cell. The apical surface of the cell displays some microvilli (*Mv*), but

they are not sufficiently long or numerous to give the appearance of a brush border (compare with Fig. 20.15). The nucleus and Golgi apparatus (*G*) are in the upper portion of the cell. Mitochondria (*M*) are chiefly in the basal region of the cell within the interdigitating processes (*IP*). As in the proximal tubule cell, the mitochondria account for the appearance of basal striations in the light microscope. A basal lamina (*BL*) is seen adjacent to the basal surface of the cell. $\times 12,000$.

Distal Convolute Tubule

The structure and function of the distal convoluted tubule depends on the delivery and uptake of Na^+ .

The **distal convoluted tubule**, located in the cortical labyrinth, is only about one-third as long ($\sim 5 \text{ mm}$) as the proximal convoluted tubule. It begins at a variable distance beyond the macula densa and extends to the connecting tubule, which connects the nephron with the cortical collecting duct. The cells of the distal convoluted tubule resemble those of the distal straight tubule (thick ascending limb) but are considerably taller and lack a well-developed brush border. Similar to the distal straight tubule, the epithelium in the distal convoluted tubule is also relatively impermeable to water. The early part of the distal convoluted tubule is the primary site for PTH-regulated Ca^{2+} reabsorption. The cells in the distal convoluted tubule have the highest Na^+/K^+ -ATPase activity in their basolateral membranes than any other segment of the nephron, which provides the driving force for ion transport. This short tubule is responsible for

- **reabsorption of Na^+** and secretion of K^+ into the ultrafiltrate to conserve Na^+ ;
- **reabsorption of bicarbonate ions**, with concomitant secretion of H^+ ions, leading to further acidification of the urine;
- **reabsorption of chloride (Cl^-)**, which is mediated by thiazide-sensitive Na^+/Cl^- transporters; and
- **secretion of ammonium** in response to the kidneys' need to excrete acid and generate bicarbonate.

Connecting Tubule

The connecting tubule represents a transition region between the distal convoluted tubule and the cortical collecting duct.

Connecting tubules of the subcapsular nephrons join directly to the cortical collecting duct, whereas the connecting tubules from the midcortical and juxtamedullary nephrons merge with other connecting tubules first to form an arched connecting tubule before uniting with the cortical collecting duct. The epithelium of this segment undergoes a gradual transition from the distal convoluted tubule to the collecting duct and consists of intermingling cells from both regions (i.e., principal cells from cortical collecting duct with distal convoluted tubule cells). Both morphologic and physiologic studies demonstrated that the connecting tubules play an important role in K^+ secretion (most likely attributed to the presence of the principal cells), which is, in part, regulated by mineralocorticoids secreted by the adrenal cortex.

Cortical and Medullary Collecting Ducts

The **cortical** and **medullary collecting ducts** determine final urine osmolality by reabsorbing water. The outer medullary collecting duct is also the site of urea reabsorption by facilitated transport utilizing urea transporter A1 (UT-A1). The collecting ducts are composed of simple epithelium. The cortical collecting ducts have flattened cells, somewhat squamous to cuboidal in shape. The medullary collecting ducts have cuboidal cells, with a transition to columnar cells as the ducts increase in size. The collecting ducts are readily distinguished from proximal and distal tubules by virtue of the cell boundaries that can be seen in the light microscope (Fig. 20.22).

FIGURE 20.22. Scanning electron micrograph and photomicrograph of collecting ducts. **a.** This scanning electron micrograph shows dark cells (*asterisks*), with numerous short lamellipodia or microridges on their surfaces, and light (principal) cells, each with a primary cilium on its free surface along with small microvilli. The terms *light* and *dark* refer to the staining character of sectioned cells and not to the density differences reflecting charge characteristics of the coated surface of the specimen. (Courtesy of Dr. C. Craig Tisher.) **b.** This photomicrograph of collecting ducts stained with hematoxylin and eosin (H&E) shows several longitudinal profiles of collecting ducts in the medulla of the kidney. Note the simple columnar epithelium lining the lumen of the collecting ducts with characteristically distinct cell boundaries visible between individual cells. Most collecting duct cells stain lightly in H&E and represent light (principal) cells. It is difficult in H&E-stained specimens to differentiate with certainty between light and dark cells. A few more intensely stained cells (*arrows*) most likely represent dark (intercalated) cells. $\times 240$. Source: Kent Christensen, PhD; J. Matthew Velkey, PhD; Lloyd M. Collecting ducts play an essential role in maintaining Na^+/Cl^- balance and acid-base homeostasis.

The epithelium of collecting ducts is composed of light (principal) cells and two different types of dark (intercalated) cells.

- **Light cells**, also called **principal cells** or **collecting duct (CD) cells**, are the predominant cell type of collecting ducts. They are pale-staining cells with true basal infoldings rather than processes that interdigitate with those of adjacent cells.

They possess a single primary cilium and relatively few short microvilli (see Fig. 20.22). They contain small, spherical mitochondria. Principal cells express an abundance of cytoplasmic mineralocorticoid receptors (MRs); thus, they are the primary target for **aldosterone** action (see later). Their major function is to reabsorb Na^+ from the lumen of the collecting duct via **epithelial sodium channels (ENaC)** and secrete K^+ via **renal outer medullary potassium (ROMK) channels**. In addition, the apical membrane of these cells possesses an abundance of antidiuretic hormone (ADH)-regulated water channels, **aquaporin-2 (AQP-2)**, which are responsible for the water permeability of the collecting ducts. Aquaporins AQP-3 and AQP-4 are also present within the basolateral membrane of these cells (Fig. 20.23).

FIGURE 20.23. Schematic representation of collecting duct cells with distribution of their main ion transporters. In the *center* of this illustration is a cross section of the collecting duct. Note that the ratio of light (principal) to dark (intercalated) cells is about 3:1. The major function of light (principal) cells is to reabsorb sodium from the lumen of the collecting duct via the epithelial Na⁺ channels (ENaC) and to secrete potassium mainly through the renal outer medullary K⁺ (ROMK) channels. Other K⁺ channels located on the basolateral membrane allow for the exit of potassium from the cell. The presence of Na⁺/K⁺-ATPase pumps at the basolateral membrane maintains the Na⁺ gradient necessary for cell function. The apical membrane has an abundance of antidiuretic hormone (ADH)-regulated water channels, aquaporin-2 (AQP-2), which, together with AQP-3 and AQP-4 at the basolateral membrane, are responsible for removing water from the lumen of the collecting tube and concentrating the urine. The dark (α-intercalated) cells facilitate acid excretion from the body

by secreting hydrogen protons via apical H^+ -ATPase- and H^+/K^+ -ATPase-dependent pumps. At the basolateral membrane, they release HCO_3^- via a Cl^-/HCO_3^- exchanger (AE1), eliminate excess potassium via K^+ channels, and remove chloride via Cl^- channels (CLC-Kb). The dark (β -intercalated) cells have opposite transporter polarities to the α -intercalated cells and secrete base (HCO_3^- bicarbonate anions) into the collecting duct lumen. Their apical membranes contain the Cl^-/HCO_3^- exchanger (pendrin) and Na^+ -dependent Cl^-/HCO_3^- (NDCBE) exchanger that facilitate the movement of chloride and bicarbonates through the apical membrane. The Cl^- channels (CLC-Kb) and H^+ -ATPases are located at the basolateral membrane.

- **Dark cells**, also called **intercalated (IC) cells**, occur in considerably smaller numbers than light cells. They make up one-third of the cells in the collecting ducts and mediate acid-base transport. They have many mitochondria, and their cytoplasm appears denser. Microplicae, cytoplasmic folds, are present on their apical surface as well as microvilli. The microplicae are readily observed with the SEM but may be mistaken for microvilli with the TEM (see Fig. 20.22). They do not show basal infoldings but have basally located interdigitations with neighboring cells. Numerous vesicles are present in the apical cytoplasm. Two functionally distinct types of intercalated cells have been identified in the collecting ducts.
- The first type, the **α -intercalated cells**, secretes acid (**H^+ protons**) into the collecting duct lumen via apical H^+ -ATPase- and H^+/K^+ -ATPase-dependent pumps and releases HCO_3^- via a Cl^-/HCO_3^- exchanger (AE1) located in their basolateral cell membrane. This polarity allows α -intercalated cells to pump H^+ into the lumen of the collecting duct, facilitating acid excretion from the body (see Fig. 20.23).
- The second type, the **β -intercalated cells**, has opposite transporter polarities and secretes base (**HCO_3^- bicarbonate anions**) into the collecting duct lumen. The transporters are similar to those in α -intercalated cells but are located on opposite cell membranes. Their apical membranes contain a Cl^-/HCO_3^- exchanger (pendrin) and the Na^+ -dependent Cl^-/HCO_3^- exchanger (NDCBE) that facilitate chloride entry into the cells

in exchange for bicarbonate excretion into the lumen of the collecting duct (see Fig. 20.23).

- Because of the nature of the diet and thus the need to excrete acid, the epithelium of collecting ducts contains more α - than β -intercalated cells. During metabolic acidosis, the number of β -intercalated cells is reduced and that of α -intercalated cells increases, whereas the total number of intercalated cells in the collecting duct remains unchanged. This finding suggests a **conversion of β - to α -intercalated cells**, giving the kidney a greater ability to secrete H^+ protons and return the pH to the normal range. This conversion event is regulated by an extracellular matrix molecule called **hensin**, (a 230 kDa member of the macrophage scavenger receptor cysteine rich [SRCR] family of proteins), secreted by the β -intercalated cells.

The cells of the collecting ducts gradually become taller as the ducts pass from the outer to the inner medulla and become columnar in the region of the renal papilla. The number of dark cells gradually decreases until there are none in the ducts as they approach the papilla.

Aldosterone does not function at the distal convoluted tubule but rather at the connecting tubules and collecting ducts.

Based on past micropuncture experiments, it was assumed that **aldosterone's** main targets were cells of the distal convoluted tubule. However, more recent molecular research shows that aldosterone acts mainly on the **principal (light) cells** of the **collecting ducts**. As mentioned earlier, the principal cells are not present in the distal convoluted tubule but do have a scattered presence in the connecting tubules. Therefore, aldosterone—similar to ADH—acts on the cortical and medullary collecting ducts, which are lined primarily by the principal cells. The reason for this confusion relates to the fact that the collected tubular fluid during micropuncture experiments often had contact with cells of the connecting tubules and cortical collecting ducts, providing an impression that the experimental treatment with aldosterone had an effect on the distal convoluted tubule. Molecular studies of gene expression provide clear

evidence of mineralocorticoid (aldosterone) receptor presence in the principal cells.

Aldosterone bound to mineralocorticoid receptors in the principal cells acts as a transcription factor for proteins involved in exchange of Na^+ for K^+ .

Aldosterone is secreted by the adrenal cortex and released under stimulation of angiotensin II or by an increase in blood K^+ concentration (hyperkalemia). It binds to the cytoplasmic mineralocorticoid receptor and then is translocated into the nucleus. The aldosterone - mineralocorticoid receptor complex acts as a transcription factor, upregulating gene expression of several proteins that are involved in the reabsorption of Na^+ and secretion of K^+ . These proteins include epithelial sodium channel (ENaC) proteins, renal outer medullary potassium channel (ROMK) proteins, and Na^+/K^+ -ATPase. Synthesis of new channel proteins and enzymes takes approximately 6 hours to implement. The net result of aldosterone action is the increase in **reabsorption of Na^+** and **secretion of K^+** by the principal cells. This increases blood serum Na^+ concentration, which, in turn, increases blood volume and blood pressure.

■ INTERSTITIAL CELLS

The connective tissue of the kidney parenchyma, called **interstitial tissue**, surrounds the nephrons, ducts, and blood and lymphatic vessels. This tissue increases considerably in amount from the cortex (where it constitutes ~7% of the volume) to the inner region of the medulla and papilla (where it may constitute >20% of the volume).

In the cortex, two types of interstitial cells are recognized: **cells that resemble fibroblasts**, found between the basement membrane of the tubules and the adjacent peritubular capillaries, and occasional **macrophages**. In their intimate relationship with the base of the tubular epithelial cells, the fibroblasts resemble the subepithelial fibroblasts of the intestine. These cells synthesize and secrete the collagen and glycosaminoglycans of the extracellular matrix of the interstitium.

In the medulla, the principal interstitial cells resemble **myofibroblasts**. They are oriented to the long axes of the tubular structures and may have a role in compressing these structures. The cells contain prominent bundles of actin filaments, abundant rough endoplasmic reticulum (rER), a well-developed Golgi complex, and lysosomes. Prominent lipid droplets in the cytoplasm appear to increase and decrease in relation to the diuretic state.

FOLDER 20.5

FUNCTIONAL CONSIDERATIONS: STRUCTURE AND FUNCTION OF AQUAPORIN WATER CHANNELS

Aquaporins (AQPs) are small, hydrophobic, transmembrane proteins that mediate water transport in the kidney and other organs (i.e., liver, gallbladder). Thirteen AQPs have been characterized and cloned. The molecular size of AQPs ranges from 26 to 34 kDa. Each protein consists of six transmembrane domains arranged to form a distinct pore. The sites where AQPs are expressed implicate their role in water transport, such as renal tubules (water reabsorption), brain and spinal cord (cerebrospinal fluid reabsorption), pancreatic acinar cells (secretion of pancreatic fluids), lacrimal apparatus (secretion and resorption of tears), and eye (aqueous humor secretion and reabsorption). Most AQPs are selective for the passage of water (AQP-1, AQP-2, AQP-4, AQP-5, AQP-6, and AQP-8), whereas others, such as AQP-3, AQP-7, and AQP-9, called *aquaglyceroporins*, also transport glycerol and other larger molecules in addition to water. Prominent members of the AQP family include:

- **AQP-1**, expressed in kidney (proximal convoluted tubules) and other cell types such as hepatocytes and red blood cells. AQP-1 is also expressed in the lymph nodes, endothelial cells lining lymphatic sinuses, and on the vascular endothelium of high endothelial venules as well as in the endothelial cells of intestinal lacteals.
- **AQP-2**, present in the terminal portion of the distal convoluted tubules, connecting tubules, and the epithelium of collecting ducts. AQP-2 is regulated by antidiuretic hormone (ADH) and is thus known as an *ADH-regulated water channel*. Mutation of the *AQP-2* gene has been linked to **congenital nephrogenic diabetes insipidus**.
- **AQP-3** and **AQP-4** have also been detected in the basolateral cell surface of the light (principal) cells of kidney collecting ducts as well in the gastrointestinal epithelium (AQP-3), pancreatic acinar cells (AQP-12), and the brain and spinal cord (AQP-4).

Research into the function and structure of the AQP proteins may lead to the development of water channel blockers that could be used to treat hypertension, congestive heart failure, and brain swelling and to regulate intracranial or intraocular pressure.

Most fibroblasts originate within the interstitial tissue through a mechanism called **epithelial-mesenchymal transition (EMT)**. The EMT is a process in which epithelial cells lose their characteristics and acquire features of mesenchymal cells. During this transition, epithelial cells lose cell-to-cell junctions, apical-basal domain polarity, and epithelial cell markers and acquire cell motility, a spindle cell shape, and mesenchymal cell markers. The reprogramming and conversion of tubular epithelial cells into a mesenchymal phenotype is initiated by an alteration in the balance of local cytokine concentrations (i.e., TGF- β , FGF, EGF) that upregulate specific transcription factors called EMT-TFs. During persistent injury and chronic inflammation of the kidney parenchyma, fibroblasts increase their numbers and, by secreting excess extracellular matrix, destroy the normal interstitial architecture of the kidney. Research studies suggest that in **renal fibrosis**, more than one-third of all disease-related fibroblasts originate from tubular epithelial cells at the site of injury. Proliferation of fibroblasts in response to local mitogens usually leads to irreversible renal failure characterized by **tubulointerstitial nephritis**. Recent therapeutic interventions in renal fibrosis are directed toward inhibiting fibroblast formation by shifting local cytokine balance in favor of **reversal mesenchymal-epithelial transition**.

■ HISTOPHYSIOLOGY OF THE KIDNEY

The countercurrent multiplier system creates hyperosmotic urine.

The term *countercurrent* indicates a flow of fluid in adjacent structures in opposite directions. The ability to excrete hyperosmotic urine depends on the **countercurrent multiplier system** that involves three structures:

- **Loop of Henle**, which acts as a countercurrent multiplier. The ultrafiltrate moves within the descending limb of the thin segment of the loop toward the renal papilla and moves back toward the corticomedullary junction within the ascending limb of the thin segment. The osmotic gradients of the medulla are established along the axis of the loop of Henle.
- **Vasa recta** form loops parallel to the loop of Henle. They act as countercurrent exchangers of water and solutes between the descending part (arteriolar rectae) and ascending part (venular rectae) of the vasa recta. The vasa recta help maintain the osmotic gradient of the medulla.
- **Collecting duct** in the medulla acts as an **osmotic equilibrating device**. Modified ultrafiltrate in the collecting ducts can be further equilibrated with the hyperosmotic medullary interstitium. The level of equilibration depends on activation of ADH-dependent water channels (AQP-2).

A standing gradient of ion concentration produces hyperosmotic urine by a countercurrent multiplier effect.

The **loop of Henle** creates and maintains a gradient of ion concentration in the medullary interstitium that increases from the corticomedullary junction to the renal papilla. As noted earlier, the thin descending limb of the loop of Henle is freely permeable to water, whereas the ascending limb of the loop of Henle is impermeable to water. Furthermore, the thin ascending limb cells add Na^+ and Cl^- to the interstitium.

Because water cannot leave the thin ascending limb, the interstitium becomes hyperosmotic relative to the luminal contents. Although some of the Cl^- and Na^+ of the interstitium diffuse back into the nephron at the thin descending limb, the ions are transported out again in the thin ascending limb and distal straight tubule (thick ascending limb). This produces the **countercurrent multiplier effect**. Thus, the concentration of NaCl in the interstitium gradually increases down the length of the loop of Henle and, consequently, through the thickness of the medulla from the corticomedullary junction to the papilla.

FUNCTIONAL CONSIDERATIONS: ANTIDIURETIC HORMONE REGULATION OF COLLECTING DUCT FUNCTION

Water permeability of the epithelium of the collecting ducts is regulated by **antidiuretic hormone (ADH, vasopressin)**, a hormone produced in the **hypothalamus** and released from the posterior lobe of the pituitary gland. ADH increases the permeability of the collecting duct to water, thereby producing more concentrated urine. At the molecular level, ADH acts on the ADH-regulated water channels aquaporin-2 (AQP-2), which is located in the epithelium of the terminal portion of the distal convoluted tubule, connecting tubules, and the epithelium of the collecting ducts. However, the action of ADH is more significant in the collecting ducts. ADH binds to receptors on the cells of these ducts and triggers the following actions:

- **Translocation of the AQP-2 - containing intracytoplasmic vesicles** into the apical cell surface—a short-term effect. This results in an increased number of available AQP-2 channels at the cell surface, thus increasing water permeability of the epithelium.
- **Synthesis of AQP-2** and their insertion into the apical cell membrane—a long-term effect

An increase in plasma osmolality or a decrease in blood volume stimulates the release of ADH, as does nicotine.

In the absence of ADH, copious, dilute urine is produced. This condition is called **central diabetes insipidus (CDI)**. Mutation of two genes encoding AQP-2 and ADH receptors is responsible for a form of CDI called **nephrogenic diabetes insipidus**. Because of the loss of normal function of the AQP-2 and ADH receptor proteins synthesized by the collecting duct epithelial cells, the kidney does not respond to ADH. Excess water consumption can also inhibit ADH release, thereby promoting the production of a large volume of hyposmotic urine.

Increased secretion of ADH can produce an extremely hyperosmotic urine, thereby conserving water in the body. Inadequate consumption of water or loss of water because of sweating, vomiting, or diarrhea stimulates the release of ADH. This leads to an increase in the permeability of the epithelium of the distal convoluted tubules and collecting ducts and promotes the production of a small volume of hyperosmotic urine.

Vasa recta containing descending arterioles and ascending venules act as countercurrent exchangers.

To understand the **countercurrent exchange mechanism**, it is necessary to resume the description of the renal circulation at

the point at which the efferent arteriole leaves the renal corpuscle.

The **efferent arterioles** of the renal corpuscles of most of the cortex branch to form the capillary network that surrounds the tubular portions of the nephron in the cortex, the **peritubular capillary network**. The efferent arterioles of the juxtamedullary renal corpuscles form several unbranched arterioles that descend into the medullary pyramid. These **arteriolae rectae** make a hairpin turn deep in the medullary pyramid and ascend as the **venulae rectae**. Together, the descending arterioles and the ascending venules are called the **vasa recta**. The arteriolae rectae form capillary plexuses lined by fenestrated endothelium that supply the tubular structures at the various levels of the medullary pyramid.

Interaction between collecting ducts, loops of Henle, and vasa recta is required for concentrating urine by the countercurrent exchange mechanism.

Because the thick ascending limb of the loop of Henle has a high level of transport activity and because it is impermeable to water, the modified ultrafiltrate that ultimately reaches the distal convoluted tubule is *hyposmotic*. When ADH is present, the distal convoluted tubules and the collecting ducts are highly permeable to water. Therefore, within the cortex, in which the interstitium is isosmotic with blood, the modified ultrafiltrate within the distal convoluted tubule equilibrates and becomes isosmotic, partly by loss of water to the interstitium and partly by addition of ions other than Na^+ and Cl^- to the ultrafiltrate. In the medulla, increasing amounts of water leave the ultrafiltrate as the collecting ducts pass through the increasingly hyperosmotic interstitium on their course to the papillae.

As noted previously, the vasa recta also form loops in the medulla that parallel the loop of Henle. This arrangement ensures that the vessels provide circulation to the medulla without disturbing the osmotic gradient established by transport of Cl^- in the epithelium of the ascending limb of the loop of Henle.

The vasa recta form a **countercurrent exchange system** in the following manner: Both the arterial and venous sides of the loop

are thin-walled vessels that form plexuses of fenestrated capillaries at all levels in the medulla. As the arterial vessels descend through the medulla, the blood loses water to the interstitium and gains salt from the interstitium so that at the tip of the loop, deep in the medulla, the blood is essentially in equilibrium with the hyperosmotic interstitial fluid.

As the venous vessels ascend toward the corticomedullary junction, the process is reversed (i.e., the hyperosmotic blood loses salt to the interstitium and gains water from the interstitium). This passive countercurrent exchange of water and salt between the blood and the interstitium occurs *without expenditure of energy* by the endothelial cells. The energy that drives this system is the same energy that drives the multiplier system, namely, the movement of Na^+ and Cl^- out of the cells of the water-impermeable ascending limb of the loop of Henle. The countercurrent exchange system and other movements of molecules in different parts of the nephron are shown in Figure 20.24.

FIGURE 20.24. Diagram showing the movement of substances into and out of the nephron and collecting system. The *symbols* indicate the mode of transport as well as specific molecule-dependent transporters that act on the nephron and collecting ducts (as noted in the key).

■ BLOOD SUPPLY

Some aspects of the **blood supply** of the kidney have been described in relation to specific functions (i.e., glomerular filtration, control of blood pressure, and countercurrent exchange). It remains, however, to provide an overall description of the blood supply of the kidney.

Each kidney receives a large branch from the abdominal aorta, called the **renal artery**. The renal artery branches within the renal sinus and sends **interlobar arteries** into the substance of the kidney (Fig. 20.25). These arteries travel between the pyramids as far as the cortex and then turn to follow an arched course along the base of the pyramid between the medulla and the cortex. Thus, these interlobar arteries are designated **arcuate arteries**.

FIGURE 20.25. Schematic diagram of the renal blood supply. The renal artery gives rise to interlobar arteries that branch into arcuate arteries at the border between the medulla and the cortex. Interlobular arteries branch from the arcuate arteries and travel toward the renal capsule, giving off afferent arterioles that contribute to the glomerular capillaries. Glomeruli in the outer part of the cortex send efferent arterioles to the peritubular cortical capillaries that surround the tubules in the cortex. Glomeruli near the medulla, the juxtamedullary glomeruli, send efferent arterioles almost entirely into the medullary network of capillaries that contains the descending vasa recta. Blood returns from the medulla by the ascending vasa recta and the capillary network via veins that enter the arcuate veins. Stellate veins near the capsule drain the capsular network, and the peritubular cortical plexus drains to both the interlobular and arcuate veins.

Interlobular arteries branch from the arcuate arteries and ascend through the cortex toward the capsule. Although the boundaries between lobules are not distinct, the interlobular arteries, when included in a section cut perpendicular to the vessel, are located midway between adjacent medullary rays, traveling in the cortical labyrinth. As they traverse the cortex toward the capsule, the interlobular arteries give off branches, the **afferent arterioles**, one to each glomerulus (Fig. 20.26). A single afferent arteriole may spring directly from the interlobular artery, or a common stem from the interlobular artery may branch to form several afferent arterioles. Some interlobular arteries terminate near the periphery of the cortex, whereas others enter the kidney capsule to provide its arterial supply.

FIGURE 20.26. Photomicrograph of the cortical labyrinth in the kidney from an adult monkey. This high-magnification photomicrograph of a hematoxylin and eosin (H&E)-stained kidney shows the glomerulus with associated tubules and blood vessels. The prominent glomerulus is surrounded by the Bowman capsule and is supplied by an afferent arteriole (AA) that originates from the interlobular artery (ILA) visible on the *left* side of the image. The afferent arteriole supplying blood to the glomerulus has a distinct circular layer of smooth muscle cells (SMC) that was sectioned perpendicularly to the long axis of the arteriole. The modified smooth muscle cells in the terminal portion of the afferent arteriole are termed *juxtaglomerular cells* (JgC). In addition to a contractile apparatus, these cells exhibit prominent

endoplasmic reticulum, Golgi apparatus, and secretory vesicles containing renin. Macula densa and extraglomerular mesangial cells are not easily discernable. The grazing section of an interlobular artery (*ILA*) reveals a much thicker layer of circular smooth muscle cells with visible nuclei crossing the lumen of the vessel. The elongated endothelial cells (*EnC*) are clearly visible. Note the accompanying intralobular vein (*ILV*) and several profiles of proximal convoluted (*PC*) and distal convoluted (*DC*) tubules of the nephron. $\times 380$. *Source: Kent Christensen, PhD; J. Matthew Velkey, PhD; Lloyd M. Stoolman, MD; Laura Hessler; Diedra Mosley-Brower; and Michael Hortsch, PhD; University of Michigan Medical School. © 2010 The Regents of the University of Michigan. For more information, questions, or permissions requests please contact: Michael Hortsch, PhD, University of Michigan Medical School, hortsch@umich.edu.*)

Afferent arterioles give rise to the capillaries that form the glomerulus. The glomerular capillaries reunite to form an efferent arteriole that, in turn, gives rise to a second network of capillaries, the **peritubular capillaries**. The arrangement of these capillaries differs according to whether they originate from cortical or juxtamedullary glomeruli:

- **Efferent arterioles from cortical glomeruli** lead into a peritubular capillary network that surrounds the local uriniferous tubules (see Fig. 20.25).
- **Efferent arterioles from juxtamedullary glomeruli** descend into the medulla alongside the loop of Henle; they break up into smaller vessels that continue toward the apex of the pyramid but make hairpin turns at various levels to return as straight vessels toward the base of the pyramid (see Fig. 20.25). Thus, the efferent arterioles from the juxtamedullary glomeruli give rise to the **descending vasa recta**, which, together with the **ascending vasa recta**, are involved in the countercurrent exchange system. They drain via a peritubular medullary capillary network into the arcuate veins. These vessels are described in the explanation of the countercurrent exchange system (page 792).

Generally, venous flow in the kidney follows a reverse course to arterial flow, with the veins running in parallel with the corresponding arteries (see Fig. 20.25). Thus, the venous flow is as follows:

- **Peritubular cortical capillaries** drain into **interlobular veins**, which, in turn, drain into arcuate veins, interlobar veins, and the renal vein.
- The **medullary vascular network** drains into **arcuate veins** and so forth.
- **Peritubular capillaries** near the kidney surface and **capillaries of the capsule** drain into **stellate veins** (so-called for their pattern of distribution when viewed from the kidney surface), which drain into **interlobular veins**, and so forth.

■ LYMPHATIC VESSELS

The kidneys contain two major networks of lymphatic vessels. These networks are not usually visible in routine histologic sections but can be demonstrated by experimental methods. One network is located in the outer regions of the cortex and drains into larger lymphatic vessels in the capsule. The other network is located more deeply in the substance of the kidney and drains into large lymphatic vessels in the renal sinus. There are numerous anastomoses between the two lymphatic networks.

■ NERVE SUPPLY

The fibers that form the **renal plexus** are unmyelinated, derived mostly from the **sympathetic division** of the autonomic nervous system. There is no evidence for parasympathetic innervation of the kidney. The sympathetic postsynaptic nerves that form the renal plexus are adrenergic (secrete **norepinephrine** at their nerve terminals). They travel along the renal artery and vein and are distributed to all segments of the renal vasculature. The highest concentrations of nerves are observed along the afferent arterioles, followed by the efferent arterioles. They cause contraction of vascular smooth muscle and consequent vasoconstriction that regulate urine production as follows:

- Constriction of the afferent arterioles to the glomeruli reduces the filtration rate and decreases the production of urine.

- Constriction of the efferent arterioles from the glomeruli increases the filtration rate and increases the production of urine.
- Loss of sympathetic innervation leads to increased urinary output.

It has been proposed that chronic hyperstimulation of sympathetic nerves in the renal plexus is an important factor in resistant hypertension. Therefore, minimally invasive techniques targeting the renal plexus are being progressively developed, including intraluminal denervation by radiofrequency ablation, denervation by high-intensity-focused ultrasound, or computed tomography-guided injection of agents (i.e., ethanol or vincristine) that obliterate nerve fibers.

Based on evidence collected from patients who received a kidney transplant, it is evident that the extrinsic nerve supply is not necessary for normal renal function. Although the nerve fibers to the kidney are severed during renal transplantation, transplanted kidneys subsequently function normally.

■ URETER, URINARY BLADDER, AND URETHRA

All excretory passages, except the urethra, have the same general organization.

On leaving the collecting ducts at the **area cribrosa**, the urine enters a series of structures that do not modify it but are specialized to store and pass the urine to the exterior of the body. The urine flows sequentially to a **minor calyx**, a **major calyx**, and the **renal pelvis** and leaves each kidney through the **ureter** to the **urinary bladder**, where it is stored. The urine is finally voided through the urethra.

All of these excretory passages, except the urethra, have the same general structures, namely, a mucosa (lined by transitional epithelium), muscularis, and adventitia (or, in some regions, a serosa).

Transitional epithelium lines the calyces, ureters, bladder, and the initial segment of the urethra.

Transitional epithelium (urothelium) lines the excretory passages leading from the kidney and forms the interface between the urinary space and underlying blood vessels, nerves, connective tissue, and smooth muscle cells (Figs. 20.27 and 20.28). This stratified epithelium is essentially impermeable to salts and water. The cells in the transitional epithelium are composed of at least three layers:

FIGURE 20.27. Photomicrograph of transitional epithelium (urothelium). This hematoxylin and eosin (H&E)-stained specimen shows the four- to five-cell layer thickness of the epithelium in the relaxed ureter. The surface cells exhibit a rounded or dome-shaped profile. The

connective tissue (lamina propria) below the epithelium (*TEp*) is relatively cellular and contains a number of lymphocytes. Blood vessels (*BV*) are also abundant in this area. $\times 450$.

FIGURE 20.28. Transmission electron micrograph of urinary bladder epithelium. The mucous membrane of the urinary bladder consists of

transitional epithelium (*TEp*) with an underlying lamina propria (*LP*). The superficial layer (*SupL*) contains dome-shaped cells with unique fusiform vesicles (*FV*), which are evident here at this relatively low magnification. These are seen at higher magnification in Figure 20.29b. The intermediate layer (*IntL*) of variable thickness contains cells that can differentiate and replace lost dome-shaped cells. The basal layer (*BasL*) contains stem cells of the transitional epithelium. $\times 5,000$.

- The **superficial layer** contains single or multinucleated large, polyhedral cells (25–250 μm in diameter) that bulge into the lumen. They are frequently described as **dome-shaped** or **umbrella cells** because of their apical surface curvature (see Fig. 20.28). The shape of these epithelial cells depends on the filling state of the excretory passage. For instance, in an empty urinary bladder, dome-shaped cells are roughly cuboidal; however, when the bladder is filled, they are highly stretched and appear flat and squamous. Edges of the cells exhibit ridges, which are formed by the interdigitations of apical surface membranes from adjacent cells. These interdigitations resemble a closed zipper line and contribute to the high-resistance paracellular barrier that reinforces tight junctions.
- The **intermediate cell layer** contains pear-shaped cells that are connected to each other and the overlying dome-shaped cells by desmosomes. The thickness of this layer varies with the state of the urinary tract expansion, which, in humans, may reach up to five layers thick. When the overlying dome-shaped cell is lost, the population of intermediate cells rapidly differentiates and replaces the lost surface cell.
- The **basal cell layer** consists of small cells containing a single nucleus that rests on the basement membrane. This layer contains **stem cells** for the urothelium.

The epithelium begins in the minor calyces as two cell layers and increases to four to five layers in the ureter and as many as six or more layers in the empty bladder. However, when the bladder is distended, as few as three layers are seen (see Fig. 20.28). This change reflects the ability of the cells to accommodate distension. The cells in the distended bladder, particularly the large, dome-shaped surface cells, flatten and those in intermediate layers slide past one another to

accommodate the increasing surface area. As the individual cells reorganize in the distended bladder, the resulting appearance is the “true” three layers.

The luminal surface of the transitional epithelium is covered by rigid urothelial plaques containing crystalline protein uroplakins, which play an important role in the permeability barrier.

When the wall of a nondistended urinary bladder is examined with the TEM, the **apical plasma membrane** of dome-shaped cells exhibits an unusual scallop-shaped appearance. Most of the apical plasma membrane is covered by the rigid-looking concave **urothelial plaques** separated by intervening narrow **hinge regions** (Fig. 20.29). In cross sections, the outer leaflet of the lipid bilayer is twice as thick as the inner leaflet; thus, the region of the urothelial plaque appears asymmetrical, hence the name **asymmetric unit membrane (AUM)**. The thicker outer leaflet of the urothelial plaque contains a crystalline array of hexagonally arranged 16-nm protein particles composed of a family of five transmembrane proteins called **uroplakins** (UPIa, UPIb, UPII, UPIIIa, and UPIIIb; Fig. 20.30). The crystalline arrangement of the uroplakin particles makes the plaque impermeable to small molecules (water, urea, and protons). In conjunction with tight junctions, urothelial plaques play an important role in the urothelial permeability barrier. The hinge areas of the plasma membrane contain all other nonplaque proteins typically found on the apical cell domain, such as receptors and channels. Approximately 85% of urinary tract infections are caused by uropathogenic *Escherichia coli*, which colonize the transitional epithelium. The initial adhesion to the epithelium allows the bacteria to gain a foothold on the epithelial surface, thus preventing them from being removed during micturition. This binding is mediated by FimH adhesins located at the tip of a filamentous attachment apparatus of *E. coli*, which interacts with the uroplakins in the asymmetric unit membrane of the urothelial plaques. In addition, the interaction with uroplakins triggers a cascade of events that lead to bacterial invasion into cells of the transitional epithelium.

FIGURE 20.29. Transmission electron micrograph of the apical portion of a dome-shaped cell. a. The cytoplasm displays small

vesicles, filaments, and mitochondria, but the most distinctive feature of the cell is its fusiform vesicles (*FV*). Note that the apical plasma membrane is covered by the rigid-looking concave urothelial plaques (*UP*) separated by intervening narrow hinge regions (*HR*). $\times 27,000$. **b.** Higher magnification shows that the membrane forming the fusiform vesicles (*arrow*) is similar to the apical plasma membrane of the urothelial plaque (*UP*). Both membranes are thickened and represent an asymmetric unit membrane (*AUM*) in which the outer leaflet of the lipid bilayer is twice as thick as the inner leaflet. Uroplakins, the specific proteins of the urothelial plaque, are produced in the rough endoplasmic reticulum (*rER*) and then transported to the Golgi apparatus, where they undergo oligomerization into 16-nm particles with the final assembly into a crystalline array. The *trans*-Golgi network packages *AUMs* into the fusiform vesicles for delivery to the apical cell membrane. $\times 60,000$.

FIGURE 20.30. Diagrams of the luminal surface of dome-shaped cells. **a.** This drawing depicts a luminal surface of dome-shaped cells

in a relaxed bladder. Note the apical plasma membrane of each cell is covered by the ridged concave urothelial plaques that are separated by intervening narrow hinge regions. The fusiform vesicles (*drawn in different color*) containing additional plaque membranes accumulate in the upper part of the cell. Most of them are vertically oriented, and some are attached to hinge regions of the apical cell membrane. b. This diagram depicts the same cell shown in a as it would appear in a stretched bladder. Note the additional plaques that have been added to the surface from the fusiform vesicles. The remaining vesicles in this stage are visible in a more horizontal position. c. The urothelial plaque in cross section exhibits features of the asymmetric unit membrane (*AUM*) in which the outer leaflet of the lipid bilayer is twice as thick as the inner leaflet. The *AUM* is present in both urothelial plaques and fusiform vesicles. d. The thicker outer leaflet of the urothelial plaque contains a crystalline array of hexagonally arranged, 16-nm in diameter proteins that is composed of transmembrane proteins called uroplakins.

Transitional epithelium maintains a urothelial permeability barrier despite dynamic changes in the wall of the urinary bladder and other urine-containing organs.

As the bladder or other urine-containing organs distend, the folded surface of the mucosa becomes stretched and expands. Dome-shaped cells also undergo changes in their apical membrane that are associated with the presence of **fusiform vesicles**. When observed with the TEM, the fusiform vesicles are oriented perpendicular and positioned in close proximity to the apical plasma membrane. They are formed by **asymmetric unit membranes** similar to those in the urothelial plaques. In response to the distention of the bladder, the apical membrane expands as a result of exocytosis of the fusiform vesicles that become part of the cell surface (see Fig. 20.28). Most of the fusiform vesicles fuse at the hinge regions to the apical cell surface, whereas the remaining vesicles assume a more parallel position in relation to the apical membrane. During micturition, the process is reversed as the added apical membrane is recovered by endocytosis and the apical membrane of the dome-shaped cells shortens.

Urothelium is an active participant in signaling mechanisms between the external environment facing the urine, nerve fibers, and smooth muscles of the urinary passages.

Experimental studies have shown that urothelium does not act only as a passive permeability barrier but also plays an active role in the signaling mechanisms of the urinary organs. The urothelium responds to chemical and mechanical stimuli and is engaged in autocrine or paracrine communication with nerve fibers and smooth muscles of the urinary passages. Expression of a variety of receptors on its surface (i.e., nicotinic, muscarinic, and adrenergic) and ion channels allows urothelial cells to respond to neurotransmitters released from nerve fibers. In addition, urothelial cells are able to produce and secrete acetylcholine (ACh), nitric oxide (NO), and nerve growth factor (NGF), which regulate the activity of underlying nerve fibers and smooth muscles.

Smooth muscle of the urinary passages is arranged in bundles.

A dense collagenous lamina propria underlies the urothelium throughout the excretory passages. Neither a muscularis mucosae nor a submucosal layer is present in their walls. In the tubular portions (ureters and urethra), usually two layers of **smooth muscle** lie beneath the lamina propria:

- **Longitudinal layer**, the inner layer that is arranged in a loose spiral pattern
- **Circular layer**, the outer layer that is arranged in a tight spiral pattern

Note that this arrangement of the smooth muscle is opposite to that of the muscularis externa of the intestinal tract. The smooth muscle of the urinary passages is mixed with connective tissue so that it forms parallel bundles rather than pure muscular sheets. Peristaltic contractions of the smooth muscle move the urine from the minor calyces through the ureter to the bladder.

Ureters

Each **ureter** conducts urine from the renal pelvis to the urinary bladder and is approximately 24–34 cm long. The distal part of the ureter enters the urinary bladder and follows an oblique path through the wall of the bladder. **Transitional epithelium**

(urothelium) lines the luminal surface of the wall of the ureter. The remainder of the wall is composed of smooth muscle and connective tissue. The smooth muscle is arranged in three layers: an inner longitudinal layer, a middle circular layer, and an outer longitudinal layer (Plate 20.5, page 810). However, the outer longitudinal layer is present only at the distal end of the ureter. Usually, the ureter is embedded in the retroperitoneal adipose tissue. The adipose tissue, vessels, and nerves form the adventitia of the ureter.

As the bladder distends with urine, the openings of the ureters are compressed, reducing the possibility of reflux of urine into the ureters. Contraction of the smooth muscle of the bladder wall also compresses the openings of the ureters into the bladder. This action helps prevent the spread of infection from the bladder and urethra, frequent sites of chronic infection (particularly in females), to the kidney.

In the terminal portion of the ureters, a thick outer layer of longitudinal muscle is present in addition to the two listed earlier, particularly in the portion of the ureter that passes through the bladder wall. Most descriptions of the bladder musculature indicate that this longitudinal layer continues into the wall of the bladder to form a principal component of its wall. The smooth muscle of the bladder, however, is not as clearly separated into distinctive layers.

Urinary Bladder

The urinary bladder is a distensible reservoir for urine, located in the pelvis, posterior to the pubic symphysis; its size and shape change as it fills. It contains three openings, two for the ureters (ureteric orifices) and one for the urethra (internal urethral orifice). The triangular region defined by these three openings, the trigone, is relatively smooth and constant in thickness, whereas the rest of the bladder wall is thick and folded when the bladder is empty and thin and smooth when the bladder is distended. These differences reflect the embryologic origins of the trigone and the rest of the bladder wall. Because the trigone is derived from the embryonic mesonephric ducts, neither a muscularis mucosae nor a submucosal layer is present. Because the major portion of the bladder wall

originates from the cloaca (a part of the hindgut), its wall possesses layers comparable to those found in the gastrointestinal tract.

The smooth muscle of the bladder wall forms the **detrusor muscle**. Toward the opening of the urethra, the muscle fibers form the involuntary **internal urethral sphincter**, a ring-like arrangement of muscle around the opening of the urethra. The smooth muscle bundles of the detrusor muscle are less regularly arranged than that of the tubular portions of the excretory passages; thus, the muscle and collagen bundles are randomly mixed (Plate 20.6, page 812). Contraction of the detrusor muscle of the bladder compresses the entire organ and forces the urine into the urethra.

The **bladder is innervated** by both sympathetic and parasympathetic divisions of the autonomic nervous system:

- **Sympathetic fibers** form a plexus in the adventitia of the bladder wall. These sympathetic postsynaptic fibers originate from the hypogastric plexus and release **noradrenaline (NA)**. NA activates both **β_3 -adrenergic receptors** to relax the detrusor muscle and **α_1 -adrenergic receptors** to contract smooth muscle fibers of the internal urethral sphincter. In this way, the sympathetic nervous system relaxes the bladder and contracts the internal urethral sphincter simultaneously.
- **Parasympathetic fibers** originate from the S2 to S4 segments of the spinal cord and travel with pelvic splanchnic nerves into the terminal ganglia located in the muscle bundles and adventitia of the bladder. Increased stimulation of parasympathetic postsynaptic nerve fibers releases **acetylcholine (ACh)**, which causes bladder contraction by stimulating **M₃ muscarinic receptors** in the smooth fibers of the detrusor muscle. These nerves also release **nitric oxide (NO)**, which relaxes smooth muscles of the internal urethral sphincter. Therefore, the parasympathetic system provides efferent fibers for the **micturition reflex**.
- **Sensory fibers** from the bladder to the sacral portion of the spinal cord are the afferent fibers of the micturition reflex.

Voluntary control over micturition is provided by the **somatic nerve fibers** from the **pudendal nerve** (S2 – S4), which innervate

the skeletal (striated) muscle of the external sphincter of the urethra. Somatic axon terminals at the neuromuscular junctions release **acetylcholine (ACh)**, which stimulates contraction of the external sphincter striated muscle by activating **nicotinic cholinergic receptors**. This sphincter surrounds the membranous urethra as it passes through the deep perineal pouch. Innervation from pudendal nerve fibers maintains constant tonic contraction of the skeletal muscle fibers of the external sphincter. During micturition, these fibers are inhibited, causing relaxation of the external sphincter and voiding of urine.

Urethra

The **urethra** is the fibromuscular tube that conveys urine from the urinary bladder to the exterior through the **external urethral orifice**. The size, structure, and functions of the urethra differ in males and females.

In the male, the urethra serves as the terminal duct for both the urinary and genital systems. It is about 20 cm long and has three distinct segments:

- **Prostatic urethra** extends for 3–4 cm from the neck of the bladder through the prostate gland (see pages 885–889). It is lined with transitional epithelium (urothelium). The ejaculatory ducts of the genital system enter the posterior wall of this segment, and many small prostatic ducts also empty into this segment.
- **Membranous urethra** extends for about 1 cm from the apex of the prostate gland to the bulb of the penis. It passes through the **deep perineal pouch** of the pelvic floor as it enters the perineum. Skeletal muscle of the deep perineal pouch surrounding the membranous urethra forms the **external (voluntary) sphincter of the urethra**. Transitional epithelium ends in the membranous urethra. This segment is lined with a stratified or pseudostratified columnar epithelium that resembles the epithelium of the genital duct system more than it resembles the epithelium of the more proximal portions of the urinary duct system.
- **Penile (spongy) urethra** extends for about 15 cm through the length of the penis and opens on the body surface at the **glans**

penis. The penile urethra is surrounded by the **corpus spongiosum** as it passes through the length of the penis. It is lined with pseudostratified columnar epithelium, except at its distal end, where it is lined with stratified squamous epithelium continuous with that of the skin of the penis. **Ducts of the bulbourethral glands (Cowper glands)** and mucus-secreting **urethral glands (glands of Littre)** empty into the penile urethra.

In the female, the urethra is short, measuring 3-5 cm in length from the bladder to the vestibule of the vagina, where it normally terminates just posterior to the clitoris (see Chapter 23, Female Reproductive System, page 944). The mucosa is traditionally described as having longitudinal folds. As in the male urethra, the lining is initially transitional epithelium, a continuation of the bladder epithelium, but changes to stratified squamous epithelium before its termination. Some investigators have reported the presence of stratified columnar and pseudostratified columnar epithelium in the midportion of the female urethra.

Numerous small urethral glands, particularly in the proximal part of the urethra, open into the urethral lumen. Other glands, the **paraurethral glands (Skene glands)**, which are homologous to the prostate gland in the male, secrete into the common **paraurethral ducts**. These ducts open on each side of the external urethral orifice. They produce an alkaline secretion. The lamina propria is a highly vascularized layer of connective tissue that resembles the corpus spongiosum in the male. Where the urethra penetrates the urogenital diaphragm (membranous part of the urethra), the striated muscle of this structure forms the external (voluntary) urethral sphincter.

URINARY SYSTEM

OVERVIEW OF THE URINARY SYSTEM

- The **urinary system** includes the kidneys, ureters, bladder, and urethra.
- Essential functions of the kidneys include **homeostasis** via control of electrolyte and water balance, plasma pH, tissue osmolality, and blood pressure; **filtration** and **excretion** of metabolic waste products; and **endocrine activities**, such as secretion of hormones to regulate bone marrow erythropoiesis (EPO), blood pressure (renin), and Ca^{2+} metabolism (activation of vitamin D).

GENERAL STRUCTURE OF THE KIDNEY

- Each kidney is surrounded by a connective tissue **capsule** and contains an outer **cortex** and inner **medulla**, which is divided into 8-12 renal **pyramids**. The cortex extends into the medulla to form **renal columns** that separate the renal pyramids from each other.
- The **cortex** is characterized by renal corpuscles and their associated **convoluted** and **straight tubules**. Aggregation of straight tubules and collecting ducts in the cortex forms the **medullary rays**.
- A renal **lobe** includes the renal pyramid and its associated cortical tissue.
- The base of each renal **pyramid** faces the cortex, and the apical portion (**papilla**) projects into the minor calyx, a branch of the **major calyx** that, in turn, is a division of the renal pelvis.
- At the **hilum**, the renal pelvis extends into the ureter, which carries urine into the urinary bladder.
- Each kidney receives blood from the **renal artery**, which branches into the **interlobar arteries** (run between pyramids) that then turn along the base of the pyramid (**arcuate arteries**) and further branch into smaller **interlobular arteries** that supply the cortex.
- In the cortex, the interlobular artery gives off the **afferent arterioles** (one to each glomerulus), which give

rise to the capillaries that form the glomerulus. The glomerular capillaries reunite to form a single **efferent arteriole** that, in turn, gives rise to a second network of capillaries, the **peritubular capillaries**.

- Some of the peritubular capillaries form long loops called the **vasa recta**, which accompany the thin segments of the nephrons.
- The peritubular capillaries drain into the **interlobular veins**, which, in turn, drain into the **arcuate veins**, **interlobar veins**, and the **renal vein**.

STRUCTURE AND FUNCTION OF NEPHRONS

- The **nephron** is the structural and functional unit of the kidney.
- The nephron consists of the **renal corpuscle** and a long tubular part that includes a proximal thick segment (**proximal convoluted tubule** and **proximal straight tubule**), thin segment (thin part of the **loop of Henle**), and distal thick segment (**distal straight tubule** and **distal convoluted tubule**). The distal convoluted tubule connects to the **collecting tubule** that opens at the renal papilla.
- The renal corpuscle contains the **glomerulus** surrounded by a double layer of the **Bowman capsule**.
- The **filtration apparatus** of the kidney consists of the **glomerular endothelium**, **glomerular basement membrane (GBM)**, and the **Bowman capsule podocytes**.
- The negatively charged **GBM**, which contains type IV and XVIII collagens, sialoglycoproteins, noncollagenous glycoproteins, proteoglycans, and glycosaminoglycans, acts as a physical barrier and an ion-selective filter.
- **Podocytes** extend their processes around the capillaries and develop numerous primary and secondary processes that give rise to **pedicels (foot processes)**, that interdigitate with other foot processes of the neighboring podocytes. The spaces between the interdigitating foot processes form **filtration slits** that are covered by the **filtration slit diaphragm**.

- Podocalyxin and nephrin play a key role in maintaining the structural and functional integrity of the kidney's filtration apparatus.
- The GBM in the renal corpuscle is shared among several capillaries to create a space for mesangial cells and their extracellular matrix.
- Mesangial cells are involved in phagocytosis and endocytosis of residues trapped in the filtration slits, secretion of paracrine substances, structural support for podocytes, and modulation of glomerular distention.
- The juxtaglomerular apparatus includes the macula densa (monitors Na^+ concentration in tubular fluid), juxtaglomerular cells (secrete renin), and extraglomerular mesangial cells. It regulates blood pressure by activating the renin-angiotensin-aldosterone system (RAAS).

KIDNEY TUBULE FUNCTION

- The glomerular ultrafiltrate from the Bowman capsule passes through a series of tubules and collecting ducts lined by epithelial cells that secrete and absorb various substances to produce the final urine.
- The proximal convoluted tubule receives the glomerular ultrafiltrate from the Bowman capsule. This tubule is the initial and major site for reabsorption of glucose, amino acids, polypeptides, water, and electrolytes.
- Reabsorption of the ultrafiltrate continues as it flows from the proximal convoluted into the proximal straight tubule (the thick descending limb of the loop of Henle) that descends into the medulla.
- The loop of Henle, with both the descending limb (highly permeable to water) and ascending limb (highly permeable to Na^+ and Cl^-), concentrates the ultrafiltrate.
- The distal straight tubule (thick ascending limb) ascends back into the cortex to reach the vicinity of its renal corpuscle, where it makes contact with the afferent arteriole. In this area, the epithelial cells of the tubule form the macula densa.

- The distal convoluted tubule empties the ultrafiltrate into the cortical collecting duct that lies in the medullary ray, which further adjusts the concentration of Na^+ and K^+ in the ultrafiltrate.
- The medullary collecting duct is lined by cuboidal cells, with a transition to columnar cells as the duct increases in size. The collecting ducts possess aquaporins and antidiuretic hormone (ADH)-regulated water channels that regulate water reabsorption.
- The collecting ducts open at the renal papilla, and the modified ultrafiltrate, now called urine, flows sequentially via the excretory passages.

URETER, URINARY BLADDER, AND URETHRA

- All excretory passages for urine, except the urethra, have the same general organization: They are lined by a mucosa containing transitional epithelium (urothelium) and have a smooth muscle layer and a connective tissue adventitia (or serosa).
- Transitional epithelium is a specialized stratified epithelium with large dome-shaped (umbrella) cells that bulge into the lumen.
- The dome-shaped cells have a modified apical membrane containing plaques and fusiform vesicles that accommodate the invaginated excess of the plasma membrane, which is needed for the extension of the apical surface when the organ is stretched.
- Transitional epithelium creates a permeability barrier and is actively involved in molecular signaling mechanisms.
- The ureter conducts urine from the renal pelvis to the urinary bladder. It is lined by transitional epithelium, underlying smooth muscle arranged in three distinct layers, and connective tissue adventitia.
- The urinary bladder is also lined by transitional epithelium and possesses many mucosal folds, except in the trigone region. Its muscular wall is thick and well developed and forms the detrusor muscle.

- The **urethra** conveys urine from the urinary bladder to the **external urethral orifice**.
- The **female urethra** is short and lined by transitional epithelium (upper half), pseudostratified columnar epithelium (lower half), and stratified squamous epithelium (before its termination).
- The **male urethra** is much longer than the female's and is divided into three regions: the **prostatic urethra** (lined by transitional epithelium), a short **membranous urethra** that pierces the external urethral sphincter (lined by stratified or pseudostratified columnar epithelium), and a long **penile urethra** (lined by pseudostratified columnar epithelium).

PLATE 20.1 ■ KIDNEY I

The urinary system consists of the paired **kidneys**; the paired **ureters**, which lead from the kidneys to the **urinary bladder**; and the **urethra**, which leads from the bladder to the exterior of the body. The kidneys conserve body fluid and electrolytes and remove metabolic wastes, such as urea, uric acid, creatinine, and breakdown products of various substances. They produce **urine**, initially an ultrafiltrate of blood that is modified by selective resorption and specific secretion by kidney tubule cells. The kidneys also function as endocrine organs, producing **erythropoietin**, a growth factor that regulates red blood cell formation, and **renin**, a hormone involved in blood pressure and blood volume control. They also hydroxylate vitamin D, a steroid prohormone, to produce its active form.

Each kidney is a flattened, bean-shaped structure ~10 cm long, 6.5 cm wide (from convex to concave border), and 3 cm thick. The concave medial border of each kidney contains a hilum, an indented region through which blood vessels, nerves, and lymphatic vessels enter and leave the kidney. The funnel-shaped origin of the ureter, the **renal pelvis**, also leaves the kidney at the hilum. A cut, hemisected fresh kidney reveals two distinct regions: a **cortex**, the reddish brown outer region, and a **medulla**, a much lighter inner part continuous with the renal pelvis. The cortex is characterized by **renal corpuscles** and their tubules, including the convoluted and straight tubules of the **nephron**, the **cortical collecting ducts**, and an extensive vascular supply.

Kidney, human, fresh specimen $\times 3$.

A frontal section through the cortex and medulla of an unembalmed kidney obtained from autopsy is shown here. The visible **hilar region** consists of minor calyces (gray/white) surrounded by *yellow* in appearance adipose tissue. The outer part of the kidney has a *reddish brown* appearance; this is the **cortex**. It is easily distinguished from the inner portion, the medulla, which is further divided into an outer portion (*OM*), identified here by the presence of straight blood vessels, the vasa recta (*VR*), and an inner portion (*IM*), which has a lighter and more homogeneous appearance. The **medulla** consists of renal pyramids, which have their base facing the cortex and their apex in the form of a papilla (*P*) directed toward the hilum. The **pyramids** are separated, sometimes only partially, as in this figure, by cortical material that is designated the **renal columns** (*RCol*). The majority of the outer part of the pyramid on the *left* has not been included in the plane of section. The papillae are free tips of the pyramids that project into the first of a series of large urine-collecting spaces referred to as the **minor calyces** (*MC*); the inner surface of the calyx is white. The minor calyces drain into **major calyces**, and in turn, these open into the **renal pelvis**, which funnels urine into the ureter.

An interesting feature in this specimen is that the blood has been retained in many of the vessels, thereby allowing for visualization of several renal vessels in their geographic location. Among the vessels that can be identified in the cut face of the kidney shown here are the interlobular vessels (*IV*) within the cortex; the arcuate veins (*AV*) and the arcuate arteries (*AA*) at the base of the pyramids; the interlobar arteries (*ILA*) and veins (*ILV*) between renal pyramids; and, in the medulla, the vessels going to and from the capillary network of the pyramid. The latter vessels, both arterioles and venules, are relatively straight and are designated collectively as the vasa recta (*VR*). (Specimen courtesy of Dr. Eric A. Pfeifer.)

Cortex and medulla, kidney, human, hematoxylin and eosin (H&E) $\times 20$.

A histologic section including the **cortex** and part of the **medulla** is shown here. Located at the boundary between the two (partly marked by the *dashed line*) are numerous profiles of arcuate arteries (*AA*) and arcuate veins (*AV*). The most distinctive feature of the renal cortex, regardless of the plane of section, is the presence of the renal corpuscles (*RC*). These are spherical structures composed of a glomerulus (glomerular vascular tuft) surrounded by the visceral and parietal epithelium of the Bowman capsule. Also seen in the cortex are

groups of tubules that are more or less straight and disposed in a radial direction from the base of the medulla (*arrows*); these are the medullary rays. In contrast, the medulla presents profiles of tubular structures that are arranged as gentle curves in the outer part of the medulla, turning slightly to become straight in the inner part of the medulla. The disposition of the tubules (and blood vessels) gives the cut face of the pyramid a slightly striated appearance that is also evident in the gross specimen (see the previous figure).

PLATE 20.2 ■ KIDNEY II

The **nephron** is the functional unit of the kidney. There are about 2 million nephrons in each human kidney. They are responsible for the production of urine and correspond to the secretory part of other glands. The **collecting ducts**, responsible for the final concentration of the urine, are analogous to the ducts of exocrine glands. The nephron is made up of the **renal corpuscle** and the **renal tubule**. The renal corpuscle consists of the **glomerulus**, a tuft of 10-20 capillary loops, surrounded by a double-layered epithelial cup, the **renal or Bowman capsule**. The glomerular capillaries are supplied at the vascular pole of the Bowman capsule by an **afferent arteriole** and drained by an **efferent arteriole** that leaves the Bowman capsule at the vascular pole and then branches to form a new capillary network to supply the kidney tubules. The opposite pole of the Bowman capsule, the urinary pole, is where the filtrate leaves the renal capsule. The tubular parts of the nephron are the **proximal thick segment** (consisting of the **proximal convoluted tubule** and the **proximal straight tubule**); the **thin segment**, which constitutes the *thin* limb of the loop of Henle; and the **distal thick segment**, consisting of the **distal straight tubule** and the **distal convoluted tubule**. The loop of Henle is the U-shaped portion of the nephron consisting of the thick straight portions of the proximal and distal tubules and the thin segment between them. The distal convoluted tubule joins the **cortical collecting duct** via either the connecting tubule or arched connecting tubule. The nephron and the connecting tubule constitute the **uriniferous tubule**.

Cortex, kidney, human, hematoxylin and eosin (H&E)
×60.

The **renal cortex** can be divided into regions referred to as the **cortical labyrinth (CL)** and the **medullary rays (MR)**. The cortical labyrinth contains the **renal corpuscles (RC)**, which appear as relatively large spherical structures. Surrounding each renal corpuscle are the proximal and distal convoluted tubules. They are also part of the cortical labyrinth. The convoluted tubules, particularly the proximal, because of their tortuosity, present a variety of profiles, most of which are oval or circular; others, more elongated, are in the shape of a letter J, a C, or even an S. The medullary rays are composed of groups of straight tubules oriented in the same direction and appear to radiate from the base of the pyramid. When the medullary rays are cut longitudinally, as they are in this figure, the tubules present

elongated profiles. The medullary rays contain proximal straight tubules (thick segments; descending limb of loop of Henle), distal straight tubules (thick segments; ascending limbs of loop of Henle), and cortical collecting ducts.

Cortex, kidney, human, H&E $\times 120$.

This figure presents another profile of the **renal cortex**, at a somewhat higher magnification, cut in a plane at a right angle to the section in the previous figure. The peripheral part of the micrograph shows the **cortical labyrinth** in which the tubules display chiefly not only round and oval profiles but also some that are more elongated and curved. The appearance is the same as the cortical labyrinth areas of the previous figure. A **renal corpuscle** (*RC*) is also present in the cortical labyrinth. In contrast, the profiles presented by the tubules of the medullary ray in this figure are quite different from those seen in the previous figure. All of the tubules bounded by the *dashed line* belong to the medullary ray (*MR*), and all are cut in cross section. A general survey of the tubules within the medullary ray reveals that several distinct types can be recognized on the basis of the size of the tubule, shape of the lumen, and size of the tubule cells. These features as well as those of the cortical labyrinth are considered in Plate 20.3 (page 806).

CL, cortical labyrinth

MR, medullary ray

RC, renal corpuscle

dashed line, approximate boundary of the medullary ray

PLATE 20.3 ■ KIDNEY III

Proximal and distal convoluted tubules display features that aid in their identification in hematoxylin and eosin (H&E)-stained paraffin sections. Proximal convoluted tubules generally have a larger diameter than distal tubules have; cross sections of the lumen often appear stellate. A brush border (apical microvilli) is often visible on the proximal tubule cells. Also, the proximal convoluted tubule is more than twice as long as the distal convoluted tubule; thus, the majority of tubular profiles in the cortical labyrinth will be of proximal tubules.

Mesangial cells and their extracellular matrix constitute the mesangium of the renal corpuscle. They underlie the endothelium of the capillaries of the glomerular tuft and extend to the vascular pole, where they become part of the juxtaglomerular apparatus. The terminal portion of the distal thick segment of the nephron lies close to the afferent arteriole. Tubule epithelial cells closest to the arteriole are thinner, taller, and more closely packed than other tubule cells and constitute the *macula densa*. Arterial smooth muscle cells opposite the macula densa are modified into juxtaglomerular cells that secrete renin in response to decreased blood NaCl concentration.

Proximal and distal convoluted tubules, kidney, human, H&E $\times 240$.

In this figure, an area of cortical labyrinth, there are six distal convoluted tubule (DC) profiles. The proximal convoluted tubules (unlabeled) have a slightly larger outside diameter than the distal tubules have. The proximal tubules have a brush border, whereas the distal tubules have a cleaner, sharper luminal surface. The lumen of the proximal tubules is often star shaped; this is not the case with distal tubules. Typically, fewer nuclei appear in a cross section of a proximal tubule than in an equivalent segment of a distal tubule.

Most of the abovementioned points can also be utilized in distinguishing the straight portions of the proximal and distal thick segments in the medullary rays, as shown in the figure on the right.

Proximal and distal straight tubules, kidney, human, H&E $\times 240$.

In this figure, all of the tubular profiles within the medullary ray are rounded, except for a proximal convoluted tubule (PC) included in the lower right corner of the figure (it belongs to the adjacent cortical labyrinth). Second, the

number of proximal straight (*P*) and distal straight (*D*) tubular profiles are about equal in the medullary ray, as is shown by the labeling of each tubule in this figure. Note that, in contrast to the **distal straight tubules**, the **proximal straight tubules** display a brush border and have a larger outside diameter, with many displaying a star-shaped lumen. The medullary ray also contains **cortical collecting ducts** (*CCD*).

Renal corpuscles, kidney, human, H&E $\times 360$.

The **renal corpuscle** appears as a spherical structure whose periphery is composed of a thin capsule that encloses a narrow clear-appearing space, the **urinary space** (*asterisks*), and a capillary tuft or glomerulus that appears as a large cellular mass. The capsule of the renal corpuscle, known as the **renal** or **Bowman capsule**, actually has two parts: a parietal layer, which is marked (*BC*), and a visceral layer. The **parietal layer** consists of simple squamous epithelial cells. The **visceral layer** consists of cells called **podocytes** (*Pod*) that lie on the outer surface of the glomerular capillary. Except where they clearly line the urinary space, as the labeled cells do in the figure on the *left*, podocytes may be difficult to distinguish from the capillary endothelial cells. To complicate matters, the mesangial cells are also a component of the glomerulus. In general, nuclei of podocytes are larger and stain less intensely than do the endothelial and mesangial cell nuclei.

A distal (*DC*) and two proximal (*PC*) convoluted tubules are marked in the figure on the *left*. The cells of the distal tubule are more crowded on one side. These crowded cells constitute the **macula densa** (*MD*) that lies adjacent to the afferent arteriole.

In the figure on the *right*, both the vascular pole and the urinary pole of the renal corpuscle are evident. The **vascular pole** is characterized by the presence of arterioles (*A*), one of which is entering or leaving (*double-headed arrow*) the corpuscle. The afferent arteriole possesses modified smooth muscle cells with granules, the juxtaglomerular cells (not evident in this figure). At the **urinary pole**, the parietal layer of the Bowman capsule is continuous with the beginning of the proximal convoluted tubule (*PC*). Here, the urinary space of the renal corpuscle continues into the lumen of the proximal tubule, and the lining cells change from simple squamous to simple cuboidal or low columnar with a brush border.

PLATE 20.4 ■ KIDNEY IV

Renal corpuscles are restricted to the cortical labyrinth. The **medulla** contains the thick straight segments of proximal and distal tubules, along with their thin segments, the collecting ducts, and the blood vessels that run in parallel with them. These structures function as the *countercurrent multiplier* and *countercurrent exchange* systems that, ultimately, produce hypertonic urine. The final urine drains from the papillary ducts (of Bellini) into calyces that then empty into the renal pelvis.

Medulla, kidney, human, hematoxylin and eosin (H&E)
×240.

A section through the **outer portion of the medulla** is shown in this figure. This region contains proximal and distal thick segments, thin segments, and medullary collecting ducts. All of the tubules are parallel, and all are cut in cross section; thus, they present circular profiles. The **proximal straight tubules** (*P*) display typical star-shaped lumina and a brush border (or the fragmented apical cell surface from which the brush border has been partially broken). These tubules have outside diameters that are generally larger than those of the **distal straight tubules** (*D*). As mentioned previously and as shown here, the distal straight tubules display a larger number of nuclei than do comparable segments of proximal straight tubule cells. Note, also, that the lumen of the distal tubule is more rounded and the apical surface of the cells is sharper. The **collecting ducts** (*CD*) have outer diameters that are about the same as those of the proximal tubules and larger than those of distal tubules. The cells forming the collecting ducts are cuboidal and smaller than those of proximal tubules; thus, they also display a relatively larger number of nuclei than do comparable segments of proximal tubule cells. Count them. Finally, boundaries between the cells that constitute the collecting ducts are usually evident (*asterisks*); this serves as one of the most dependable features for the identification of collecting ducts.

The thin segments (*T*) have the thinnest walls of all renal tubules seen in the medulla. They are formed by a low cuboidal or simple squamous epithelium, as seen here, and the lumina are relatively large. Occasionally, a section includes the region of transition from a thick to a thin segment and can be recognized even in a cross section through the tubule. One such junction is evident in this figure (the tubule with *two arrows* in the lumen). On one side, the tubule cell (*left-pointing arrow*) is characteristic of the proximal segment; it possesses a

distinctive brush border. The other side of the tubule (*right-pointing arrow*) is composed of low cuboidal cells that resemble the cells forming the thin segments. In addition to the uriniferous tubules and collecting ducts, there are many other small tubular structures in this figure. Thin walled and lined by endothelium, they are small blood vessels.

Renal pyramid, kidney, human, H&E $\times 20$.

This figure shows a **renal pyramid** at low magnification. The pyramid is a conical structure composed principally of medullary straight tubules, ducts, and the straight blood vessels (*vasa recta*). The *dashed line* at the *left* of the micrograph is placed at the junction between cortex and medulla; thus, it marks the base of the pyramid. Note the **arcuate vessels** (*AV*) that lie at the boundary of cortex and medulla. They define the boundary line. The few renal corpuscles (*RC*), *upper left*, belong to the renal column of the medulla. They are referred to as *juxtamedullary corpuscles*.

The pyramid is somewhat distorted in this specimen, as evidenced by regions of longitudinally sectioned tubules, *lower left*, and cross-sectioned and obliquely sectioned tubules in other regions. In effect, part of the pyramid was bent, thus the change in the plane of section of the tubules.

The apical portion of the pyramid (*arrowhead*), known as the **renal papilla**, is lodged in a cup- or funnel-like structure referred to as the *calyx*. It collects the urine that leaves the tip of the papilla from the papillary ducts (of Bellini). (The actual tip of the papilla is not seen within the plane of section, nor are the openings of the ducts at this low magnification.) The surface of the papilla that faces the lumen of the **minor calyx** is simple columnar or cuboidal epithelium (*SCEp*). (In places, this epithelium has separated from the surface of the papilla and appears as a thin strand of tissue.) The calyx is lined by transitional epithelium (*TEp*). Although not evident at the low magnification shown here, the boundary between the columnar epithelium covering the papilla and the transitional epithelium covering the inner surface of the calyx is marked by the *diamonds*.

AV, arcuate vessels

PLATE 20.5 ■ URETER

The **ureters** are paired tubular structures that convey urine from the kidneys to the urinary bladder. They are lined with **transitional epithelium (urothelium)**, an impervious layer that lines the urinary excretory passages from the renal calyces through the urethra. The ability of this epithelium to become thinner and flatter allows all of these passages to accommodate to distension by the urine.

The epithelium rests on a dense collagenous lamina propria, which, in turn, rests on an inner longitudinal and an outer circular layer of smooth muscle. Regular peristaltic contractions of this muscle contribute to the flow of urine from the kidney to the urinary bladder.

ORIENTATION MICROGRAPH: As shown in this low-power orientation micrograph, the wall of the ureter consists of a **mucosa** (*Muc*), a **muscularis** (*Mus*), and an **adventitia** (*Adv*). Note that the ureters are located behind the peritoneum of the abdominal cavity in their course to the bladder. Thus, a **serosa** (*Ser*) may be found covering a portion of the circumference of the tube. Also, because of contraction of the smooth muscle of the muscularis, the luminal surface is characteristically folded, thus creating a star-shaped lumen.

Ureter, monkey, hematoxylin and eosin (H&E) $\times 160$.

The wall of the ureter from the *rectangular area* in the orientation micrograph is examined at higher magnification in this figure. One can immediately recognize the thick epithelial lining, which appears distinct and sharply delineated from the remainder of the wall. This is the **transitional epithelium (urothelium) (Ep)**. The remainder of the wall is made up of connective tissue (CT) and smooth muscle. The latter can be recognized as the darker staining layer. The section also shows some adipose tissue (AT), a component of the adventitia.

The transitional epithelium and its supporting connective tissue constitute the **mucosa (Muc)**. A distinct submucosa is not present, although the term is sometimes applied to the connective tissue that is closest to the muscle.

The **muscularis (Mus)** is arranged as an inner longitudinal layer (SM[l]), a middle circular layer (SM[c]), and an outer longitudinal layer (SM[l]). However, the outer longitudinal layer is present only at the lower end of the ureter. In a cross section through the ureter, the inner and outer smooth muscle layers are cut in cross section, whereas the middle circular layer of the muscle cells is cut longitudinally. This is as they appear in this figure.

Transitional epithelium, ureter, monkey, H&E ×400.

This figure shows the **inner longitudinal smooth muscle layer (SM[l])** at higher magnification. Note that the nuclei appear as round profiles, indicating that the muscle cells have been cross-sectioned. This figure also shows the **transitional epithelium (Ep)** to advantage. The surface cells of the transitional epithelium (urothelium) are characteristically the largest, and some are binucleate (*arrow*). The basal cells are the smallest, and typically, the nuclei appear crowded because of the minimal cytoplasm of each cell. The intermediate cells appear to consist of several layers and are composed of cells larger in size than the basal cells but smaller than the surface cells.

PLATE 20.6 ■ URINARY BLADDER

The urinary bladder receives the urine from the two ureters and stores it until neural stimulation causes it to contract and expel the urine via the urethra. It, too, is lined with **transitional epithelium (urothelium)**. Beneath the epithelium and its underlying connective tissue, the wall of the urinary bladder contains **smooth muscle** that is usually described as being arranged as an inner longitudinal layer, a middle circular layer, and an outer longitudinal layer. As in most distensible hollow viscera that empty their contents through a narrow aperture, the smooth muscle in the wall of the urinary bladder is less regularly arranged than the description indicates, allowing contraction to reduce the volume relatively evenly throughout the bladder.

ORIENTATION MICROGRAPH: This orientation micrograph of the urinary bladder reveals the full thickness of the bladder wall. The luminal surface epithelium is at the *top* of the micrograph. One of the ureters can be seen as it passes through the bladder wall to empty its contents into the bladder lumen. Most of the tissue to the sides and below the ureteral profile is smooth muscle.

Urinary bladder, human, hematoxylin and eosin (H&E) $\times 60$.

This micrograph shows most of the entire thickness of the urinary bladder. An unusual feature is the presence of one of the ureters (*U*) as it is passing through the bladder wall to empty its contents into the bladder lumen. The **transitional epithelium** (*Ep*) lining the bladder is seen on the *right*. Beneath the epithelium is a relatively thick layer of connective tissue (*CT*) containing blood vessels (*BV*) of various sizes. Note that the connective tissue stains more eosinophilic than the smooth muscle of the underlying

muscularis (*M*). The epithelium and connective tissue constitute the mucosa of the bladder. The muscularis consists of smooth muscle arranged in three indistinct layers. It should be noted that as the ureter passes through the bladder wall, it carries with it a layer of longitudinally oriented smooth muscle (*SM[L]*). Medium-sized arteries (*A*) and veins (*V*) are occasionally seen in the muscularis.

**Transitional epithelium, urinary bladder,
human, H&E $\times 250$.**

This higher magnification of the *left rectangle* of the previous figure shows the **transitional epithelium** (*Ep*) and the underlying connective tissue (*CT*) that represent the mucosa of the ureter. Adjacent to the mucosa are bundles of longitudinally sectioned smooth muscle (*SM[L]*) that belong to the ureter. A small lymphatic vessel (*Lym*) is present in the connective tissue adjacent to the smooth muscle. Note the lymphocytes, identified by their small round densely stained nuclei, within the lumen of the vessel.

**Transitional epithelium, urinary bladder,
human, H&E $\times 250$.**

This higher magnification of the *right rectangle* of the previous figure shows the bladder **transitional epithelium** (*Ep*) and the underlying connective tissue (*CT*) of the bladder wall. The transitional epithelium is often characterized by the presence of surface cells that are dome shaped. In addition, many of these cells are binucleate (*arrows*). The thickness of transitional epithelium is variable. When the bladder is fully distended, as few as three cell layers are seen. Here, in the contracted bladder, it appears that there are as many as 10 cell layers, a result of the cells folding over one another as the smooth muscle contracts and the lining surface is reduced. The connective tissue consists of bundles of collagen fibers interspersed with varying numbers of lymphocytes identified by their densely stained round nuclei. A vein (*V*) filled with red blood cells is also evident in the mucosal connective tissue.

HISTOLOGY

■ OVERVIEW OF THE ENDOCRINE SYSTEM

The **endocrine system** produces various secretions called **hormones** [*Gr. hormaein, to excite, to set in motion*] that serve as effectors to regulate the activities of various cells, tissues, and organs in the body. Its functions are essential in maintaining homeostasis and coordinating body growth and development and are similar to that of the **nervous system**: Both communicate information to peripheral cells and organs. Communication in the nervous system is through transmission of neural impulses along nerve cell processes and the discharge of neurotransmitter. Communication in the endocrine system is through hormones, which are carried to their destination via connective tissue

spaces and the vascular system. These two systems are functionally interrelated. The endocrine system produces a slower and more prolonged response than the nervous system. Both systems may act simultaneously on the same target cells and tissues, and some nerve cells secrete hormones.

Endocrine glands possess no excretory ducts, and their secretions are carried to specific destinations via the extracellular matrix of connective tissue and the vascular system.

In general, **endocrine glands** are aggregates of **epithelioid cells** (epithelial cells that lack a free surface) that are embedded within connective tissue. Despite the fact that the endocrine glands vary in size, shape, and location in the body (Fig. 21.1), they still have several common characteristics. Endocrine glands do not possess excretory ducts; therefore, their secretion is discharged into the extracellular matrix of connective tissue, usually near the capillaries. From here, the secretory products (i.e., hormones) are transported into the lumen of the blood (or lymphatic) vessels for body-wide distribution. These secretory products influence target organs or tissues at some distance from the gland. For this reason, endocrine glands are well vascularized and surrounded by rich vascular networks. The exception is the placenta, where hormones produced by the syncytiotrophoblast pass directly into the maternal blood surrounding the placental villi (see Chapter 23, Female Reproductive System, page 937).

FIGURE 21.1. Location of the major endocrine glands and organs containing hormone-secreting cells. This drawing shows the major endocrine glands in which the hormone-secreting cells constitute the majority of the gland parenchyma. Note that the placenta is a temporary organ developed from maternal and fetal tissues and is also a major endocrine organ that secretes steroid and protein hormones during pregnancy (see Chapter 23, Female Reproductive System, pages 933-938). Hormone-secreting cells, commonly

classified as part of the diffuse neuroendocrine system (DNES), are present in many organs to regulate their activity. In addition, adipose tissue is an important hormonally active tissue that secretes a variety of hormones, growth factors, and cytokines, collectively called *adipokines* (see Chapter 9, Adipose Tissue, page 280).

As mentioned earlier, the majority of hormone-producing cells have an **epithelial origin**, either from the **central nervous system (CNS)** (i.e., posterior lobe of pituitary gland, pineal gland), **neural crest** (i.e., medulla of suprarenal gland), or from epithelial lining of the developing **gut tube** (i.e., anterior lobe of pituitary gland, thyroid and parathyroid glands). Only a few endocrine glands/cells have a mesenchymal origin and are derived from the **urogenital ridges** (i.e., cortex of the adrenal gland, Leydig cells in the testis, and steroid-secreting cells of developing follicles in the ovary).

This chapter primarily describes the major **endocrine glands** in which the hormone-secreting cells constitute the majority of the gland parenchyma. Secretory cells in the gland parenchyma form various arrangements, such as follicles (thyroid gland), anastomosing cords (adrenal glands), or nests (parathyroid glands). They are also present in clusters (nuclei in the hypothalamus) or layers surrounding the functional and structural elements of the organ (testis, ovaries, or placenta). These characteristics are useful in the microscopic identification of specific endocrine organs.

Individual hormone-secreting cells are present in many organs to regulate their activity.

The collection of **individual endocrine cells** in various organs constitutes the **diffuse neuroendocrine system** (DNES; see page 644). In addition to their endocrine function, cells of the DNES system exercise autocrine and paracrine control of the activity of their own and adjacent epithelial cells by diffusion of peptide secretions. Other chapters discuss the endocrine function of adipose tissue and individual cells within the liver, pancreas, kidney, and the gastrointestinal, cardiovascular, respiratory, reproductive, lymphatic, and integumentary systems (see Fig. 21.1).

Hormones and Their Receptors

In general, a hormone is described as a biological substance acting on specific target cells.

In the classic definition, a **hormone** is a secretory product of endocrine cells and organs that passes into the circulatory system (bloodstream) for transport to target cells. For many years, this

endocrine control of target tissues became a central part of endocrinology. However, a variety of hormones and hormonally active substances are not always discharged into the bloodstream but are released into connective tissue spaces. They may act on adjacent cells or diffuse to nearby target cells that express specific receptors for that particular hormone (Fig. 21.2). This type of hormonal action is referred to as **paracrine control**. In addition, some cells express receptors for hormones that they secrete. This type of hormonal action is referred to as **autocrine control**. These hormones regulate the cell's own activity. Figure 21.2 summarizes various hormonal control mechanisms.

FIGURE 21.2. Hormonal control mechanisms. This schematic diagram shows three basic types of control mechanisms. **a.** In endocrine control, the hormone is discharged from a cell into the bloodstream and is transported to the effector cells. **b.** In paracrine control, the hormone is secreted from one cell and acts on adjacent cells that express specific receptors. **c.** In autocrine control, the hormone responds to the receptors located on the cell that produces it.

New research characterizes exosomes as important components of the endocrine system that provide endocrine, paracrine, and autocrine signals to target cells in the body.

Research over the past decade indicates that in addition to the nervous and endocrine systems, a third system of intercellular or interorgan communication exists that involves **exosomes**. As discussed in Chapter 2, Cell Cytoplasm (pages 47–48), exosomes are small, membrane-bound **cargo vesicles** secreted into the extracellular space by virtually every cell in the body. They are released and detected in all bodily fluids,

including blood, lymph, cerebrospinal fluid, vitreous body, interstitial fluids, saliva, breast milk, amniotic fluid, semen, and urine. Most secreted exosomes are disseminated via blood circulation and travel to specific targets in the body. They transfer **messages** and **cargo molecules** from the original (parent) cells to the target destination. The exosomes and their cargo molecules either fuse directly with the plasma membrane of target cells, become endocytosed, or engage in receptor-ligand-mediated interactions (Fig. 21.3). Exosomes can carry a variety of molecules that include **growth factors; lipids; proteins; several forms of DNA molecules**, such as viral DNA (vDNA), mitochondrial DNA (mtDNA), and fragments of double-stranded DNA (dsDNA) or single-stranded DNA (ssDNA); and **several types of RNA molecules**, such as messenger RNA (mRNA), transfer RNA (tRNA), small nuclear RNA (snRNA), small nucleolar RNA (snoRNA), mitochondrial RNA (mtRNA), microRNA (miRNA), viral microRNA (vmiRNA), circular RNA (CircRNA), small noncoding RNA (Y-RNA), toxic small RNA (tsRNA), Piwi-interacting RNA (piRNA), and others. For details on exosomal contents, see Figure 2.21 (page 47).

FIGURE 21.3. Exosomal intercellular signaling. This drawing summarizes exosomal signaling, an intercellular communication pathway in which proteins, metabolites, and nucleic acids are delivered to recipient cells using exosomes as transfer vehicles. Exosomes are very small, membrane-bound cargo vesicles derived from multivesicular bodies (MVB) and secreted into the extracellular space. Most exosomes use the blood circulation to reach specific target cells in the body. Exosomes transfer messages in the form of cargo molecules, membrane-associated proteins, and nucleic acids from donor cells to the target destination. Exosomes and their cargo molecules either fuse directly with the plasma membrane of target cells, become endocytosed, or engage in receptor-ligand-mediated interactions. Exosomes then release their contents directly into the cytoplasm of the recipient cell, initiating downstream signaling

cascades. Note specific transmembrane proteins (tetraspanins) that serve as exosomal biomarkers.

In disease states, exosomes also carry viruses such as SARS-CoV-2 (COVID-19) and HIV-1 (AIDS). Their cargo can be transmitted from cell to cell (often in distant locations) to alter cells' metabolism, influence immune cell responses, promote differentiation, and facilitate disease development (e.g., viral diseases and cancer). For example, the actin-binding protein gelsolin (pGSN) transported in exosomes promotes ovarian cancer cell survival through autocrine and paracrine mechanisms that transform chemosensitive cancer cells into resistant forms. Thus, exosomal pGSN is a determinant of chemoresistance in ovarian cancer.

Hormones include three classes of compounds.

Cells of the endocrine system release more than 100 hormones and hormonally active substances that are chemically divided into three classes of compounds:

- **Peptides** (small peptides, polypeptides, and proteins) form the largest group of hormones. They are synthesized and secreted by cells of the hypothalamus, pituitary gland, thyroid gland, parathyroid gland, pancreas, and scattered enteroendocrine cells of the gastrointestinal tract and respiratory system. This group of hormones (insulin, glucagon, growth hormone [GH], adrenocorticotrophic hormone [ACTH], follicle-stimulating hormone [FSH], luteinizing hormone [LH], antidiuretic hormone [ADH], oxytocin, interleukins, and various growth factors), when released into the circulation, dissolve readily in the blood and generally do not require special transport proteins. However, most, if not all, polypeptides and proteins have specific carrier proteins (e.g., insulin-like growth factor-binding protein [IGFBP]).
- **Steroids**, cholesterol-derived compounds, are synthesized and secreted by cells of the ovaries, testes, and adrenal cortex. These hormones (gonadal and adrenocortical steroids) are released into the bloodstream and transported to target cells with the help of plasma proteins or specialized carrier proteins, such as androgen-binding protein. Hormone-binding carrier proteins protect the hormone from degradation during transport to the target tissue. When needed, the hormone is released from the carrier protein to become active.
- **Amino acids** and **arachidonic acid analogs** and their derivatives, including the catecholamines (norepinephrine and epinephrine-phenylalanine/tyrosine derivatives) and prostaglandins, prostacyclins, and leukotrienes (arachidonic acid derivatives), are

synthesized and secreted by many neurons as well as a variety of cells, including cells of the adrenal medulla. Also included in this group of compounds are **thyroid hormones**, the iodinated derivatives of the amino acid tyrosine that are synthesized and secreted by the thyroid gland. When released into the circulation, catecholamines dissolve readily in the blood, in contrast to thyroid hormones, the majority of which are bound to three carrier proteins: a specialized **thyroxine-binding globulin (TBG)**, prealbumin fraction of serum proteins (**transthyretin**), and a nonspecific fraction of albumins.

Hormones interact with specific hormone receptors to alter biological activity of the target cells.

The first step in hormone action on a target cell is its binding to a **specific hormone receptor**. However, recent studies suggest that some hormones are involved in non-receptor-mediated responses. Hormones interact with their receptors exposed on the surface of the target cell or within its cytoplasm or nucleus. In general, two groups of hormone receptors have been identified:

- **Cell surface receptors** interact with peptide hormones or catecholamines that are unable to penetrate the cell membrane. Activation of these receptors as a result of hormone binding rapidly generates large quantities of small intracellular molecules called **second messengers** (Fig. 21.4a). These molecules amplify the signal initiated by hormone-receptor interaction and are produced by activation of membrane-associated **G-proteins** (named for the ability to hydrolyze guanosine triphosphate [GTP]). Examples of such systems include the **adenylate cyclase/cyclic adenosine monophosphate (cAMP) system** (for most protein hormones and catecholamines), the **guanylyl cyclase/cyclic guanosine monophosphate (cGMP) system** (an antagonistic system for action of cAMP in some protein hormones), the **tyrosine kinase system** (for insulin and epidermal growth factor [EGF]), the **phosphatidylinositol system** (for certain hormones such as oxytocin, gonadotropin-releasing hormone [GnRH], angiotensin II, and neurotransmitters such as epinephrine), and **activation of ion channels** (as with most neurotransmitters). The majority of second messenger molecules exert a stimulatory function on cell metabolism. Examples of second messenger molecules include **cAMP**, **1,2-diacylglycerol (DAG)**, **inositol 1,4,5-triphosphate (IP₃)**, and **Ca²⁺**. An inhibitory response is mainly achieved by **cGMP**, which interferes with the production of cAMP. The second messenger molecules produced in the cascade reactions of these systems alter the cell's metabolism and produce hormone-specific responses (see Fig. 21.4a).

FIGURE 21.4. General mechanisms of protein and steroid hormone actions. **a.** This schematic diagram shows the basis for protein hormone action involving cell surface receptors. Hormone molecules bind to the cell surface receptors (*orange glow* indicates activated receptor) and initiate a cascade of intracellular signaling reactions that may include G-protein and various protein kinases resulting in the synthesis of second messenger molecules. These molecules, in turn, elicit hormone-specific responses in the stimulated cell that may influence channel proteins, nuclear transcription, and protein synthesis or degradation. **b.** This diagram shows two mechanisms of action for steroid hormones, which include nuclear-initiated steroid signaling (involves intracellular receptors) and membrane-initiated steroid signaling. In the nuclear-initiated steroid signaling (*green arrows*), some steroid hormones (e.g., glucocorticoids, androgens) cross the plasma membrane and bind to specific cytoplasmic receptors. This binding of the hormone causes allosteric transformation of the receptor, and the resulting complex travels to the nucleus guided by the nuclear localization signal (*NLS*), where it binds to DNA and regulates the transcription of specific genes (*orange glow*). Other steroid hormones (e.g., estrogens, progestogens) bind to their specific receptors directly in the nucleus (*blue arrows*). This binding of hormone to the nuclear receptor transforms this complex into the DNA transcription factor (*orange glow*) and leads to mRNA transcription and the subsequent production of new proteins responsible for hormone-specific responses of the stimulated cell. In membrane-initiated steroid signaling (*red arrows*), the steroid receptors are expressed on the cell membrane, usually in the caveolae, and their pathway is similar to that of the cell surface receptor signaling mechanism.

- **Intracellular receptors**, which are localized within the cell, are used by **steroid hormones**, **thyroid hormones**, and **vitamins A and D** (Fig. 21.4b). Steroid hormones and vitamins A and D can easily penetrate both plasma and nuclear membranes. In the absence of hormone, steroid receptors for glucocorticoids and gonadocorticoids (adrenal androgens) reside in the cytoplasm, whereas estrogen and

progesterone receptors are located in the nucleus. Unoccupied inactive receptors for thyroid hormones and vitamins A and D also reside in the nucleus. Intracellular receptors consist of large multiprotein complexes containing three binding domains: a hormone- or ligand-binding region at the COOH-terminus, a DNA-binding region, and the NH₂-terminus containing the gene regulatory region. Because the receptor-ligand complex must enter the nucleus to regulate transcription, intracellular receptors contain a nuclear localization signal (NLS) for trafficking into the nucleus (see Fig. 21.4b). Binding of the hormone to the receptor causes the allosteric transformation of the receptor into a form that binds to the chromosomal DNA and activates **RNA polymerase activity**. This, in turn, increases transcription of mRNA, resulting in the production of new proteins that regulate cell metabolism. Therefore, hormones acting on the intracellular receptors influence gene expression directly, without the help of a second messenger (see Fig. 21.4b). This type of signaling is often described as **nuclear-initiated steroid signaling**.

Action of steroid hormones on the cell's genome to induce a biological response in the form of new protein synthesis takes time (hours or days). However, some cells react more rapidly (in seconds or minutes) to steroid hormone stimulation by increasing intracellular Ca⁺ concentration and activating several intracellular proteins. This finding led to the discovery of **steroid membrane receptors**, which have a similar structure to intracellular receptors but are localized on the plasma membrane most often within the caveolae. Binding to steroid membrane receptors activates the signaling cascade of G-protein, which, in turn, activates protein kinases, causing a rapid change in cell activity (see Fig. 21.4b). This type of signaling is known as **membrane-initiated steroid signaling**. Both nuclear- and membrane-initiated steroid signaling pathways converge to provide a full biological response of the target cell to the steroid hormone stimulation.

Regulation of Hormone Secretion and Feedback Mechanism

Regulation of hormonal function is controlled by feedback mechanisms.

Hormonal production is often controlled through **feedback mechanisms** from the target organ. In general, feedback occurs when the response to a stimulus (action of a hormone) has an effect on the original stimulus (hormone-secreting cell). The nature of this response determines the type of feedback. Two types of feedback are recognized: **Negative feedback** occurs when the response diminishes the original stimulus and

is much more common than **positive feedback**, which occurs when the response enhances the original stimulus.

To better understand the function of feedback mechanisms, one can point to an air conditioning system, which also uses a simple negative feedback system. When the compressor produces enough cold air to lower the temperature below the set point of the thermostat, the thermostat is triggered and shuts off the compressor. In this negative feedback system, the lower temperature is then fed back to the compressor and diminishes its response (it shuts off its production of cold air). When the temperature rises back above the set point, the negative feedback is abolished and the compressor comes back on (for more information on negative feedback, see Folder 21.1).

FOLDER 21.1

FUNCTIONAL CONSIDERATIONS: REGULATION OF PITUITARY GLAND SECRETION

The release of hormones from the anterior lobe of the pituitary gland is carefully regulated by three tiers of control mechanisms that include the following:

- **Tier I: Hypothalamic secretion of hypothalamic-regulating hormones.** The pituitary gland is under significant control by the hypothalamus, which regulates the release of hypothalamic-regulating hormones into the hypophyseal portal veins. The hypothalamic-regulating hormones are produced by the cells of the hypothalamus in response to circulating levels of systemic hormones and impulses from the central nervous system (CNS). These hormones act directly on the highly specific G-protein-linked receptors on the plasma membranes of cells residing in the anterior lobe of the pituitary gland. Activation of receptors elicits positive or negative signals that affect gene transcription and lead to stimulation or inhibition of pituitary hormone secretion. Most of the tropic hormones produced by the anterior lobe of the pituitary gland are regulated by polypeptide-releasing hormones, with the notable exception of dopamine. Prolactin (PRL) production is primarily regulated by the inhibitory effect of dopamine (i.e., PRL secretion is tonically inhibited by the release of dopamine from the hypothalamus).
- **Tier II: Paracrine and autocrine secretions of the pituitary cells.** Release of hormones from the pituitary gland is also regulated by soluble growth factors and cytokines produced by the cells residing in the pituitary gland.
- **Tier III: Feedback effect of circulating hormones.** The level of hormones in the systemic circulation regulates the secretion of cells in the anterior lobe of the pituitary gland. This is primarily achieved by negative feedback regulation of hormones secreted by the pituitary gland by target hormones. For instance, secretion of thyroid-stimulating hormone (TSH) is inhibited by thyroid hormones produced in the thyroid gland under TSH influence.

To better understand the mechanism of negative regulation, consider a simple **negative feedback system** that controls the synthesis and discharge of T_3 and T_4 thyroid hormones (see Fig. 21.18). The secretion of thyroid

hormones is controlled by the release of TSH from the anterior lobe of the pituitary gland into the bloodstream. If blood levels of T_3 and T_4 are high, TRH is not produced or released. If blood levels of T_3 and T_4 are low, the hypothalamus discharges TRH into the hypothalamohypophyseal portal system. Release of TRH stimulates specific cells within the anterior lobe of the pituitary gland to produce TSH, which, in turn, stimulates the thyroid to produce and release more thyroid hormones. As the thyroid hormone levels rise, the negative feedback system stops the hypothalamus from discharging thyrotropin-releasing hormone (TRH). Using the same mechanism of negative feedback regulation, thyroid hormones also act on the thyrotropes in the anterior lobe of the pituitary gland to inhibit their secretion of TSH.

Activities of hormones are constantly monitored on many levels, beginning with molecular biosynthetic processes to the final end points of hormonal action. Several examples of feedback mechanisms are discussed in the sections on the pituitary, hypothalamus, and thyroid glands.

■ PITUITARY GLAND (HYPOPHYSIS)

The **pituitary gland** and the **hypothalamus**, the portion of the brain to which the pituitary gland is attached, are morphologically and functionally linked in the endocrine and neuroendocrine control of other endocrine glands. Because they play central roles in a number of regulatory feedback systems, they are often called the *master organs* of the endocrine system. In the past, the control of pituitary hormone secretion by the hypothalamus was classically regarded as the major function of the **neuroendocrine system**. However, the field of neuroendocrinology today has expanded to encompass multiple reciprocal interactions between the CNS, autonomic nervous system (ANS), endocrine system, and immune system in the regulation of homeostasis and behavioral responses to environmental stimuli. For example, the neuroendocrine axis's role in maintaining energy homeostasis is discussed in Chapter 9, Adipose Tissue (pages 283–285).

Gross Structure and Development

The pituitary gland is composed of glandular epithelial tissue and neural (secretory) tissue.

The **pituitary gland** [*Lat. pituta, phlegm—reflecting its nasopharyngeal origin*] is a pea-sized, compound endocrine gland that weighs 0.5 g in males and 1.5 g in multiparous women (i.e., a woman who has given birth ≥ 2 times). It is centrally located at the base of the brain, where it lies in a saddle-shaped depression of the sphenoid bone called the

sella turcica. A short stalk, the **infundibulum**, and a vascular network connect the pituitary gland to the hypothalamus.

The pituitary gland has two functional components (Fig. 21.5):

FIGURE 21.5. Pituitary gland. **a.** Photomicrograph of a pituitary gland. Lobes of the pituitary gland can be identified on the basis of their appearance, location, and relation to each other. $\times 7$. **b.** This drawing shows parts of the pituitary gland and related regions of the hypothalamus. The anterior lobe of the pituitary gland consists of the pars distalis, pars tuberalis, and pars intermedia; the posterior lobe consists of the infundibulum and pars nervosa. Note the distribution of the neurosecretory nuclei in the hypothalamus. The paraventricular nuclei produce oxytocin, and the supraoptic nuclei produce antidiuretic hormone (*ADH*). These hormones are released in the pars nervosa of the posterior lobe. Neurosecretory cells in the ventral nuclei of the hypothalamus secrete releasing and inhibitory hormones that are discharged into capillaries (located in the median eminence and infundibulum) of the hypophyseal portal system to reach pars distalis of the anterior lobe.

- **Anterior lobe (adenohypophysis)**, the glandular epithelial tissue
- **Posterior lobe (neurohypophysis)**, the neural secretory tissue

These two portions are of different embryologic origin. The anterior lobe of the pituitary gland is derived from an evagination of the **ectoderm of the oropharynx** toward the brain (**Rathke pouch**). The posterior lobe of the pituitary gland is derived from a downgrowth (the future infundibulum) of **neuroectoderm of the floor of the third ventricle** (the diencephalon) of the developing brain (Fig. 21.6).

FIGURE 21.6. Development of the pituitary gland. **a.** The pituitary gland develops from two different structures: an ectodermal diverticulum of the roof of the oropharynx (Rathke pouch) and a downward extension of the neuroectoderm at the floor of diencephalon. This drawing shows the relationship between these two structures in a 6-week-old embryo. **b.** The pituitary gland at 10 weeks of development shows ectodermal tissue from the oropharynx in close proximity to neural tissue. The Rathke pouch is about to lose connection with the oropharynx. **c.** Cells from the Rathke pouch divide and differentiate rapidly into the pars distalis and encircle the infundibulum, which with pars nervosa forms the neuroectodermally derived posterior lobe of the pituitary gland.

The **anterior lobe of the pituitary gland** consists of three derivatives of the Rathke pouch:

- **Pars distalis**, which comprises the bulk of the anterior lobe of the pituitary gland and arises from the thickened anterior wall of the pouch
- **Pars intermedia**, a thin remnant of the posterior wall of the pouch that abuts the pars distalis
- **Pars tuberalis**, which develops from the thickened lateral walls of the pouch and forms a collar or sheath around the infundibulum

The embryonic infundibulum gives rise to the posterior lobe of the pituitary gland. The **posterior lobe of the pituitary gland** consists of the following:

- **Pars nervosa**, which contains neurosecretory axons and their endings
- **Infundibulum**, which is continuous with the **median eminence** and contains the neurosecretory axons forming the **hypothalamohypophyseal tracts** (see Fig. 21.5)

Blood Supply

Knowledge of the unusual blood supply of the pituitary gland is important to understanding its functions. The pituitary blood supply is

derived from two sets of vessels (Fig. 21.7):

FIGURE 21.7. Diagram of the blood supply and hypothalamohypophyseal portal system of the pituitary gland. The superior and inferior hypophyseal arteries originate from branches of the internal carotid arteries. The superior hypophyseal artery supplies the pars tuberalis, median eminence, and infundibulum of the hypothalamus, where it gives rise to a capillary network that drains into the hypophyseal portal veins. These veins give rise to a second capillary network in the pars distalis, where the neuroendocrine secretions produced in the hypothalamus and collected in the median eminence and infundibulum are released. The inferior hypophyseal artery provides the blood supply to the pars nervosa and has very few (if any) connections with the hypothalamohypophyseal portal system. The blood from the pituitary gland drains into the cavernous sinus and leaves the cranial cavity via the internal jugular veins.

- **Superior hypophyseal arteries** supply the pars tuberalis, median eminence, and infundibulum. These vessels arise from the internal carotid arteries and posterior communicating artery of the circle of Willis.

- **Inferior hypophyseal arteries** primarily supply the pars nervosa. These vessels arise solely from the internal carotid arteries. An important functional observation is that most of the anterior lobe of the pituitary gland has no direct arterial supply.

The hypothalamohypophyseal portal system provides the crucial link between the hypothalamus and the pituitary gland.

The arteries that supply the pars tuberalis, median eminence, and infundibulum give rise to fenestrated capillaries (the primary capillary plexus). These capillaries drain into portal veins, called the **hypophyseal portal veins**, which run along the pars tuberalis and give rise to a second fenestrated sinusoidal capillary network (the secondary capillary plexus). This system of vessels carries the neuroendocrine secretions of hypothalamic neurons from their sites of release in the median eminence and infundibulum directly to the cells of the pars distalis.

Most of the blood from the pituitary gland drains into the cavernous sinus at the base of the diencephalon and then into the systemic circulation. Some evidence suggests, however, that blood can flow via short portal veins from the pars distalis to the pars nervosa and that blood from the pars nervosa may flow toward the hypothalamus. These short pathways provide a route by which the hormones of the anterior lobe of the pituitary gland could provide feedback directly to the brain without making the full circuit of the systemic circulation.

Nerve Supply

The nerves that enter the infundibulum and pars nervosa from the hypothalamic nuclei are components of the posterior lobe of the pituitary gland (see the section that follows on the posterior lobe). The nerves that enter the anterior lobe of the pituitary gland are postsynaptic fibers of the ANS and have vasomotor function.

Anterior Lobe of the Pituitary Gland (Adenohypophysis)

The anterior lobe of the pituitary gland regulates other endocrine glands and some nonendocrine tissues.

Most of the **anterior lobe of the pituitary gland** has the typical organization of endocrine tissue. The cells are organized in clumps and cords separated by fenestrated sinusoidal capillaries of relatively large diameter. These cells respond to signals from the hypothalamus

and synthesize and secrete a number of pituitary hormones. Four hormones of the anterior lobe—**adrenocorticotrophic hormone (ACTH)**, **thyroid-stimulating (thyrotropic) hormone (TSH; thyrotropin)**, **follicle-stimulating hormone (FSH)**, and **luteinizing hormone (LH)**—are called **tropic hormones** because they regulate the activity of cells in other endocrine glands throughout the body. The two remaining hormones of the anterior lobe, **growth hormone (GH)** and **prolactin (PRL)**, are not considered tropic because they act directly on target organs that are not endocrine. The general character and effects of the pituitary hormones of the anterior lobe are summarized in Table 21.1.

TABLE 21.1 Hormones of the Anterior Lobe of the Pituitary Gland			
Hormone	Composition	MW (kDa)	Major Functions
Growth hormone (somatotropin, GH)	Straight-chain protein (191 aa)	21,700	Stimulates liver and other organs to synthesize and secrete insulin-like growth factor I (IGF-I), which, in turn, stimulates division of progenitor cells located in growth plates and skeletal muscles, resulting in body growth
Prolactin (PRL)	Straight-chain protein (198 aa)	22,500	Promotes mammary gland development; initiates milk formation; stimulates and maintains secretion of casein, lactalbumin, lipids, and carbohydrates into the milk
Adrenocorticotrophic hormone (ACTH)	Small polypeptide (39 aa)	4,000	Maintains structure and stimulates secretion of glucocorticoids and gonadocorticoids (adrenal androgens) by the zona fasciculata and zona reticularis of the adrenal cortex
Follicle-stimulating hormone (FSH)	2-chain glycoprotein ^a (α, 92 aa; β, 111 aa)	28,000	Stimulates follicular development in the ovary and spermatogenesis in the testis
Luteinizing hormone (LH)	2-chain glycoprotein ^a (α, 92 aa; β, 116 aa)	28,300	Regulates final maturation of ovarian follicle, ovulation, and corpus luteum formation;

			stimulates steroid secretion by follicle and corpus luteum; in males, essential for maintenance of and androgen secretion by the Leydig (interstitial) cells of the testis
Thyroid-stimulating hormone (TSH)	2-chain glycoprotein ^a (α , 92 aa; β , 112 aa)	28,000	Stimulates growth of thyroid epithelial cells; stimulates production and release of thyroglobulin and thyroid hormones

aa, amino acids.

^aThe α -chains of FSH, LH, and TSH are identical and encoded by a single gene; the β -chains are specific for each hormone.

Pars distalis

The cells within the pars distalis vary in size, shape, and staining properties.

The cells within the **pars distalis** are arranged in cords and nests with interweaving capillaries. Early descriptions of the cells within the pars distalis were based solely on the staining properties of secretory vesicles within the cells. Using mixtures of acidic and basic dyes (Fig. 21.8), histologists identified three types of cells according to their staining reaction, namely, **basophils (10%)**, **acidophils (40%)**, and **chromophobes (50%)**. However, this classification provides no information regarding the hormonal secretory activity or functional role of these cells.

FIGURE 21.8. Pars distalis. This specimen of the pars distalis is stained with brilliant crystal scarlet, aniline blue, and Martius yellow to distinguish the various cell types and connective tissue stroma. The cords of cells are surrounded by a delicate connective tissue stroma stained *blue*. The sinusoidal capillaries are seen in close association with the parenchyma and contain erythrocytes stained *yellow*. In the region shown here, the acidophils (*Ac*) are the most numerous cell type present. Their cytoplasm stains *cherry red*. The basophils (*Bas*) stain *blue*. The chromophobes (*Ch*), although few in number in this particular region, are virtually unstained. $\times 640$.

Five functional cell types are identified in the pars distalis on the basis of immunocytochemical reactions.

All known hormones of the anterior lobe of the pituitary gland are small proteins or glycoproteins. This important fact has led to definitive identification of specific cell types by immunocytochemistry (Table 21.2). These studies have classified cells of the anterior lobe of the pituitary gland into five cell types:

TABLE 21.2 Staining Characteristics of Cells Found in the Anterior Lobe of the Pituitary Gland

Cell Type	Percentage of Total Cells	General Staining	Specific Staining	Product
Somatotrope (GH cell)	50	Acidophil	Orange G (PAS-)	Growth hormone (GH)
Lactotrope (PRL cell)	15-20	Acidophil	Orange G (PAS-) Herlant erythrosine Brooke carmoisine	Prolactin (PRL)
Corticotrope (ACTH cell)	15-20	Basophil	Lead hematoxylin (PAS+)	Proopiomelanocortin (POMC), which is cleaved in humans into adrenocorticotrophic hormone (ACTH) and β -lipotropic hormone (β -LPH)
Gonadotrope (FSH and LH cells)	10	Basophil	Aldehyde-fuchsin Aldehyde-thionine (PAS+)	Follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
Thyrotrope (TSH cell)	~5	Basophil	Aldehyde-fuchsin Aldehyde-thionine (PAS+)	Thyroid-stimulating hormone (TSH)

PAS, periodic acid-Schiff.

- **Somatotropes (GH cells)** are most commonly found within the pars distalis and constitute approximately 50% of the parenchymal cells in the anterior lobe of the pituitary gland. These medium-sized, oval cells exhibit round, centrally located nuclei and produce **growth hormone (GH; somatotropin)**. The presence of eosinophilic vesicles in their cytoplasm classifies them as acidophils. Three hormones regulate the release of GH from somatotropes. Two of these hormones are opposing hypothalamic-releasing hormones: **growth hormone-releasing hormone (GHRH)**, which stimulates GH release from the somatotropes, and **somatostatin**, which inhibits GH release from the somatotropes. A third hormone, a 28-amino-acid peptide called **ghrelin**, was isolated from the stomach in 1999. It is a potent stimulator of GH secretion and appears to coordinate food intake with GH secretion. Hormonally active tumors that originate from somatotropes are associated with hypersecretion of GH and cause gigantism in children and acromegaly in adults.
- **Lactotropes (PRL cells, mammatropes)** constitute 15% - 20% of the parenchymal cells in the anterior lobe of the pituitary gland. These are large, polygonal cells with oval nuclei. They produce **prolactin (PRL)**. In their storage phase, lactotropes exhibit numerous

acidophilic vesicles (the histologic feature of an acidophil). When the contents of these vesicles are released, the cytoplasm of the lactotrope does not stain (the histologic feature of a chromophobe). Secretion of PRL is under inhibitory control by **dopamine**, the catecholamine produced by the hypothalamus. However, **thyrotropin-releasing hormone (TRH)** and **vasoactive inhibitory peptide (VIP)** are known to stimulate the synthesis and secretion of PRL. During pregnancy and lactation, these cells undergo hypertrophy and hyperplasia, causing the pituitary gland to increase in size. These processes account for the larger size of the pituitary gland in multiparous women.

- **Corticotropes (ACTH cells)** also constitute 15%–20% of the parenchymal cells in the anterior lobe of the pituitary gland. These polygonal, medium-sized cells with round and eccentric nuclei produce a precursor molecule of **adrenocorticotrophic hormone (ACTH)** known as **proopiomelanocortin (POMC)**. Corticotropes stain as basophils and also exhibit a strong positive reaction with periodic acid–Schiff (PAS) reagent because of the carbohydrate moieties associated with POMC. POMC is further cleaved by proteolytic enzymes within the corticotrope into several fragments, namely, ACTH, β -lipotropic hormone (β -LPH), melanocyte-stimulating hormone (MSH), β -endorphin, and enkephalin. ACTH release is regulated by **corticotropin-releasing hormone (CRH)** produced by the hypothalamus.
- **Gonadotropes (FSH and LH cells)** constitute about 10% of the parenchymal cells in the anterior lobe of the pituitary gland. These small, oval cells with round and eccentric nuclei produce both **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**. They are scattered throughout the pars distalis and stain intensely with both basic stains (thus classifying them as the basophil cell type) and PAS reagent. Many gonadotropes are capable of producing both FSH and LH. However, immunocytochemical studies indicate that some gonadotropes may produce only one hormone or the other. The release of FSH and LH is regulated by **gonadotropin-releasing hormone (GnRH)** produced by the hypothalamus. Both FSH and LH play an important role in male and female reproduction, which is discussed in Chapter 22, Male Reproductive System (see pages 869–870 and 879–880), and Chapter 23, Female Reproductive System (see Folder 23.3, pages 926–927).
- **Thyrotropes (TSH cells)** constitute about 5% of the parenchymal cells in the anterior lobe of the pituitary gland. These large, polygonal cells with round and eccentric nuclei produce thyrotropic hormone called **thyroid-stimulating hormone (TSH)**, which acts on the follicular cells of the thyroid gland to stimulate the production of thyroglobulin and thyroid hormones. Thyrotropes exhibit cytoplasmic

basophilia (basophils) and stain positively with PAS reagent. Release of TSH is under the hypothalamic control of **thyrotropin-releasing hormone (TRH)**, which also stimulates secretion of PRL. **Somatostatin** has an inhibitory effect on thyrotropes and decreases secretion of the TSH.

Distinctive characteristics of the five cell types of the anterior lobe of the pituitary gland are readily seen with transmission electron microscopy (TEM). These characteristics are summarized in Table 21.3.

TABLE 21.3

Electron Microscopic Characteristics of Cells Found in the Anterior Lobe of the Pituitary Gland

Cell Type	Size/Shape	Nucleus/Location	Secretory Vesicle Size/ Characteristics	Other Cytoplasmic Characteristics
Somatotrope	Medium/oval	Round/central, with prominent nucleoli	Dense: 350 nm, closely packed	None
Lactotrope	Large/polygonal	Oval/central	Inactive: 200 nm, sparse Active: dense, pleomorphic, 600 nm, sparse	Lysosomes increase after lactation
Corticotrope	Medium/polygonal	Round/eccentric	100–300 nm	Lipid droplets, large lysosomes, perinuclear bundles of intermediate filaments
Gonadotrope	Small/oval	Round/eccentric	Dense: 200–250 nm	Prominent Golgi apparatus, distended rER cisternae
Thyrotrope	Large/polygonal	Round/eccentric	Dense: <150 nm	Prominent Golgi apparatus with numerous vesicles

rER, rough-surfaced endoplasmic reticulum.

In addition to the five types of hormone-producing cells, the anterior lobe of the pituitary gland contains folliculostellate cells.

Folliculostellate cells present in the anterior lobe of the pituitary gland are characterized by a star-like appearance with their cytoplasmic processes encircling hormone-producing cells. They are primarily non-hormone-secreting cells that have the ability to form cell clusters or small follicles and make up about 5%–10% of cells of the anterior lobe of the pituitary gland. Folliculostellate cells are interconnected by gap junctions containing **connexin-43** protein. Based on immunocytochemical and electrophysiologic studies, it is hypothesized that the network of folliculostellate cells interconnected by gap junctions transmits signals from the pars tuberalis to pars distalis. These signals coordinate and modulate hormone release throughout the anterior lobe of the pituitary gland. Discovery of gap junctions interconnecting folliculostellate cells with hormone-producing cells supports this proposed signaling mechanism in the anterior lobe of the pituitary gland. Thus, the **folliculostellate**

network appears to have a regulatory function in addition to the hypophyseal portal vein system.

Pars intermedia

The pars intermedia surrounds a series of small cystic cavities that represent the residual lumen of the Rathke pouch.

The parenchymal cells of the **pars intermedia** surround colloid-filled follicles. The cells lining these follicles appear to be derived either from folliculostellate cells or various hormone-secreting cells. The TEM reveals that these cells form apical junctional complexes and have vesicles larger than those found in the pars distalis. The nature of this follicular colloid is yet to be determined; however, often, cell debris is found within it. The pars intermedia contains **basophils** and **chromophobes** (Fig. 21.9). Frequently, the basophils and cystic cavities extend into the pars nervosa.

FIGURE 21.9. Photomicrograph of the pars intermedia of an adult human pituitary gland. This photomicrograph of a toluidine blue-stained specimen shows the pars intermedia located between the pars distalis (*on the left*) and the pars nervosa (*on the right*). In humans, this portion of the gland is somewhat rudimentary. However, a characteristic feature of the pars intermedia is the presence of different-sized follicles filled with colloid (*CF*) and small groups of cells consisting of chromophobes and basophils. $\times 120$.

The function of the pars intermedia cells in humans remains unclear. From studies of other species, however, it is known that basophils have scattered vesicles in their cytoplasm that contain either α - or β -endorphin (a morphine-related compound). In frogs, the basophils produce melanocyte-stimulating hormones (MSH), which stimulate pigment production in melanocytes and pigment dispersion in melanophores. In humans, MSH is not a distinct, functional hormone but is a by-product of β -LPH post-translational processing. Because MSH is found in the

human pars intermedia in small amounts, the basophils of the pars intermedia are assumed to be **corticotropes**.

Pars tuberalis

The pars tuberalis is an extension of the anterior lobe along the stalk-like infundibulum.

The **pars tuberalis** is a highly vascular region containing veins of the hypothalamohypophyseal system. The parenchymal cells are arranged in small clusters or cords in association with the blood vessels. Nests of squamous cells and small follicles lined with cuboidal cells are scattered in this region. These cells often show immunoreactivity for ACTH, FSH, and LH.

Posterior Lobe of the Pituitary Gland (Neurohypophysis)

The posterior lobe of the pituitary gland is an extension of the central nervous system (CNS) that stores and releases secretory products from the hypothalamus.

The **posterior lobe of the pituitary gland**, also known as the *neurohypophysis*, consists of the **pars nervosa** and the **infundibulum** that connects it to the hypothalamus. The pars nervosa, the neural lobe of the pituitary, contains the unmyelinated axons and their nerve endings of approximately 100,000 **neurosecretory neurons** whose cell bodies lie in the **supraoptic nuclei** and **paraventricular nuclei** of the hypothalamus. The axons form the **hypothalamohypophyseal tract** and are unique in two respects. First, they do not terminate on other neurons or target cells but end in close proximity to the fenestrated capillary network of the pars nervosa. Second, they contain secretory vesicles in all parts of the cells (i.e., the cell body, axon, and axon terminal). Because of their intense secretory activity, the neurons have well-developed Nissl bodies and, in this respect, resemble ventral horn and ganglion cells.

The posterior lobe of the pituitary gland is *not an endocrine gland*. Rather, it is a **storage site for neurosecretions** of the neurons of the supraoptic and paraventricular nuclei of the hypothalamus. The unmyelinated axons convey neurosecretory products to the pars nervosa. Other neurons from the hypothalamic nuclei (described later in this chapter) also release their secretory products into the fenestrated capillary network of the infundibulum, the first capillary bed of the hypothalamohypophyseal portal system.

Electron microscopy reveals three morphologically distinct neurosecretory vesicles in the nerve endings of the pars nervosa.

Three sizes of membrane-bound vesicles are present in the pars nervosa:

- **Neurosecretory vesicles** with diameters ranging between 10 and 30 nm accumulate in the axon terminals. They also form accumulations that dilate portions of the axon near the terminals (Fig. 21.10). These dilations, called **Herring bodies**, are visible in the light microscope (Plate 21.1, page 850). In the electron microscope, Herring bodies, in addition to abundant neurosecretory vesicles, contain mitochondria, few microtubules, and profiles of smooth-surfaced endoplasmic reticulum (sER) (Fig. 21.11).

FIGURE 21.10. Electron micrograph of Herring bodies of rat posterior lobe. Dilated portions of axons near their terminals called Herring bodies (*HB*) contain numerous neurosecretory vesicles filled with either oxytocin or

antidiuretic hormone (ADH). They are surrounded by the specialized glial cells called pituicytes (*P*). Note that Herring bodies reside in close proximity to blood vessels (*BV*), mainly fenestrated capillaries, lined by endothelial cells (*En*). $\times 6,000$. (Courtesy of Dr. Holger Jastrow.)

FIGURE 21.11. Electron micrograph of rat posterior lobe. Neurosecretory granules and small vesicles are present in the terminal portions of the

axonal processes of the hypothalamohypophyseal tract fibers. Capillaries with fenestrated endothelium are present in close proximity to the nerve endings. $\times 20,000$. (Courtesy of Drs. Sanford L. Palay and P. Orkland.)

- Nerve terminals also contain 30-nm vesicles that contain acetylcholine. These vesicles may play a specific role in the release of neurosecretory vesicles.
- Larger 50- to 80-nm vesicles that resemble the dense-core vesicles of the adrenal medulla and adrenergic nerve endings are present in the same terminal as the other membrane-bound vesicles. The membrane-bound neurosecretory vesicles that aggregate to form Herring bodies contain either **oxytocin** or **antidiuretic hormone** (ADH; also called **vasopressin**; Table 21.4). Each hormone is a small peptide of nine amino acid residues. The two hormones differ in only two of these residues. Each vesicle also contains **ATP** and a **neurophysin**, a protein that binds to the hormone by noncovalent bonds. Oxytocin and ADH are synthesized as part of a large molecule that includes the hormone and its specific neurophysin. The large molecule is proteolytically cleaved into the hormone and neurophysin as it travels from the nerve cell body to the axon terminal. Immunocytochemical staining demonstrates that oxytocin and ADH are secreted by different cells in the hypothalamic nuclei.

TABLE 21.4

Hormones of the Posterior Lobe of the Pituitary Gland

Hormone	Composition	Source	Major Functions
Oxytocin	Polypeptide containing nine amino acids	Cell bodies of neurons located in the supraoptic and paraventricular nuclei of the hypothalamus ^a	Stimulates activity of the contractile cells around the ducts of the mammary glands to eject milk from the glands; stimulates contraction of smooth muscle cells in the pregnant uterus
Antidiuretic hormone (ADH; vasopressin)	Polypeptide containing nine amino acids; two forms: arginine-ADH (most common in humans) and lysine-ADH	Cell bodies of neurons located in the supraoptic and paraventricular nuclei of the hypothalamus ^a	Decreases urine volume by increasing reabsorption of water by collecting ducts of the kidney; decreases the rate of perspiration in response to

dehydration;
increases blood
pressure by
stimulating
contractions of
smooth muscle cells
in the wall of
arterioles

^aImmunocytochemical studies indicate that oxytocin and ADH are produced by separate sets of neurons within the supraoptic and paraventricular nuclei of the hypothalamus. Biochemical studies have demonstrated that the supraoptic nucleus contains equal amounts of both hormones, whereas the paraventricular nucleus contains more oxytocin than ADH but less than the amount found in the supraoptic nucleus.

ADH facilitates reabsorption of water from the distal tubules and collecting ducts of the kidney by altering the permeability of the cells to water.

ADH's original name, vasopressin, was derived from the observation that large nonphysiologic doses increase blood pressure by promoting the contraction of smooth muscle in small arteries and arterioles. However, physiologic levels of ADH have only minimal effects on blood pressure. ADH is the main hormone involved in the regulation of **water homeostasis** and **osmolarity of body fluids**. The primary physiologic effect of ADH on the kidney is the insertion of water channels (**aquaporins**) into cells of the distal convoluted tubules and collecting ducts, which increases their permeability for water. Insertion of aquaporin-2 (AQP-2) into the apical domain and AQP-3 into the basolateral domain of these cells is responsible for rapid resorption of water across the tubule epithelium. ADH acts through its specific V2 receptor on the basolateral domain of cells lining the distal convoluted tubules and collecting ducts; mutation of this receptor is responsible for **nephrogenic diabetes insipidus** (Folder 21.3).

Plasma osmolality and blood volume are monitored by specialized receptors of the cardiovascular system (e.g., carotid bodies and juxtaglomerular apparatus). An increase in osmolality or a decrease in blood volume stimulates ADH release. In addition, the cell bodies of the hypothalamic secretory neurons may also serve as osmoreceptors, initiating ADH release. Pain, trauma, emotional stress, and drugs such as nicotine also stimulate the release of ADH.

Oxytocin promotes contraction of smooth muscle of the uterus and myoepithelial cells of the breast.

Oxytocin is a more potent promoter of smooth muscle contraction than ADH. Its primary effect includes promotion of contraction of the

following cells and tissues:

- **Uterine smooth muscle** during orgasm, menstruation, and parturition. As parturition approaches, uterine smooth muscle cells demonstrate about a 200-fold increase in responsiveness to oxytocin. This is accompanied by increased formation of gap junctions between smooth muscle cells and increased density of oxytocin receptors.
- **Myoepithelial cells** of the secretory alveoli and alveolar ducts of the mammary gland. Oxytocin secretion is triggered by neural stimuli that reach the hypothalamus. These stimuli initiate a neurohumoral reflex that resembles a simple sensorimotor reflex. In the uterus, the neurohumoral reflex is initiated by distension of the vagina and cervix. In the breast, the reflex is initiated by breastfeeding (suckling). Contraction of the myoepithelial cells that surround the base of the alveolar secretory cells and cells of the larger ducts causes milk to be released and passes through the ducts that open onto the nipple (i.e., milk ejection; see page 947).
Synthetic analogs of oxytocin are often used in intravenous infusion pumps to initiate and strengthen uterine contractions during active labor and delivery.

The pituicyte is the only cell specific to the posterior lobe of the pituitary gland.

In addition to the numerous axons and terminals of the hypothalamic neurosecretory neurons, the posterior lobe of the pituitary gland contains fibroblasts, mast cells, and specialized glial cells called **pituicytes** associated with the fenestrated capillaries (Plate 21.2, page 852). These cells are irregular in shape, with many branches, and resemble astroglial cells. Their nuclei are round or oval, and pigment vesicles are present in the cytoplasm. Like astroglia, they possess specific intermediate filaments assembled from **glial fibrillary acidic proteins (GFAP)**. Pituicytes often have processes that terminate in the perivascular space. Because of their many processes and relationships to the blood, the pituicyte serves a supporting role similar to that of astrocytes in the rest of the CNS (see pages 410–412).

■ HYPOTHALAMUS

The hypothalamus regulates pituitary gland activity.

The **hypothalamus** is located in the middle of the base of the brain, and it encapsulates the ventral portion of the third ventricle. It coordinates most endocrine functions of the body and serves as one of

the major controlling centers of the ANS. Some of the functions that it regulates include blood pressure, body temperature, fluid and electrolyte balance, body weight, and appetite. The hypothalamus produces numerous neurosecretory products. In addition to **oxytocin** and **ADH**, hypothalamic neurons secrete polypeptides that promote and inhibit the secretion and release of hormones from the anterior lobe of the pituitary gland (Table 21.5). These **hypothalamic polypeptides** also accumulate in nerve endings near the median eminence and infundibulum and are released into the capillary bed of the **hypothalamohypophyseal portal system** for transport to the pars distalis of the pituitary gland.

TABLE 21.5 Hypothalamic-Regulating Hormones			
Hormone	Composition	Source	Major Functions
Growth hormone -releasing hormone (GHRH)	Two forms in humans: polypeptides containing 40 and 44 amino acids	Cell bodies of neurons located in the arcuate nucleus of hypothalamus	Stimulates secretion and gene expression of GH by somatotropes
Somatostatin	Two forms in humans: polypeptides containing 14 and 28 amino acids	Cell bodies of neurons located in the periventricular, paraventricular, and arcuate nuclei of the hypothalamus	Inhibits secretion of GH by somatotropes and TSH by thyrotropes; inhibits insulin secretion by B cells of pancreatic islets
Dopamine	Catecholamine (amino acid derivative)	Cell bodies of neurons located in the arcuate nucleus of hypothalamus	Inhibits secretion of PRL by lactotropes
Corticotropin-releasing hormone (CRH)	Polypeptide containing 41 amino acids	Cell bodies of neurons located in the arcuate, periventricular, and medial paraventricular nuclei of hypothalamus	Stimulates secretion of ACTH by corticotropes; stimulates gene expression for POMC in corticotropes
Gonadotropin-releasing hormone (GnRH)	Polypeptide containing 10 amino acids	Cell bodies of neurons located in the arcuate, ventromedial, dorsal, and paraventricular	Stimulates secretion of LH and FSH by gonadotropes

		nuclei of hypothalamus	
Thyrotropin-releasing hormone (TRH)	Polypeptide containing 3 amino acids	Cell bodies of neurons located by the ventromedial, dorsal, and paraventricular nuclei of hypothalamus	Stimulates secretion and gene expression of TSH by thyrotropes; stimulates synthesis and secretion of PRL

ACTH, adrenocorticotrophic hormone; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *LH*, luteinizing hormone; *POMC*, proopiomelanocortin; *PRL*, prolactin; *TSH*, thyroid-stimulating hormone.

FOLDER 21.2

CLINICAL CORRELATION: PRINCIPLES OF ENDOCRINE DISEASES

Abnormalities in the signaling mechanisms that coordinate and control the function of multiple organs and biological processes are the bases of many endocrine diseases. Classic biochemistry, physiology, and advances in cell and molecular biology and genetics combined with clinical observations are able to explain the mechanisms of hormonal action and endocrine diseases. Endocrine diseases can be classified into four major categories:

- **Hormone overproduction.** The most common cause of hormone overproduction is an increase in the total number of cells producing a specific hormone. An example of this mechanism is hyperthyroidism (Graves disease; see Folder 21.4). Briefly, the presence of abnormal antibodies that mimic the action of thyroid-stimulating hormone (TSH) stimulates a dramatic increase in the number of thyroid cells. In some instances, increased hormone secretion is related to genetic abnormality that affects the regulation of hormone synthesis and release. In addition, mutation in tumor suppressor genes and proto-oncogenes may lead to proliferation of mutant cells that produce the specific hormone. This commonly occurs in cells of the anterior lobe of the pituitary gland.
- **Hormone underproduction.** Underproduction of hormones may result from destruction of an endocrine organ by a disease process (e.g., tuberculosis of the adrenal glands) or autoimmunity (e.g., Hashimoto disease in which abnormal antibodies target and destroy thyroid hormone-producing cells). Also, genetic abnormalities that lead to abnormal development of endocrine glands (e.g., hypogonadotropic hypogonadism), abnormal hormone synthesis (e.g., deletion of the GH gene), or abnormal regulation of hormone secretion (e.g., hypoparathyroidism associated with mutation of the calcium-sensing receptor expressed on parathyroid cells) can cause decreased serum levels or lack of active hormones. Iatrogenic injury to endocrine glands such as occurs when the parathyroid gland is removed during thyroidectomy (thyroid gland removal) may also be responsible.
- **Altered tissue responses to hormones.** This category of endocrine disease is often caused by a variety of genetic mutation in hormone receptors (e.g., TSH, luteinizing hormone [LH], and parathyroid hormone [PTH]). In diabetic patients, the resistance to insulin in muscles and the liver is mainly caused by signals originating from adipose tissue (see Chapter 9, Adipose Tissue, page 280).

- **Tumors of endocrine glands.** Most of the tumors of endocrine gland are hormonally active and are responsible for hormone overproduction. However, some tumors of endocrine glands do not produce hormones but compress neighboring organs or cause destructions of other organs due to metastasis. An example of such a tumor is thyroid cancer that can metastasize throughout the body without presenting signs of thyroid hormone overproduction (hyperthyroidism).

Hormones are used to treat endocrine diseases. A common use is as **hormone replacement therapies** when a specific endocrine gland is not developed or ceases to produce the required hormone. Hormones and their synthetic analogs can be used to suppress the effects of other hormones. In general, thyroid and steroid hormones can be administered orally, whereas protein hormones (e.g., insulin, growth hormone [GH]) need to be injected. Recent technological innovations, including computerized mini-pumps and depot intramuscular injections, have made therapy more manageable for patients.

A feedback system regulates endocrine function at two levels: hormone production in the pituitary gland and hypothalamic-releasing hormone production in the hypothalamus.

The circulating level of a specific secretory product of a target organ, a hormone or its metabolite, may act directly on the cells of the anterior lobe of the pituitary gland or the hypothalamus to regulate the secretion of hypothalamic-releasing hormones (see Fig. 21.19 for a diagram of the hypothalamus-pituitary-thyroid feedback loop). The two levels of feedback allow exquisite sensitivity in the control of secretory function. The hormone itself normally regulates the secretory activity of the cells in the hypothalamus and pituitary gland that regulate its secretion.

In addition, information from most physiologic and psychological stimuli that reach the brain also reaches the hypothalamus. The **hypothalamohypophyseal feedback loop** provides a regulatory pathway whereby general information from the CNS contributes to the regulation of the anterior lobe of the pituitary gland and, consequently, to the regulation of the entire endocrine system. The secretion of hypothalamic regulatory peptides is the primary mechanism by which changes in emotional state are translated into changes in the physiologic homeostatic state.

■ PINEAL GLAND

The **pineal gland** (pineal body, epiphysis cerebri) is an endocrine or neuroendocrine gland that regulates daily body rhythm. It develops from neuroectoderm of the posterior portion of the roof of the diencephalon and remains attached to the brain by a short stalk. In humans, it is

located at the posterior wall of the third ventricle near the center of the brain. The pineal gland is a flattened, pine cone-shaped structure, hence its name (Fig. 21.12). It measures 5-8 mm high and 3-5 mm in diameter and weighs between 100 and 200 mg.

FIGURE 21.12. Photomicrograph of infant pineal gland. This hematoxylin and eosin (H&E)-stained section is obtained from a median cut through the pine cone-shaped gland. The conical anterior end of the gland is at the *top* of the micrograph. The *arrows* indicate the part of the gland that connects with the posterior commissure. The gland is formed by an evagination of the posterior portion of the roof of the third ventricle (diencephalon). The dark areas indicated by *asterisks* are caused by bleeding within the gland. $\times 25$.

FOLDER 21.3

CLINICAL CORRELATION: PATHOLOGIES ASSOCIATED WITH ANTIDIURETIC HORMONE SECRETION

The absence or reduced production of antidiuretic hormone (ADH) leads to a condition known as **diabetes insipidus**, which is characterized by polyuria (production of large volumes of diluted urine—up to 20 L/d) with hypotonic and tasteless (insipid) urine. Individuals with this condition have extreme thirst, which allows them to counteract the loss of water by drinking large amounts of fluids. This disease commonly results from head injuries, tumors, or other lesions that can damage the hypothalamus or posterior lobe of the pituitary gland. This form of the disease is classified as **hypothalamic diabetes insipidus** in contrast to **nephrogenic diabetes insipidus**, in which secretion of the ADH is normal or elevated, but there is a lack of renal response to circulating levels of ADH. Nephrogenic diabetes is usually a congenital disorder related to the mutation of the aquaporin-2 (AQP-2) water channel gene or different ADH V2 receptor mutations in kidney tubules. Hypothalamic diabetes insipidus is usually treated by administration of synthetic analogs of ADH (desmopressin), whereas the treatment of the nephrogenic type of this disease is aimed at reducing the volume of urine output.

Abnormally high levels of ADH are found in the **syndrome of inappropriate antidiuretic hormone secretion (SIADH)**, which is characterized by hyponatremia (low serum levels of sodium), decreased serum osmolality associated with excessive urine sodium excretion and elevated urine osmolality. In SIADH, the elevated level of ADH increases the absorption of water, thereby leading to the production of concentrated urine, inability to excrete water, and hyponatremia that results from excess water rather than sodium deficiency. The increase in ADH secretion may be related to central nervous system (CNS) disorders (tumors, injuries, infections, or cerebrovascular accidents), pulmonary diseases (pneumonia, chronic obstructive pulmonary disease, a lung abscess, or tuberculosis), tumors that secrete ADH (small cell carcinoma of the lung, tumors of the pancreas, thymoma, or lymphomas), and certain drugs (anti-inflammatories, nicotine, diuretics, and many others). Treatment of SIADH depends on the underlying etiology and includes fluid restrictions as well as pharmacologic treatment. An ADH V2-receptor antagonist (conivaptan) is now available to improve hyponatremia and to increase the free water diuresis without loss of other ions in the urine of patients with SIADH.

The pineal gland contains two types of parenchymal cells: pinealocytes and interstitial (glial) cells.

Pinealocytes are the chief cells of the pineal gland. They are arranged in clumps or cords within lobules formed by connective tissue septa

that extend into the gland from the pia mater that covers its surface. These cells have a large, deeply infolded nucleus with one or more prominent nucleoli and contain lipid droplets within their cytoplasm. When examined with the TEM, pinealocytes show typical cytoplasmic organelles along with numerous, dense-core, membrane-bound vesicles in their elaborate, elongated cytoplasmic processes. The processes also contain numerous parallel bundles of microtubules. The expanded, club-like endings of the processes are associated with the blood capillaries. This feature strongly suggests neuroendocrine activity.

The **interstitial (glial) cells** constitute about 5% of the cells in the gland. They have staining and ultrastructural features that closely resemble those of astrocytes and are reminiscent of the pituicytes of the posterior lobe of the pituitary gland.

In addition to the two cell types, the human pineal gland is characterized by the presence of calcified concretions, called **corpora arenacea** or **brain sand** (Fig. 21.13 and Plate 21.3, page 854). These concretions appear to be derived from precipitation of calcium phosphates and carbonates on carrier proteins that are released into the cytoplasm when the pineal secretions are exocytosed. **The concretions are recognizable in childhood and increase in number with age. Because they are opaque to x-rays and located in the midline of the brain, they serve as convenient markers in radiographic and computed tomography (CT) studies.**

FIGURE 21.13. Photomicrograph of human pineal gland. This higher magnification photomicrograph shows the characteristic concretions called *brain sand* or *corpora arenacea*. Pinealocytes (chief cells of the pineal gland) account for the majority of the cells seen in the specimen. They are arranged in clumps or cords. Those blood vessels (*BV*) that contain red blood cells are readily apparent; numerous other blood vessels are also present but are not recognized at this magnification without evidence of the blood cells. $\times 250$.

The human pineal gland relates light intensity and duration to endocrine activity.

The pineal gland is a photosensitive organ and an important timekeeper and regulator of the day/night cycle (circadian rhythm). It obtains information about light and dark cycles from the retina via the **retinohypothalamic tract**, which connects the suprachiasmatic nucleus with sympathetic neural tracts traveling into the pineal gland. During the day, light impulses inhibit the production of the major pineal gland hormone, **melatonin**. Therefore, pineal activity, as measured by changes in the plasma level of melatonin, increases during darkness and decreases during light. In humans, these circadian changes of melatonin secretion play an important role in regulating **daily body (circadian) rhythms**.

Melatonin is released in the dark and regulates reproductive function in mammals by inhibiting the steroidogenic activity of the gonads (Table 21.6). **Production of gonadal steroids is decreased by the inhibitory action of melatonin on neurosecretory neurons located in the hypothalamus (arcuate nucleus) that produce GnRH. Inhibition of GnRH causes a decrease in the release of FSH and LH from the anterior lobe of the pituitary gland. In addition to melatonin, extracts of pineal glands from many animals contain numerous neurotransmitters, such as serotonin, norepinephrine, dopamine, and histamine, and hypothalamic-regulating hormones, such as somatostatin and TRH. Clinically, tumors that destroy the pineal gland are associated with precocious (early-onset) puberty.**

TABLE 21.6

Hormones of the Pineal Gland

Hormone	Composition	Source	Major Functions
Melatonin	Indolamine (<i>N</i> -acetyl-5-methoxytryptamine)	Pinealocytes	Regulates daily body rhythms and day/night cycle (circadian rhythms); inhibits secretion of GnRH and regulates steroidogenic activity of the gonads particularly as related to the menstrual cycle; in animals, influences seasonal sexual activity

GnRH, gonadotropin-releasing hormone.

Animal studies demonstrate that information relating to the length of daylight reaches the pineal gland from photoreceptors in the retina. The pineal gland thus influences seasonal sexual activity. **The pineal**

gland has a role in adjusting to sudden changes in day length, such as those experienced by travelers who suffer from jet lag. In addition, the pineal gland plays a role in altering emotional responses to the reduced length of day during winter in temperate and subarctic zones known as seasonal affective disorder (SAD).

■ THYROID GLAND

The thyroid gland is located in the anterior neck region adjacent to the larynx and trachea.

The **thyroid gland** is a bilobate endocrine gland located in the anterior neck region and consists of two large **lateral lobes** connected by an **isthmus**, a thin band of thyroid tissue. The two lobes, each approximately 5 cm in length, 2.5 cm in width, and 20–30 g in weight, lie on either side of the larynx and upper trachea. The isthmus crosses the anterior surface of the second and third tracheal cartilages. A **pyramidal lobe** often extends upward from the isthmus. A thin connective tissue capsule surrounds the gland (Fig. 21.14). It sends trabeculae into the parenchyma that partially outlines irregular lobes and lobules. **Thyroid follicles** constitute the functional units of the gland.

 indicates locations of parathyroid glands on the posterior surface of the lateral lobes

FIGURE 21.14. Topography and blood supply of the thyroid gland. This drawing shows the location of the thyroid gland in the anterior region of the neck in close proximity to the trachea and laryngeal cartilages. The gland consists of two lateral lobes connected by an isthmus. In about 40% of cases, the thyroid gland exhibits a pyramidal lobe, which is a remnant of the thyroglossal duct, a developmental connection with the base of the tongue. The thyroid gland is supplied by blood from the superior and inferior thyroid arteries, and blood from the gland is drained by the superior, middle, and inferior thyroid veins. On the posterior (deep) surface of the lateral lobes, there are two pairs of small ovoid structures that are designated as superior and inferior parathyroid glands. Note the outlined areas of the parathyroid glands' location visible from the anterior view.

The thyroid gland develops from the endodermal lining of the floor of the primitive pharynx.

The **thyroid gland** begins to develop during the fourth week of gestation from a primordium originating as an endodermal thickening of the floor of the primitive pharynx. The primordium grows caudally and forms a duct-like invagination known as the **thyroglossal duct**. The thyroglossal duct descends through the tissue of the neck to its final destination in front of the trachea, where it divides into two lobes. During this downward migration, the thyroglossal duct undergoes atrophy, leaving an embryologic remnant, the pyramidal lobe of the thyroid, which is present in about 40% of the population.

At about the ninth week of gestation, endodermal cells differentiate into plates of **follicular cells** that become arranged into follicles. By week 14, well-developed follicles lined by the follicular cells contain colloid in their lumens. During week 7, parallel to the development of thyroid follicles, epithelial cells lining the invagination of the fourth pharyngeal (branchial) pouches, known as the **ultimobranchial bodies**, start their migration toward the developing thyroid gland and become incorporated into the lateral lobes. After fusing with the thyroid, ultimobranchial body cells disperse among the follicles, giving rise to **parafollicular cells** that become incorporated into the follicular epithelium.

The thyroid follicle is the structural and functional unit of the thyroid gland.

A **thyroid follicle** is a roughly spherical cyst-like compartment with a wall formed by a simple cuboidal or low columnar epithelium, the **follicular epithelium**. Hundreds of thousands of follicles that vary in diameter from about 0.2 to 1.0 mm constitute nearly the entire mass of the human thyroid gland. The follicles contain a gel-like mass called **colloid** (Fig. 21.15 and Plate 21.4, page 856). The apical surfaces of the follicular cells are in contact with the colloid, and the basal surfaces rest on a typical basal lamina.

FIGURE 21.15. Thyroid gland. This photomicrograph of a human thyroid is from a section stained with hematoxylin and eosin (H&E). It shows the colloid-containing follicles of the gland. Each follicle consists of a single layer of epithelial cells surrounding a central mass of colloid. The *arrows* indicate some of the blood capillaries between the follicles. $\times 500$.

Follicular epithelium contains two types of cells: follicular and parafollicular cells.

The parenchyma of the thyroid gland is composed of epithelium containing two types of cells:

- **Follicular cells (principal cells)** are responsible for the production of the thyroid hormones T_4 and T_3 . These cells vary in shape and size according to the functional state of the gland. In routine hematoxylin and eosin (H&E) preparations, follicular cells exhibit a slightly basophilic basal cytoplasm with spherical nuclei containing one or more prominent nucleoli. The Golgi apparatus has a supranuclear position. Lipid droplets and PAS-positive droplets can be identified with appropriate staining. At the ultrastructural level, the follicle cells reveal organelles commonly associated with both secretory and absorptive cells (Fig. 21.16), including typical junctional complexes at the apical end of the cell and short microvilli on the apical cell surface. Numerous profiles of rough-surfaced endoplasmic reticulum (rER) are present in the basal region. Small vesicles present in the apical cytoplasm are morphologically similar to vesicles associated with the Golgi apparatus. Abundant endocytic vesicles, identified as **colloidal resorption droplets**, and lysosomes are also present in the apical cytoplasm.

FIGURE 21.16. Electron micrograph of follicular cells in rat thyroid gland. This electron micrograph shows a single layer of epithelium containing low columnar follicular cells. The apical surfaces with visible microvilli (*Mv*) are in contact with the colloid, whereas basal surfaces of follicular cells rest on the basal lamina (*FBL*). A narrow extracellular connective tissue space separates the follicular cells from the lumen of the capillary. Note that the fenestrated endothelial cells (*En*) lining the capillary lumen rest on the basal lamina (*EBL*). Accumulation of lysosomes (*L*) and colloid resorption droplets (*CRD*), extensive Golgi apparatus (*G*), rough-surfaced endoplasmic reticulum (*rER*), and the presence of enlarged intercellular spaces are indicative of intensive activity of follicular cells. *JC*, junctional complex; *N*, nucleus. $\times 14,000$. (Courtesy of Dr. Holger Jastrow.)

- **Parafollicular cells (C cells)** are located in the periphery of the follicular epithelium and lie within the follicle basal lamina. These cells have no exposure to the follicle lumen. They secrete **calcitonin**, a hormone that regulates calcium metabolism. In routine

H&E preparations, C cells are pale staining and occur as solitary cells or small clusters of cells. Human parafollicular cells are difficult to identify with light microscopy. At the electron microscope level, the parafollicular cells reveal numerous small secretory vesicles, which range in diameter from 60 to 550 nm, and a prominent Golgi apparatus (Fig. 21.17).

FIGURE 21.17. Electron micrograph of a parafollicular cell. Cytoplasmic processes of follicular cells (*arrows*) partially surround the parafollicular cell (*PC*), which contains numerous electron-dense granules and a prominent Golgi apparatus (*G*). A basal lamina (*BL*) is associated with the follicular cells (*FC*). A portion of the central mass of colloidal material (*C*) in two adjacent follicles can be seen in the *left corners* of the micrograph. $\times 12,000$. (Courtesy of Dr. Emmanuel-Adrien Nunez.)

An extensive network of fenestrated capillaries derived from the superior and inferior thyroid arteries surrounds the follicles. Blind-ended lymphatic capillaries are present in the interfollicular connective tissue and may also provide a second route for conveying the hormones from the gland.

Thyroid gland function is essential to normal growth and development.

The thyroid gland produces three hormones, each of which is essential to normal metabolism and homeostasis (Table 21.7):

TABLE 21.7

Hormones of the Thyroid Gland

Hormone	Composition	Source	Major Functions
Thyroxine (tetraiodothyronine, T_4 and triiodothyronine, T_3) ^a	Iodinated tyrosine derivatives	Follicular cells (principal cells)	Regulates tissue basal metabolism (increases rate of carbohydrate use, protein synthesis and degradation, and fat synthesis and degradation), regulates heat production, influences body and tissue growth and development of the nervous system in the fetus and young child, ^b increases absorption of carbohydrates from the intestine
Calcitonin (thyrocalcitonin)	Polypeptide containing 32 amino acids	Parafollicular cells (C cells)	Decreases blood calcium levels by inhibiting bone resorption and stimulating absorption of calcium by the bones

^aThyroid gland secretes substantially more T_4 than T_3 ; however, about 40% of T_4 is peripherally converted to T_3 , which acts more rapidly and is a more potent hormone.

^bDeficiency of T_3 and T_4 during development results in fewer and smaller neurons, defective myelination, and severe intellectual disability.

- **Thyroxine** (3,3',5,5'-tetraiodothyronine, T_4) and **3,3',5-triiodothyronine** (T_3) are synthesized and secreted by **follicular cells**. Both hormones regulate cell and tissue basal metabolism and heat production and influence body growth and development. Secretion of these hormones is regulated by TSH released from the anterior lobe of the pituitary gland.
- **Calcitonin** (thyrocalcitonin) is synthesized by the **parafollicular cells** (C cells) and is a physiologic antagonist to parathyroid hormone (PTH). Calcitonin has an important role in regulating serum calcium levels in lower animals; however, its physiologic role in humans remains elusive. Calcitonin lowers blood calcium levels by

suppressing the resorptive action of osteoclasts and promotes calcium deposition in bones by increasing the rate of osteoid calcification. Secretion of calcitonin is regulated directly by blood calcium levels. High levels of calcium stimulate secretion; low levels inhibit it. Secretion of calcitonin is unaffected by the hypothalamus and pituitary gland. Calcitonin is secreted by several endocrine tumors (e.g., medullary carcinoma of the thyroid); therefore, it is used as a tumor marker to monitor the progress of recovery after surgical resection of the tumor. Although calcitonin is used to treat patients with several disorders associated with excess bone resorption (e.g., osteoporosis and Paget disease), no clinical disease has been associated with its deficiency or even its absence after total thyroidectomy.

The principal component of colloid is thyroglobulin, an inactive storage form of thyroid hormones.

The principal component of colloid is a large (660 kDa), iodinated glycoprotein called thyroglobulin containing about 120 tyrosine residues. Colloid also contains several enzymes and other glycoproteins. It stains with both basic and acidic dyes and is strongly PAS positive. Thyroglobulin is not a hormone. It is an inactive storage form of thyroid hormones. Active thyroid hormones are liberated from thyroglobulin and released into the fenestrated blood capillaries that surround the follicles only after further cellular processing. The thyroid is unique among endocrine glands because it stores large amounts of its secretory product extracellularly.

Synthesis of thyroid hormone involves several steps.

The synthesis of the two major thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3), takes place in the thyroid follicle in a series of discrete steps (Fig. 21.18):

FIGURE 21.18. Diagram of steps in thyroid hormone synthesis. This diagram depicts two follicular cells: one in the process of thyroglobulin synthesis (*on the left with red pathways*) and the other in the process of thyroglobulin resorption (*on the right with blue pathways*). The numbers, which are described more fully in the text, indicate the sequential steps that occur: 1, synthesis and secretion of thyroglobulin; 2, uptake and concentration of iodide from the blood by sodium/iodide symporters (NIS), release of iodide into the colloid via iodide/chloride (pendrin) transporters, and oxidation of iodide to iodine by thyroid peroxidase; 3, iodination of thyroglobulin in the colloid; 4, formation of T₃ and T₄ hormones in the colloid by oxidative coupling reactions; 5L, resorption of colloid via lysosomal pathway (major pathway); 5TE, resorption of colloid via megalin receptor-mediated transepithelial pathway; and 6, release of T₄ and T₃ from the cell into the circulation. DIT, diiodotyrosine; MIT, monoiodotyrosine; rER, rough-surfaced endoplasmic reticulum.

1. **Synthesis of thyroglobulin.** The precursor of thyroglobulin is synthesized in the rER of the follicular epithelial cells. Thyroglobulin is post-translationally glycosylated in the rER and the Golgi apparatus before it is packaged into vesicles and secreted by exocytosis into the lumen of the follicle.
2. **Resorption, diffusion, and oxidation of iodide.** Follicular epithelial cells actively transport **iodide** from the blood into their cytoplasm using ATPase-dependent **sodium/iodide symporters (NIS)**. The NIS is the 87-kDa transmembrane protein that mediates active iodide uptake in the basolateral membrane of the follicular epithelial cells. These cells are capable of establishing an intracellular concentration of iodide that is 30-40 times greater than that of the serum. Iodide ions then diffuse rapidly toward the apical cell membrane. From here, iodide ions are transported to the lumen of the follicle by the 86-kDa **iodide/chloride transporter** called **pendrin** located in the apical cell membrane. Iodide is then immediately oxidized to **iodine**, the active form of iodide. This process occurs in the colloid and is catalyzed by membrane-bound **thyroid peroxidase (TPO)**.
3. **Iodination of thyroglobulin.** One or two iodine atoms are then added to the specific tyrosine residues of thyroglobulin. This process occurs in the colloid at the microvillar surface of the follicular cells and is also catalyzed by **thyroid peroxidase (TPO)**. Addition of one iodine atom to a single tyrosine residue forms **monoiodotyrosine (MIT)**. Addition of a second iodine atom to the MIT residue forms a **diiodotyrosine (DIT)**.
4. **Formation of T_3 and T_4** by oxidative coupling reactions. Thyroid hormones are formed by oxidative coupling reactions of two iodinated tyrosine residues in close proximity. For example, when neighboring DIT and MIT residues undergo a coupling reaction, T_3 is formed; when two DIT residues react with each other, T_4 is formed. After iodination, T_4 and T_3 as well as the DIT and MIT residues that are still linked to a thyroglobulin molecule are stored as the colloid within the lumen of the follicle.
5. **Resorption of colloid.** In response to TSH, follicular cells take up thyroglobulin from the colloid by a process of receptor-mediated endocytosis. **If the levels of TSH remain high, the amount of colloid in the follicle is reduced because it is synthesized, secreted, iodinated, and resorbed too rapidly to accumulate.** After endocytosis, thyroglobulin follows at least two different intracellular pathways.
 - In the **lysosomal pathway**, thyroglobulin is internalized and transported within endocytic vesicles to early endosomes. They

eventually mature into lysosomes or fuse with existing lysosomes. Resorption of thyroglobulin at this stage can be confirmed by the presence of large endocytic vesicles called **colloidal resorption droplets** in the apical region of the follicular cells. Thyroglobulin is then degraded by lysosomal proteases into constituent amino acids and carbohydrates, leaving free T_4 , T_3 , DIT, and MIT molecules (see 5L labeled pathway in Fig. 21.18). Under physiologic conditions, this is the major pathway of colloid resorption.

- In the **transepithelial pathway**, thyroglobulin is transported intact from the apical to the basolateral surface of follicular cells. To enter this pathway, thyroglobulin binds to its receptor, **megalín**, a 330-kDa member of the low-density lipoprotein (LDL) endocytic receptor family. Megalín is a transmembrane protein expressed at the apical surface of follicular epithelial cells directly facing colloid. Thyroglobulin internalized by megalín avoids the lysosomal pathway, and endocytic vesicles are delivered to the basolateral membrane of follicular cells (see 5TE labeled pathway in Fig. 21.18). In pathologic conditions of high TSH or TSH-like stimulation, **megalín** expression is increased, and large amounts of thyroglobulin follow the transepithelial pathway. This pathway may reduce the extent of T_4 and T_3 release by diverting thyroglobulin away from the lysosomal pathway. Individuals with **Graves disease** and other thyroid diseases have detectable amounts of circulating thyroglobulin that contains portions of megalín receptor.

6. **Release of T_4 and T_3** from follicular cells into the circulation. Follicular cells predominately produce T_4 in a T_4 -to- T_3 ratio of 20:1. Most of the T_4 and T_3 produced is liberated from thyroglobulin in the lysosomal pathway, and only negligible amounts of T_4 and T_3 are released bound to thyroglobulin. Both T_4 and T_3 cross the basal membrane and enter the blood and lymphatic capillaries. Most of the released hormones are immediately bound to a specific plasma protein (54 kDa), **thyroxine-binding globulin (TBG)** (~70%), or a prealbumin fraction of serum protein called **transthyretin** (~20%). T_4 has a stronger bond to TBG, whereas T_3 has a stronger bond to transthyretin. Less than approximately 10% of released hormones are bound to a nonspecific fraction of **albumin**, leaving only small amounts (~1%) of free circulating hormones that are metabolically active. The free circulating hormones also function in the feedback system that regulates the secretory activity of the thyroid (Fig. 21.19). One-third of circulating T_4 is converted to T_3 in peripheral

organs, such as the kidney, liver, and heart. T_3 is five times more potent than T_4 and is mainly responsible for biological activity by binding to the thyroid nuclear receptors in the target cells.

FIGURE 21.19. Production, transport, and regulation of thyroid hormones. Production of T_4 and T_3 is regulated through a negative feedback system. The follicular cells of the thyroid gland predominately produce about 20 times more T_4 than T_3 ; however, T_4 is converted in the peripheral organs (e.g., liver, kidney) to a more active form of T_3 . Approximately 99% of T_4 and T_3 released from the thyroid gland into the circulation bind to specific plasma proteins. The remaining free (unbound) T_4 and T_3 exert negative feedback on the system and inhibit the further release of T_4 and T_3 . This inhibition occurs at the level of the anterior lobe of the pituitary gland and the hypothalamus. At the pituitary level, T_4 and T_3 inhibit secretion of TSH by thyrotropes. To elicit an inhibitory effect on the hypothalamus, both T_4 and T_3 need to cross the blood-brain barrier by utilizing the OATP thyroid hormone transporter expressed on the membrane of the endothelial cells. Increased concentration of T_4 and T_3 reduces expression of OATP transporters as part of the negative feedback loop, thus decreasing the amount of available thyroid hormones in the brain. After crossing the blood-brain barrier, T_4 and T_3 are transferred into neighboring astrocytes, where T_4 is converted to T_3 . Note that T_3 is the predominant hormone that enters the neurons. T_4 and T_3 are also secreted into the cerebrospinal fluid and are taken up by the tanycytes (specialized

ependymal cells) and astrocytes, where T_4 is converted to T_3 . In addition to TRH, which also stimulates the production of prolactin in lactotropes, the hypothalamus secretes somatostatin that has an inhibitory effect on TSH production by thyrotropes. The feedback system is activated in response to low thyroid hormone levels in the blood or metabolic needs. In addition to chemical control mechanisms, a variety of nerve endings in the hypothalamus regulate secretion of TRH. For example, cold stress increases secretion of TRH, whereas increased body temperature inhibits TRH secretion. *CNS*, central nervous system; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone (thyrotropin); *OATP*, organic anion-transporting polypeptides.

Transport across the cell membrane is essential for thyroid hormone action and metabolism.

Based on the biochemical structure of thyroid hormones, it was long thought that thyroid hormones can enter the cell by simple diffusion. However, it is now well established that thyroid hormones are transported across cell membranes by several **thyroid hormone transporter molecules**. Within the CNS, T_3 and T_4 are transported via the blood-brain barrier to the nerve and glial cells by **monocarboxylate transporter-8 (MCT8)** and **MCT10** as well as a family of **organic anion-transporting polypeptides (OATPs)**. For example, the OATP1C1 transporter is exclusively expressed on the endothelial cells forming the blood-brain barrier and is responsible for T_4 uptake into the brain. The MCT8 is also found in the heart, kidney, liver, and skeletal muscle. **Mutations in the MCT8 gene cause severe psychomotor and intellectual disability associated with high serum T_3 levels in affected male individuals, a condition known as Allan-Herndon-Dudley syndrome.** Defective MCT8 transporters are unable to transport T_3 into nerve cells, which disrupts normal brain development. Because T_3 is not utilized by nerve cells, excessive amounts of this hormone continue to circulate in the blood, causing signs and symptoms of thyroid hormone toxicity.

The triiodothyronine (T_3) hormone is more biologically active than thyroxine (T_4).

Once T_3 and T_4 molecules enter the cell, they interact with a specific **thyroid nuclear receptor** that is similar to the nuclear-initiated steroid signaling pathway (see Fig. 21.4b). T_3 binds to nuclear receptors much faster and with higher affinity than T_4 ; thus, T_3 is more rapidly and biologically active than T_4 . In addition, T_3 binds to mitochondria, increasing the production of adenosine triphosphate (ATP). Therefore, **biological activity** and metabolic effect of the

thyroid hormone are largely determined by the intracellular concentration of T_3 .

Several factors impact the intracellular concentration of T_3 . These include serum concentration of circulating T_3 , which depends on the conversion rate of T_4 to T_3 in the peripheral organs; transport of thyroid hormones across the cell membrane by specialized thyroid hormone transporters; and the presence of **iodothyronine deiodinase** enzymes, which activate or inactivate thyroid hormones. For instance, two deiodinase enzymes called D_1 and D_2 convert T_4 to the more active T_3 , whereas the third enzyme called D_3 degrades T_4 to the inactive form of rT_3 (reverse T_3) and DIT. Both T_3 and T_4 are deiodinated and deaminated in the target tissues, conjugated in the liver, and then passed into the bile, where they are excreted into the intestine. Conjugated and free hormones are also excreted by the kidney.

Thyroid hormones play an essential role in normal fetal development.

In humans, **thyroid hormones** are essential to normal growth and development. In normal pregnancy, both T_3 and T_4 cross the placental barrier and are critical in the early stages of brain development. In addition, the fetal thyroid gland begins to function during the 14th week of gestation and also contributes additional thyroid hormones. Thyroid hormone deficiency during fetal development results in irreversible damage to the central nervous system (CNS), causing reduced numbers of neurons, defective myelination, and intellectual disability. If maternal thyroid deficiency is present before the development of the fetal thyroid gland, intellectual disability can be severe. Recent studies reveal that thyroid hormones also stimulate gene expression for GH in the somatotropes. Therefore, in addition to neural abnormalities, a generalized stunted body growth is typical. The combination of these two abnormalities is called **congenital hypothyroidism**.

FOLDER 21.4

CLINICAL CORRELATION: ABNORMAL THYROID FUNCTION

The most common symptom of thyroid disease is **goiter**, the enlargement of the thyroid gland. It may indicate either hypothyroidism or hyperthyroidism.

Hypothyroidism can be caused by insufficient dietary iodine (**iodine-deficiency goiter**, **endemic goiter**) or by one of several inherited autoimmune diseases, such as **autoimmune thyroiditis** (**Hashimoto thyroiditis**). Autoimmune thyroiditis is characterized by the presence of abnormal autoimmunoglobulins directed against thyroglobulin (TgAb), thyroid peroxidase (TPOAb), and the thyroid-stimulating hormone (TSH) receptor (TSHAb). The results are thyroid cell apoptosis and follicular destruction. The low levels of circulating thyroid hormone stimulate release of excessive

amounts of TSH, which cause hypertrophy of the thyroid through synthesis of more thyroglobulin. Adult **hypothyroidism**, formerly called *myxedema* (due to the puffy appearance of the skin), is characterized by mental and physical sluggishness. The edema that occurs in the severe stages of hypothyroidism is caused by the accumulation of large amounts of hyaluronan in the extracellular matrix of the connective tissue of the dermis.

In **hyperthyroidism** (toxic goiter or Graves disease), excessive amounts of thyroid hormones are released into the circulation. Individuals with Graves disease have detectable levels of autoantibodies. These abnormal immunoglobulins G (IgG) bind to the TSH receptors on the follicular cells and stimulate adenylate cyclase activity. As a result, increased levels of cyclic adenosine monophosphate (cAMP) in follicular cells lead to continuous stimulation of the cells and increased thyroid hormone secretion. Because of negative feedback, the levels of TSH in the circulation are usually normal. However, under such stimulation, the thyroid gland undergoes hypertrophy, and thyroid hormone is secreted at abnormally high rates, causing increased metabolism. Most of the clinical features are associated with increased metabolic rate and increased sympathetic nerve activities. These include weight loss, excessive sweating, tachycardia, and nervousness. Noticeable signs include protrusion of the eyeballs and retraction of the eyelids, resulting from increased sympathetic activity and increased deposition of extracellular matrix in the adipose tissue located behind the eyeball (Fig. F21.4.1a). The thyroid gland is enlarged. Microscopic features include the presence of columnar follicular cells lining the thyroid follicles. Because of the high utilization of colloid, the colloid tends to be depleted in the areas of contact with the apical surface of follicular cells (Fig. F21.4.1b). Treatment for Graves disease is either surgery to remove the thyroid gland or radiotherapy by ingestion of radioactive iodine (^{131}I), which destroys most active follicular cells.

FIGURE F21.4.1. Hyperthyroidism. a. A young woman with signs of hyperthyroidism. Note the enlarged mass on the neck and the typical ocular symptoms known as *exophthalmos*. b. Photomicrograph of a thyroid gland

specimen from an individual with Graves disease. Owing to the increased utilization of colloid, there is a lack of staining at the periphery of the colloid near the apical surface of the follicular cell. Note that the majority of the cells are columnar in shape. (Reprinted with permission from Rubin E, Gorstein F, Rubin R, et al. *Rubin's Pathology, Clinicopathologic Foundations of Medicine*. 4th ed. Lippincott Williams & Wilkins; 2005.)

■ PARATHYROID GLANDS

The **parathyroid glands** are small endocrine glands closely associated with the thyroid. They are ovoid, a few millimeters in diameter, and arranged in two pairs, constituting the **superior** and **inferior parathyroid glands**. They are usually located in the connective tissue on the posterior surface of the lateral lobes of the thyroid gland (see Fig. 21.14 and Plate 21.4, page 856). However, the number and location may vary. In 2%-10% of individuals, additional glands are associated with the thymus.

Structurally, each parathyroid gland is surrounded by a thin connective tissue capsule that separates it from the thyroid. Septa extend from the capsule into the gland to divide it into poorly defined lobules and to separate the densely packed cords of cells. The connective tissue is more evident in the adult, with the development of fat cells that increase with age and ultimately constitute as much as 60%-70% of the glandular mass.

The glands receive their blood supply from the inferior thyroid arteries or anastomoses between the superior and inferior thyroid arteries. Typical of endocrine glands, rich networks of fenestrated blood capillaries and lymphatic capillaries surround the parenchyma of the parathyroids.

Parathyroid glands develop from the endodermal cells derived from the third and fourth pharyngeal pouches.

Embryologically, the **inferior parathyroid glands** (and the thymus) are derived from the superiorly located third pharyngeal pouch; the **superior parathyroid glands** (and ultimobranchial body) are derived from the fourth pharyngeal pouch. Initially, the inferior parathyroid glands descend with the thymus. Later, the inferior parathyroid glands separate from the thymus and come to lie below the superior parathyroid glands. **Failure of these structures to separate results in the atypical association of the parathyroid glands with the thymus in the adult.** The principal (chief) cells differentiate during embryonic development and are functionally active in regulating fetal calcium metabolism. The oxyphil cells differentiate later at puberty.

Principal cells and oxyphil cells constitute the epithelial cells of the parathyroid gland.

- **Principal (chief) cells**, the more numerous of the parenchymal cells of the parathyroid (Fig. 21.20), are responsible for regulating the synthesis, storage, and secretion of large amounts of **PTH**. They are small, polygonal cells, with a diameter of 7-10 μm and a centrally located nucleus. The pale-staining, slightly acidophilic cytoplasm contains lipofuscin-containing vesicles, large accumulations of glycogen, and lipid droplets. Small, dense, membrane-limited vesicles seen with the TEM or after using special stains with the light microscope are thought to be the storage form of PTH. Principal cells can replicate when they are chronically stimulated by changes in blood calcium levels.

FIGURE 21.20. Photomicrograph of human parathyroid gland. This hematoxylin and eosin (H&E)-stained specimen shows the gland with part of its connective tissue capsule (*Cap*). The blood vessels (*BV*) are located in the connective tissue septum between the lobes of the gland. The principal cells are arranged in two masses (*top* and *bottom*) and are separated by a large cluster of oxyphil cells (*center*). The oxyphil cells are the larger cell type with prominent eosinophilic cytoplasm. They may occur in small groups or larger masses, as seen here. The principal cells are more numerous. They are smaller, have less cytoplasm, and consequently exhibit closer proximity to

their nuclei. Adipose cells (*AC*) are present in variable, although limited, numbers. $\times 175$.

- **Oxyphil cells** constitute a minor portion of the parenchymal cells and are not known to have a secretory role. They are found either singly or in clusters; the cells are more rounded, considerably larger than the principal cells, and have a distinctly acidophilic cytoplasm (see Fig. 21.20). Mitochondria, often with bizarre shapes and sizes, almost fill the cytoplasm and are responsible for the strong acidophilia of these cells. No secretory vesicles and little, if any, rER are present. Cytoplasmic inclusion bodies consist of occasional lysosomes, lipid droplets, and glycogen distributed among the mitochondria.

Parathyroid hormone regulates calcium and phosphate levels in the blood.

The parathyroids function in the regulation of calcium and phosphate levels. **Parathyroid hormone (PTH)** is essential for life. Therefore, care must be taken during thyroidectomy to leave some functioning parathyroid tissue. If the glands are totally removed, death will ensue because muscles, including the laryngeal and other respiratory muscles, go into tetanic contraction as the blood calcium level falls.

PTH is an 84-amino-acid linear peptide (Table 21.8). It binds to a specific PTH receptor on target cells that interacts with G-protein to activate a second messenger system. PTH release causes the **level of calcium in the blood to increase**. Simultaneously, it reduces the concentration of serum phosphate. Secretion of PTH is regulated by the serum calcium level through a simple feedback system. When parathyroid calcium-sensing receptors on principal cells detect low serum calcium levels, they stimulate secretion of PTH; high levels of serum calcium inhibit its secretion.

TABLE 21.8

Parathyroid Hormone

Hormone	Composition	Source	Major Functions
Parathyroid hormone (PTH)	Polypeptide containing 84 amino acids	Principal (chief) cells ^a	Increases blood calcium level in three ways: (1) promotes calcium release from bone (acting on osteoblasts via RANK-RANKL signaling system, it increases the relative number of osteoclasts); (2) acts on the kidney to stimulate calcium reabsorption by the distal

tubule while inhibiting phosphate reabsorption in the proximal tubule; and (3) increases formation of hormonally active 1,25-dihydroxycholecalciferol (1,25-[OH]₂ vitamin D₃) in the kidney, which promotes tubular reabsorption of calcium

^aSome evidence suggests that oxyphil cells, which first appear in the parathyroid gland at about 4–7 years of age and increase in number after puberty, may also produce PTH.

RANK-RANKL, receptor activator of NF- κ B-receptor activator NF- κ B ligand.

PTH functions at several sites:

- **Action on bone tissue.** Until recently, bone resorption had been considered the major effect of PTH action on bone. However, the actions of PTH on bone are more complicated. PTH acts directly and indirectly on several cell types. Receptors for PTH are found on osteoprogenitor cells, osteoblasts, osteocytes, and bone-lining cells. Surprisingly, the bone-resorbing osteoclasts do not have PTH receptors; thus, they are indirectly activated by the RANK-RANKL signaling mechanism of osteoblasts (pages 250–251). The prolonged continuous exposure of PTH increases local RANK production in the osteoblasts and decreases osteoprotegerin (OPG) secretion. These changes then stimulate osteoclast differentiation, which leads to increased bone resorption and release of calcium and phosphates into the extracellular fluid. Briefly, intermittent exposure to PTH increases bone mass through the cAMP/IGF-I pathway in osteocytes and osteoblasts. **This anabolic effect of increasing bone mass by intermittent dosing of PTH is utilized in the treatment of osteoporosis (see Folder 8.2 in Chapter 8, Bone, pages 263–264).**
- **Kidney excretion of calcium** is decreased by PTH stimulation of tubular reabsorption, thus conserving calcium.
- **Urinary phosphate excretion** is increased by PTH secretion, thus lowering phosphate concentration in the blood and extracellular fluids.
- **Kidney conversion of 25-OH vitamin D₃ to hormonally active 1,25-(OH)₂ vitamin D₃** is regulated primarily by PTH, which stimulates the activity of 1 α -hydroxylase and increases the production of active hormone.
- **Intestinal absorption of calcium** is increased under the influence of PTH. Vitamin D₃, however, has a greater effect than PTH on the intestinal absorption of calcium.

PTH and calcitonin have reciprocal effects in the regulation of blood calcium levels.

Although PTH increases blood calcium levels, the peak increase after its release is not reached for several hours. PTH appears to have a rather slow, long-term homeostatic action. Calcitonin, however, rapidly lowers blood calcium levels and has its peak effect in about 1 hour; therefore, it has a rapid, acute homeostatic action.

■ ADRENAL GLANDS

The adrenal (suprarenal) glands are paired organs located in the retroperitoneal space of the abdominal cavity. The right gland is flattened and triangular, and the left gland is semilunar in shape. They are both embedded in the perirenal fat at the superior poles of the kidneys (Fig. 21.21). The adrenal glands secrete steroid hormones and catecholamines.

FIGURE 21.21. Topography and blood supply of the adrenal (suprarenal) gland. This drawing shows the location of the left adrenal gland at the superior pole of the left kidney. The perirenal fat has been removed from this image to show blood supply to the organ. Note that the adrenal gland is supplied by three arteries. The middle suprarenal artery originates directly from the aorta, whereas the superior and inferior suprarenal arteries originate from the left inferior phrenic and left renal arteries, respectively. Blood drains into the suprarenal vein, which, on the *left* side, empties into the left renal vein and, on the *right* side, directly into the inferior vena cava.

The adrenal glands are covered with a thick connective tissue **capsule** from which trabeculae extend into the parenchyma, carrying blood vessels and nerves. The secretory parenchymal tissue is organized into two distinct regions (Fig. 21.22 and Plate 21.5, page 858):

FIGURE 21.22. Photomicrograph of the adrenal gland. This low-power micrograph of a hematoxylin and eosin (H&E)-stained specimen shows the full thickness of the adrenal gland with the cortex seen on both surfaces and a central region containing the medulla. Within the medulla are profiles of the central vein. Note that the deeper portion of the cortex stains darker than the outer portion, a reflection of the washed-out lipid in the zona glomerulosa and outer region of the zona fasciculata. This section also includes a cross section of the adrenal vein, which is characterized by the longitudinally arranged bundles of smooth muscle in its wall. $\times 20$.

- The **cortex** is the steroid-secreting portion. It lies beneath the capsule and constitutes nearly 90% of the gland by weight.
- The **medulla** is the catecholamine-secreting portion. It lies deep into the cortex and forms the center of the gland.

Parenchymal cells of the cortex and medulla are of different embryologic origin.

Embryologically, the cortical cells originate from **mesodermal mesenchyme**, whereas the medulla originates from **neural crest** cells that migrate into the developing gland (Fig. 21.23). Although embryologically distinct, the two portions of the adrenal gland are functionally related (see later). The parenchymal cells of the adrenal cortex are controlled in part by the anterior lobe of the pituitary gland and function in regulating metabolism and maintaining normal electrolyte balance (Table 21.9).

TABLE 21.9 Hormones of the Adrenal Glands

Hormone	Composition	Source	Major Functions
Adrenal Cortex			
Mineralocorticoids: aldosterone (95% of mineralocorticoid activity in aldosterone)	Steroid hormones (cholesterol derivatives)	Parenchymal cells of the zona glomerulosa	Aid in controlling electrolyte homeostasis (act on distal tubule of kidney to increase sodium reabsorption and decrease potassium reabsorption); function in maintaining the osmotic balance in the urine and in preventing serum acidosis
Glucocorticoids: corticosterone and cortisol (95% of glucocorticoid activity is in cortisol)	Steroid hormones (cholesterol derivatives)	Parenchymal cells of the zona fasciculata (and, to a lesser extent, of	Promote normal metabolism, particularly carbohydrate metabolism (increase rate of amino acid transport to

the zona

FIGURE 21.23. Development of the adrenal gland. **a.** In this early stage, the cortex is shown developing from cells of the intermediate mesoderm, and the medulla is shown differentiating from cells in the neural crest and migrating from the neighboring sympathetic ganglion. The cells that form the fetal cortex originate from mesothelial cells located between the root of the dorsal mesentery and the developing urogenital ridges (future gonads). They divide and differentiate into fetal cortex cells. **b.** Mesodermal cells from the fetal

cortex surround the cells of the developing medulla. Later, more mesenchymal cells arrive from the mesothelium of the posterior abdominal wall. They surround the original mass of cells containing the fetal cortex cells and chromaffin cells. These cells later give rise to the permanent cortex. c. At this stage (about 7 months of development), the fetal cortex occupies about 70% of the cortex. The permanent cortex develops outside the fetal cortex. d. The fully developed adrenal cortex is visible at the age of 4 months. The permanent cortex replaces the fetal cortex, which at this age has completely disappeared. Note the fully developed zonation of the permanent cortex.

Blood Supply

Each **adrenal gland** is supplied with blood by the **superior, middle, and inferior suprarenal arteries** and drained by the **suprarenal veins** (see Fig. 21.21). On the left side, the suprarenal vein drains into the left renal vein, whereas on the right side, the suprarenal vein drains directly into the inferior vena cava. These vessels branch before entering the capsule to produce many small arteries that penetrate the capsule. In the capsule, the arteries branch to give rise to three principal patterns of blood distribution (Fig. 21.24). The vessels form a system that consists of the following:

FIGURE 21.24. Organization and blood supply of the human adrenal gland. This diagram shows the blood supply to the adrenal cortex and medulla. The cortical arterioles form a cortical network of capillaries, which drain into a second capillary network in the medulla. The medullary capillary network is formed primarily by the medullary arterioles and drains into the central medullary vein. Adrenal medulla, zones of the cortex, and features of basic cell types and their secretory products are noted. *DHEA*, dehydroepiandrosterone; *DHEAS*, dehydroepiandrosterone sulfate.

- **Capsular capillaries** that supply the capsule

- **Fenestrated cortical sinusoidal capillaries** that supply the cortex and then drain into the fenestrated medullary capillary sinusoids
- **Medullary arterioles** that traverse the cortex, traveling within the trabeculae, and bring arterial blood to the **medullary capillary sinusoids**

The medulla thus has a dual blood supply: arterial blood from the medullary arterioles and venous blood from the cortical sinusoidal capillaries that have already supplied the cortex. The venules that arise from the cortical and medullary sinusoids drain into the small adrenomedullary collecting veins that join to form the large **central adrenomedullary vein**, which then drains directly as the suprarenal vein into the inferior vena cava on the right side and into the left renal vein on the left side (see Fig. 21.21). In humans, the central adrenomedullary vein and its tributaries are unusual in that they have a tunica media containing conspicuous, longitudinally oriented bundles of smooth muscle cells (Fig. 21.25). Synchronous contraction of longitudinal smooth muscle bundles along the central adrenomedullary vein and its tributaries causes the volume of the adrenal gland to decrease. This decreased volume enhances the efflux of hormones from the adrenal medulla into the circulation, an action comparable to squeezing a wet sponge.

FIGURE 21.25. Photomicrograph of the central adrenomedullary vein. This photomicrograph shows the center of the adrenal gland with a central adrenomedullary vein in the *middle*. The wall of the vein has a highly irregular appearance, containing several prominent smooth muscle (*SM*) projections (also called *muscle cushions*) into the lumen. These projections represent longitudinal bundles of smooth muscles of the tunica media. In areas where muscle bundles are absent, cells of the adrenal medulla (*lower part of the*

image) or sometimes adrenal cortex (*upper part of the image*) are separated from the lumen only by a thin layer of tunica intima. Note the close proximity of zona reticularis to the lumen of the vein. $\times 180$.

Lymphatic vessels are present in the capsule and the connective tissue around the larger blood vessels in the gland. They also have been found in the parenchyma of the adrenal medulla. The lymphatic vessels have an important role in distributing **chromogranin A**, a secretory product of chromaffin cells. Chromogranin A is a 48-kDa intracellular storage protein complex for epinephrine and norepinephrine and is also a precursor molecule for several regulatory peptides, including vasostatin 1 and 2 (VST I, VST II), pancreastatin (PST), catestatin (CST), and parastatin (PARA). These peptides negatively modulate the neuroendocrine function of the chromaffin cells (autocrine effect) and other hormone-producing cells in distant organs.

Cells of the Adrenal Medulla

Chromaffin cells located in the adrenal medulla are innervated by presynaptic sympathetic neurons.

The central portion of the adrenal gland, the **medulla**, is composed of a parenchyma of large, pale-staining epithelioid cells called **chromaffin cells (medullary cells)**, connective tissue, numerous sinusoidal blood capillaries, and nerves. The chromaffin cells are, in effect, modified neurons (Folder 21.5). Numerous myelinated, presynaptic sympathetic nerve fibers pass directly to the chromaffin cells of the medulla (see Chapter 12, Nerve Tissue, page 421). When nerve impulses carried by the sympathetic fibers reach the catecholamine-secreting chromaffin cells, they release their secretory products. Therefore, chromaffin cells are considered the equivalent of postsynaptic neurons. However, they lack axonal processes. Experimental studies reveal that when chromaffin cells are grown in culture, they extend axon-like processes. However, axonal growth can be inhibited by glucocorticoids—hormones secreted by the adrenal cortex. Thus, the hormones of the adrenal cortex exert control over the morphology of the chromaffin cells and prevent them from forming neural processes. Chromaffin cells, therefore, more closely resemble typical endocrine cells, in that their secretory product enters the bloodstream via the fenestrated capillaries.

FOLDER 21.5

CLINICAL CORRELATION: CHROMAFFIN CELLS AND PHEOCHROMOCYTOMA

Chromaffin cells (so named because they react with chromate salts) of the adrenal medulla are part of the amine precursor uptake and decarboxylation

(APUD) system of cells. The chromaffin reaction is thought to involve oxidation and polymerization of the catecholamines contained within the secretory vesicles of these cells. Classically, chromaffin cells have been defined as being derived from neuroectoderm, innervated by presynaptic sympathetic nerve fibers, and capable of synthesizing and secreting catecholamines.

A rare tumor derived from chromaffin cells, called **pheochromocytoma**, produces excessive amounts of catecholamines. Because chromaffin cells are also found outside the adrenal medulla in paravertebral and prevertebral sympathetic ganglia and other locations, tumors may arise from outside the adrenal gland. These extra-adrenal pheochromocytomas are called **paragangliomas** because scattered groups of chromaffin cells located among or near the components of the autonomic nervous system (ANS) are called *paraganglia*. Pheochromocytomas may cause episodic symptoms related to the pharmacologic effects of excessive catecholamine secretion and are often described according to the “rule of 10s” :

- 10% are extra-adrenal (paragangliomas), and of those, 10% reside outside the abdomen.
- 10% occur in children.
- 10% are multiple or bilateral.
- 10% are not associated with hypertension.
- 10% are malignant.
- 10% are familial.
- 10% recur after surgical removal.
- 10% are found incidentally during unrelated imaging studies.

Pheochromocytomas may precipitate life-threatening hypertension, cardiac arrhythmias, anxiety, and fear of impending death. Most pheochromocytomas contain predominantly chromaffin cells that secrete norepinephrine compared with the normal adrenal medulla that comprises about 85% epinephrine-secreting cells. Stimulation of α -adrenergic receptors results in elevated blood pressure, increased cardiac contractility, glycogenolysis, gluconeogenesis, and intestinal relaxation. Stimulation of β -adrenergic receptors results in an increased heart rate and contractility. Surgical resection of the tumor is the treatment of choice. Careful monitoring with α - and β -blockers is required during surgery to prevent hypertensive crises.

Ganglion cells are also present in the medulla. Their axons extend peripherally to the parenchyma of the adrenal cortex to modulate its secretory activity and innervate blood vessels and extend outside the gland to the splanchnic nerves innervating abdominal organs.

Chromaffin cells of the adrenal medulla have a secretory function.

Chromaffin cells are organized in ovoid clusters and short interconnecting cords (Plate 21.6, page 860). The blood capillaries are arranged in intimate relation to the parenchyma. They originate either from the cortical capillaries or, as branches, from the cortical arterioles.

Ultrastructurally, the chromaffin cells are characterized by numerous secretory vesicles with diameters of 100–300 nm, profiles of

rER, and a well-developed Golgi apparatus. The secretory material in the vesicles can be stained specifically to demonstrate histochemically that the catecholamines epinephrine and norepinephrine secreted by the chromaffin cells are produced by different cell types (Fig. 21.26). The TEM also reveals two populations of chromaffin cells distinguished by the nature of their membrane-bound vesicles:

FIGURE 21.26. Electron micrograph of medullary cells. Two types of medullary cells are present. The norepinephrine-secreting cells (*NE*) are identified by their vesicles, which contain a very dense core. The epinephrine-secreting cells (*E*) possess vesicles with less intensely staining granules. $\times 15,000$.

- One population of cells contains only large **dense-core vesicles**. These cells secrete norepinephrine.
- The other population of cells **contains vesicles** that are smaller, more homogeneous, and less dense. These cells secrete epinephrine.

Exocytosis of the secretory vesicles is triggered by the release of acetylcholine from presynaptic sympathetic axons that synapse with each chromaffin cell.

Epinephrine and **norepinephrine** account for less than 20% of the contents of the medullary secretory vesicles. The vesicles also contain large amounts of soluble 48-kDa proteins, called **chromogranins**, that appear to impart the density of the vesicles' contents. These proteins, along with ATP and Ca^{2+} , may help bind the low-molecular-weight catecholamines and are released with the hormones during exocytosis. The catecholamines, synthesized in the cytosol, are transported into the vesicles through the action of a magnesium-activated ATPase in the membrane of the vesicle. **Drugs such as reserpine, which cause depletion of catecholamines from the vesicles, may act by inhibiting this transport mechanism.**

Glucocorticoids secreted in the cortex induce the conversion of norepinephrine to epinephrine in chromaffin cells.

Glucocorticoids produced in the adrenal cortex reach the medulla directly through the continuity of the cortical and medullary sinusoidal capillaries. They induce the enzyme that catalyzes the methylation of norepinephrine to produce epinephrine. The nature of the blood flow correlates with regional differences in the distribution of norepinephrine- and epinephrine-containing chromaffin cells. The epinephrine-containing cells are more numerous in areas of the medulla supplied with blood that has passed through the cortical sinusoids and thus contains secreted glucocorticoids. In some species, the norepinephrine-containing cells are more numerous in those regions of the medulla supplied by capillaries derived from the cortical arterioles.

The catecholamines, in concert with the glucocorticoids, prepare the body for the “fight-or-flight” response.

The **sudden release of catecholamines** establishes conditions for maximum use of energy and thus maximum physical effort. Both epinephrine and norepinephrine stimulate glycogenolysis (release glucose into the bloodstream) and mobilization of free fatty acids from adipose tissue. The release of catecholamines also causes an increase in blood pressure, dilation of the coronary blood vessels, vasodilation

of vessels supplying skeletal muscle, vasoconstriction of vessels conveying blood to the skin and gut, an increase in heart rate and output, and an increase in the rate and depth of breathing.

Zonation of the Adrenal Cortex

The **adrenal cortex** is divided into three zones on the basis of the arrangement of its cells (Fig. 21.27):

FIGURE 21.27. Photomicrographs of the cortex and medulla of the human adrenal gland. **a.** This photomicrograph shows a hematoxylin and eosin (H&E)-stained specimen of the outer cortex. It includes the connective tissue capsule, the zona glomerulosa, and the zona fasciculata. Continuous with the zona glomerulosa are the straight cords of cells that characterize the zona fasciculata. Between the cords are the capillaries and the less numerous arterioles. The *red* linear stripes represent capillaries that are engorged with red blood cells. $\times 120$. **b.** The deep parts of the zona fasciculata, zona reticularis, and medulla are shown here. Note that the linear arrays of the cords in the zona fasciculata give way to irregular groups of cells of the zona reticularis. The medulla, in contrast, consists of ovoid groups of cells and short interconnecting cords of cells. A central adrenomedullary vein is also seen here. Note a cross section of the thick longitudinally arranged smooth muscle bundle in part of its wall. $\times 120$.

- **Zona glomerulosa**, the narrow outer zone that constitutes up to 15% of the cortical volume
- **Zona fasciculata**, the thick middle zone that constitutes nearly 80% of the cortical volume
- **Zona reticularis**, the inner zone that constitutes only 5%–7% of the cortical volume but is thicker than the glomerulosa because of its

more central location

Zona Glomerulosa

The cells of the **zona glomerulosa** [*Lat. glomus, ball*] are arranged in closely packed ovoid clusters and curved columns that are continuous with the cellular cords in the zona fasciculata (see Fig. 21.27a). Cells of the zona glomerulosa are relatively small and columnar or pyramidal (see Fig. 21.24). Their spherical nuclei appear closely packed and stain densely. In humans, some areas of the cortex may lack a recognizable zona glomerulosa. A rich network of fenestrated sinusoidal capillaries surrounds each cell cluster. The cells have abundant sER, multiple Golgi complexes, large mitochondria with shelf-like cristae, free ribosomes, and some rER. Lipid droplets are sparse.

The zona glomerulosa secretes aldosterone, which functions in the control of blood pressure.

The cells of the zona glomerulosa secrete the primary **mineralocorticoid** called **aldosterone**, a compound that functions in the regulation of sodium and potassium homeostasis and water balance. Aldosterone acts on the principal cells in the distal tubules of the nephron in the kidney, the gastric mucosa, and the salivary and sweat glands to stimulate resorption of sodium at these sites as well as to stimulate excretion of potassium by the kidney. Aldosterone is produced from **cholesterol** by a series of enzymatic reactions controlled by angiotensin II (see later). The final step of aldosterone biosynthesis is facilitated by **aldosterone synthase**, which is exclusively expressed in cells of the zona glomerulosa. Cells of the zona glomerulosa lack the enzyme 17α -hydrolase and, therefore, are unable to produce other adrenal steroid hormones, such as cortisol or adrenal androgens.

The renin-angiotensin-aldosterone system provides feedback control for the zona glomerulosa.

The zona glomerulosa is under feedback control of the **renin-angiotensin-aldosterone system (RAAS)**. The **juxtaglomerular cells** in the kidney release **renin** in response to a decrease in blood pressure or a low blood sodium level. Circulating renin catalyzes the conversion of circulating **angiotensinogen** to **angiotensin I**, which, in turn, is converted by angiotensin-converting enzyme (ACE) in the lung to **angiotensin II**. Angiotensin II then stimulates the cells of the zona glomerulosa to produce and secrete **aldosterone**. As the blood pressure, sodium concentration, and blood volume increase in response to aldosterone, the release of renin from the juxtaglomerular cells is

inhibited. Drugs that inhibit ACE in the lung are effective in the treatment of chronic essential hypertension.

Zona Fasciculata

The cells of the **zona fasciculata** [*Lat. fascis, bundle*] are large and polyhedral. They are arranged in long straight cords, one or two cells thick, that are separated by sinusoidal capillaries (see Fig. 21.27a). The cells of the zona fasciculata have a lightly staining spherical nucleus. Binucleate cells are common in this zone. TEM studies reveal characteristics typical of steroid-secreting cells, that is, a highly developed sER (more so than cells of the zona glomerulosa) and mitochondria with tubular cristae. They also have a well-developed Golgi apparatus and numerous profiles of rER that may give a slight basophilia to some parts of the cytoplasm (Fig. 21.28). In general, however, the cytoplasm is acidophilic and contains numerous lipid droplets, although it usually appears vacuolated in routine histologic sections because of the extraction of lipid during dehydration. The lipid droplets contain neutral fats, fatty acids, cholesterol, and phospholipids that are precursors for the steroid hormones secreted by these cells.

FIGURE 21.28. Electron micrograph of cells in the zona fasciculata. The boundary between adjacent cells of the cord is indicated by the *arrowheads*. Lipid droplets (*L*) are numerous (the lipid has been partially extracted). $\times 15,000$. Inset. A higher magnification of an area in the cell at the *top* of the micrograph reveals the extensive sER that is characteristic of steroid-secreting cells. Portions of the Golgi apparatus are also evident. $\times 40,000$. *sER*, smooth-surfaced endoplasmic reticulum.

The principal secretion of the zona fasciculata is glucocorticoids that regulate glucose and fatty acid metabolism.

Cells in the zona fasciculata cannot produce aldosterone because they lack the enzyme aldosterone synthase. However, they do possess two other important enzymes, 17α -hydrolase and $17,20$ -lyase, to produce **glucocorticoids** and small amounts of **gonadocorticoids (adrenal androgens)**. Glucocorticoids are named for their role in regulating **gluconeogenesis** (glucose synthesis) and **glycogenesis** (glycogen polymerization). One of the major glucocorticoids secreted by the zona fasciculata, **cortisol**, acts on many different cells and tissues to increase the metabolic availability of glucose and fatty acids, both of which are immediate sources of energy. The other glucocorticoid, **corticosterone**, is secreted and circulates in the blood at 10- to 20-fold lower levels than cortisol. Within this broad function,

glucocorticoids may have different, even opposite, effects in different tissues:

- In the **liver**, glucocorticoids stimulate conversion of amino acids to glucose, stimulate the polymerization of glucose to glycogen, and promote the uptake of amino acids and fatty acids.
- In **adipose tissue**, glucocorticoids stimulate the breakdown of lipids to glycerol and free fatty acids.
- In **other tissues**, they reduce the rate of glucose use and promote the oxidation of fatty acids.
- In **cells** such as fibroblasts, they inhibit protein synthesis and even promote protein catabolism to provide amino acids for conversion to glucose in the liver.

Glucocorticoids also depress the immune and inflammatory responses and, as a result of the latter, inhibit wound healing. Hydrocortisone, a synthetic form of cortisol, is used in the treatment of allergies and inflammation. It depresses the inflammatory response by suppressing interleukin-1 (IL-1) and IL-2 production by lymphocytes and macrophages. Glucocorticoids also stimulate destruction of lymphocytes in lymph nodes and inhibit mitosis in transformed lymphoblasts.

ACTH regulates secretion of the zona fasciculata.

The secretion and production of glucocorticoids and sex steroids by the zona fasciculata is under feedback control of the **CRH - ACTH system**. ACTH is necessary for cell growth and maintenance and also stimulates steroid synthesis and increases blood flow through the adrenal gland. In animals, administration of ACTH causes hypertrophy of the zona fasciculata.

Circulating glucocorticoids may act directly on the pituitary gland, but they most commonly exert their feedback control on neurons in the arcuate nucleus of the hypothalamus, causing the release of corticotropin-releasing hormone (CRH) into the hypothalamohypophyseal portal circulation. Evidence also suggests that circulating glucocorticoids and the physiologic effects that they produce stimulate higher brain centers that, in turn, cause the hypothalamic neurons to release CRH.

Zona Reticularis

The cells of the **zona reticularis** [*Lat. rete, net*] are noticeably smaller than those of the zona fasciculata, and their nuclei are more deeply stained (see Fig. 21.24). They are arranged in anastomosing cords separated by fenestrated capillaries. The cells have relatively

few lipid droplets. Both light and dark cells are seen. Dark cells have abundant large lipofuscin pigment granules, and deeply staining nuclei are evident. The cells in this zone are small because they have less cytoplasm than the cells in the zona fasciculata; thus, the nuclei appear more closely packed. They exhibit features of steroid-secreting cells, namely, a well-developed sER and numerous elongated mitochondria with tubular cristae, but they have little rER.

The principal secretion of the zona reticularis is gonadocorticoids (adrenal androgens).

The principal secretion of the cells in the zona reticularis consists of gonadocorticoids (adrenal androgens), mostly dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), and androstenedione. The cells also secrete some glucocorticoids but in much smaller amounts than those of the zona fasciculata. Here, too, the principal glucocorticoid secreted is cortisol.

DHEA and DHEAS are less potent than androgens produced by the gonads, but they do have an effect on the development of secondary sex characteristics. In men, adrenal androgens have negligible importance because testosterone produced by the testis is a much more powerful androgen. However, in women, adrenal androgens stimulate the growth of axillary and pubic hair during puberty and adolescence. DHEA can be converted into androstenedione and then more potent androgens, such as testosterone and estrogens in peripheral tissues. The key enzyme that facilitates the conversion of androstenedione to testosterone is 17-ketosteroid reductase (17KSR), and this reaction represents a major pathway in testosterone production in women.

The zona reticularis is also regulated by the feedback control of the CRH- ACTH system and atrophies after hypophysectomy. Exogenous ACTH maintains the structure and function of the zona reticularis after hypophysectomy.

Fetal Adrenal Gland

The fetal adrenal gland consists of an outer narrow permanent cortex and an inner thick fetal cortex or fetal zone.

Once fully established, the fetal adrenal gland is unusual in terms of its organization and its large size relative to other developing organs. The gland arises from mesothelial cells of mesodermal origin located between the root of the mesentery and the developing urogenital ridges (see Fig. 21.23a). The mesodermal cells penetrate the underlying mesenchyme and give rise to a large eosinophilic cell mass that will

become the functional fetal cortex (see Fig. 21.23b). Later, a second wave of cells derived from the mesothelium of the posterior abdominal wall surrounds the primary cell mass (see Fig. 21.23b). By the fourth fetal month, the adrenal gland reaches its maximum mass in terms of body weight and is only slightly smaller than the adjacent kidney (see Fig. 21.23c). At term, the adrenal glands are equivalent in size and weight to those of the adult and produce 100–200 mg of steroid compounds per day, about twice that of the adult glands.

The histologic appearance of the fetal adrenal gland is superficially similar to that of the adult adrenal gland. During late fetal life, most of the gland consists of cords of large eosinophilic cells that constitute approximately 80% of its mass. This portion of the gland, referred to as the **fetal cortex** (also called **fetal zone**), arises from the initial mesodermal cell migration. The remainder of the gland is composed of the peripheral layer of small cells with scanty cytoplasm. This portion, referred to as the **permanent cortex**, arises from the secondary mesodermal cell migration. The narrow permanent cortex, when fully established in the embryo, appears similar to the adult zona glomerulosa. The cells are arranged in arched groups that extend into short cords. They, in turn, become continuous with the cords of the underlying fetal zone (Fig. 21.29). In H&E preparations, the cytoplasm of the cells in the permanent cortex exhibits some basophilia; in combination with the closely packed nuclei, this gives this part of the gland a blue appearance, in contrast to the eosinophilic staining of the fetal zone.

FIGURE 21.29. Photomicrographs of a human fetal adrenal gland. **a.** Low-power micrograph of a hematoxylin and eosin (H&E)-stained section of a fetal adrenal gland. The permanent cortex (*PC*) is indicated in the *upper portion* of the micrograph. Below is the fetal zone (*FZ*) in which the cells are arranged in anastomosing linear cords. Some of the capillaries (*C*) are engorged with red blood cells, thereby making them more apparent. $\times 100$. **b.** Higher power micrograph of the same specimen showing the capsule (*Cap*) and the underlying permanent cortex. The cells are arranged in arched groups that extend into short cords. Note the close proximity of the nuclei and the small amount of cytoplasm in these cells. $\times 200$. **c.** This micrograph shows the cells of the fetal zone at the same magnification as in **b**. Note the slightly larger size of the nuclei and the considerable amount of cytoplasm in each of the fetal zone cells. Also note the eosinophilia of the cytoplasm, compared with the more basophilic cytoplasm of the cells of the permanent cortex. $\times 200$. (Original specimen courtesy of Dr. William H. Donnelly.)

FOLDER 21.6

FUNCTIONAL CONSIDERATIONS: BIOSYNTHESIS OF ADRENAL HORMONES

Cholesterol is the basic precursor of several steroid hormones, namely, corticosteroids, sex hormones, bile acids, and vitamin D. About one-half of the cholesterol in the body comes from the diet, and the other one-half derives from *de novo* biosynthesis. Cholesterol synthesis occurs in the cytoplasm and organelles from acetyl-CoA. Biosynthesis in the liver accounts for ~10%, and in the intestines, ~15% of the amount is produced each day. In addition, a small portion of cholesterol is synthesized by the adrenal cortical cells. Both dietary cholesterol and that synthesized *de novo* are transported within low-density lipoproteins (LDLs). Cholesterol is stored in lipid droplets within the cytoplasm of adrenal cortical cells in the form of cholesterol esters.

Steroid hormones in adrenal glands are synthesized from cholesterol esters by removal of part of the side chain and modifications at specific sites on the remainder of the molecule. The enzymes catalyzing these modifications are located in different zones of the cortex as well as in different cytoplasmic sites within the cells. For instance, cleavage of the cholesterol side chain is catalyzed by **P450-linked side chain cleavage enzyme (P450_{scc})** or desmolase, which is found only in the mitochondria of steroid-producing cells. This enzyme is induced by angiotensin II in the zona glomerulosa and by ACTH in the zona fasciculata and zona reticularis. The other enzymes necessary for steroid production are located within smooth-surfaced endoplasmic reticulum (sER), cytosol, and mitochondria. Thus, a precursor molecule may move from the sER to a mitochondrion and back again several times before the definitive molecular structure of a given corticosteroid is obtained.

Cholesterol esters removed from cytoplasmic lipid droplets and used in steroid hormone synthesis are quickly replenished from the cholesterol esters contained within LDL carried in the bloodstream. These esters are the primary source of the cholesterol used in corticosteroid synthesis. Under conditions of short-term or prolonged ACTH stimulation, the lipid stores in adrenal cortical cells are recruited for corticosteroid synthesis.

With the TEM, the cells of the permanent cortex exhibit small mitochondria with shelf-like cristae, abundant ribosomes, and small

Golgi profiles. The cells of the fetal zone, in contrast, are considerably larger and are arranged in irregular cords of varying width. With the TEM, these cells exhibit spherical mitochondria with tubular cristae, small lipid droplets, an extensive sER that accounts for the eosinophilia of the cytoplasm, and multiple Golgi profiles. Collectively, these features are characteristic of steroid-secreting cells.

The development of the fetal adrenal gland is part of a complex process of maturation and preparation of the fetus for extrauterine life.

The fetal adrenal gland **lacks a definitive medulla**. Chromaffin cells are present but are scattered among the cells of the fetal zone and are difficult to recognize in H&E preparations. The chromaffin cells originate from the neural crest (see Fig. 21.23a) and invade the fetal zone at the time of its formation (see Fig. 21.23b). They remain in this location in small, scattered cell clusters during fetal life (see Fig. 21.23c).

The blood supply to both the permanent cortex and the fetal zone is through sinusoidal capillaries that course between the cords and join to form larger venous channels in the center of the gland. Unlike the postnatal adrenal, arterioles are absent in the parenchyma of the fetal adrenal gland.

Functionally, the fetal adrenal gland is under the control of the CRH- ACTH feedback system through the fetal pituitary. It interacts with the placenta to function as a steroid-secreting organ because it lacks certain enzymes necessary for steroid synthesis that are present in the placenta. Similarly, the placenta lacks certain enzymes necessary for steroid synthesis that are present in the fetal adrenal gland. Thus, the fetal adrenal gland is part of a **fetal - placental unit**. Precursor molecules are transported back and forth between the two organs to enable the synthesis of glucocorticoids, aldosterone, androgens, and estrogens.

At birth, the fetal cortex undergoes a rapid involution that reduces the gland within the first postnatal month to about a quarter of its previous size. The permanent cortex grows and matures to form the characteristic zonation of the adult cortex. With the involution and disappearance of the fetal zone cells, the chromaffin cells aggregate to form the medulla. **If the adrenal glands fail to develop properly, congenital adrenal hyperplasia (CAH) may result. CAH represents a group of autosomal recessive disorders characterized by a deficiency of an enzyme involved in the synthesis of cortisol and/or aldosterone. Deficiency of enzyme 21-hydroxylase involved in the aldosterone**

synthesis pathway is the most common form of CAH, accounting for more than 90% of cases.

ENDOCRINE ORGANS

OVERVIEW OF THE ENDOCRINE SYSTEM

- The **endocrine system** produces various secretions called **hormones** and hormonally active substances that enter the circulatory system for transport to target cells.
- Hormones and hormonally active substances are divided into three classes of compounds: **peptides** (e.g., insulin, GH, ACTH), **steroids** (gonadal and adrenocortical steroids), and **amino acids** and **arachidonic acid analogs** (e.g., catecholamines, prostaglandins).
- Hormones interact with specific **cell surface receptors** (peptide hormones or catecholamines) or **intracellular receptors** (steroids and thyroid hormones).
- Regulation of hormonal function is controlled by **feedback mechanisms** from the target organs.

PITUITARY GLAND (HYPOPHYSIS)

- The **pituitary gland** is composed of two parts: the **anterior lobe** (adenohypophysis), which is composed of glandular epithelial tissues, and the **posterior lobe** (neurohypophysis), which is composed of neural secretory tissue that developed from the neuroectoderm of the CNS.
- The **anterior lobe** of the pituitary gland consists of three parts: **pars distalis**, **pars intermedia**, and **pars tuberalis**, which surrounds the infundibulum.
- The **hypothalamohypophyseal portal system** provides the blood supply to the pituitary gland and serves as the link between the hypothalamus and the pituitary gland.
- **Portal circulation** involves a network of fenestrated capillaries in the infundibulum and median eminence of the hypothalamus as well as hypophyseal portal veins and a secondary network of

capillaries in the pars distalis. Circulation carries releasing hormones from the hypothalamic neurons to the cells in the pars distalis, where cell secretion is controlled.

- Based on staining reactions of endocrine cell secretory granules, cells in the pars distalis are identified as basophils (10%), acidophils (40%), and chromophobes (50%).
- Based on immunocytochemical reactions, five functional cell types are identified in the pars distalis: somatotropes (GH cells) produce growth hormone (GH; somatotropin); lactotropes (PRL cells, mammotropes) produce prolactin (PRL); corticotropes (ACTH cells) produce proopiomelanocortin (POMC), a precursor molecule of adrenocorticotrophic hormone (ACTH); gonadotropes (FSH and LH cells) produce both luteinizing hormone (LH) and follicle-stimulating hormone (FSH); and thyrotropes (TSH cells) produce thyroid-stimulating hormone (TSH).
- The posterior lobe of the pituitary gland (pars nervosa and the infundibulum) is an extension of the CNS. It releases hormones produced in the supraoptic nuclei (antidiuretic hormone [ADH] or vasopressin) and paraventricular nuclei (oxytocin) of the hypothalamus.
- The hypothalamohypophyseal tract delivers ADH and oxytocin to the posterior lobe, where they are stored in axon terminals (Herring bodies) and released into circulation.

PINEAL GLAND

- The pineal gland is a neuroendocrine gland that develops from the neuroectoderm and remains attached to the brain. Because the pineal gland has connections with the eye via the retinohypothalamic tract, it is an important regulator of circadian rhythm.
- The pineal gland contains two types of parenchymal cells: pinealocytes that secrete melatonin and supporting interstitial (glial) cells. It also possesses characteristic calcified concretions called corpora arenacea or brain sand.

THYROID GLAND

- The thyroid gland is located in the neck and develops from the endodermal lining of the floor of the primitive pharynx.

- The thyroid gland consists mainly of **thyroid follicles**, which generally are formed from simple cuboidal **follicular epithelium**. The lumen of the follicles is filled with a gel-like mass called **colloid**, which contains thyroglobulin, an inactive storage form of thyroid hormones.
- Follicular epithelium contains two types of cells: **follicular cells** that produce thyroid hormones T_4 and T_3 and **parafollicular cells** that produce calcitonin.
- **Synthesis** of T_4 and T_3 takes place in follicular cells and the lumen of the follicle. It involves a series of steps, from the synthesis of thyroglobulin, to the uptake and oxidation of iodide, to iodination of the thyroglobulin to form T_4 and T_3 .
- In response to **TSH stimulation**, follicular cells resorb colloid and transport T_4 and T_3 into circulation.

PARATHYROID GLANDS

- The **parathyroid glands** (two pairs) are located on the posterior surface of the thyroid gland. They develop from the third and fourth pharyngeal pouches.
- Parathyroid glands consist of two major epithelial cells: **principal cells**, which are the most numerous and secrete **parathyroid hormone (PTH)**, and **oxyphil cells**.
- **PTH** regulates calcium and phosphate levels in the blood. It binds to the PTH receptors on target cells and increases the Ca^{2+} level in the blood.

ADRENAL (SUPRARENAL) GLANDS

- The **adrenal glands** are paired triangular organs embedded in the perirenal fat at the upper poles of the kidneys.
- Adrenal glands are organized into two distinct regions: the **cortex**, a steroid-secreting portion that developed from the mesoderm, and the **medulla**, a catecholamine-secreting portion that developed from neural crest cells.
- During development, the **fetal adrenal gland** is composed of the fetal cortex without a definitive medulla.
- The **adrenal medulla** contains chromaffin cells that synthesize epinephrine and norepinephrine to prepare the body for a “fight-or-flight” response.

- The **adrenal cortex** is divided into three zones: **zona glomerulosa** (outer); **zona fasciculata** (thick middle); and **zona reticularis** (inner), which communicates with the medulla.
- **Zona glomerulosa** cells form ovoid clusters and produce **mineralocorticoids** (e.g., aldosterone). The **renin-angiotensin-aldosterone system** provides the feedback mechanism to control secretion of the zona glomerulosa cells.
- **Zona fasciculata** cells are arranged in long straight cords and produce **glucocorticoids** (e.g., cortisol) that regulate gluconeogenesis (glucose synthesis) and glycogenesis (glycogen polymerization). ACTH regulates secretion of the zona fasciculata cells.
- **Zona reticularis** cells are arranged in anastomosing cords separated by fenestrated capillaries and produce weak **androgens** (mostly DHEA). ACTH regulates secretion of the zona reticularis cells.

PLATE 21.1 ■ PITUITARY I

The **pituitary gland** is located at the base of the brain and rests in a depression of the sphenoid bone called the *sella turcica* on the floor of the middle cranial fossa. It is connected by a short stalk to the hypothalamus. Although joined to the brain, only the **posterior lobe** of the gland, the **neurohypophysis**, develops from neuroectoderm. The larger **anterior lobe** of the gland, the **adenohypophysis**, develops from oropharyngeal ectoderm as a diverticulum of the buccal epithelium, called the Rathke pouch.

The anterior lobe regulates other endocrine glands. It is composed of clumps and cords of epithelioid cells, separated by large-diameter fenestrated capillaries. The posterior lobe is a nerve tract whose terminals store and release secretory products synthesized by their cell bodies located in the **supraoptic** and **paraventricular nuclei**. The secretions contain either **oxytocin** or **antidiuretic hormone (ADH)**. Other neurons from the hypothalamus release secretions into the fenestrated capillaries of the infundibulum, the first capillary bed of the **hypophyseal portal system** that carries blood to the fenestrated capillaries of the anterior lobe. These hypothalamic secretions regulate the activity of the anterior lobe of the pituitary gland.

Pituitary, human, hematoxylin and eosin (H&E) ×50.

This specimen is a sagittal section of the pituitary gland. The **posterior lobe** of the gland is delineated by the *dashed line* (indicated by *arrows*) that

separates it from the anterior lobe. The **pars nervosa** (*PN*) is the expanded portion of the posterior lobe that is continuous with the infundibulum. The **pars tuberalis** (*PT*) of the **anterior lobe** is located around the infundibular stem but may cover the pars nervosa to a variable extent. The **pars intermedia** (*PI*) is a narrow band of tissue that lies between the **pars distalis** (*PD*) and the pars nervosa. It borders a small cleft (*CI*) that constitutes the remains of the lumen of the Rathke pouch. The pars distalis, the anterior lobe of the gland, is its largest part. It contains a variety of cell types that are not uniformly distributed. This accounts for differences in staining (light- and dark-staining areas) that are seen throughout the pars distalis. The pituitary gland contains a connective tissue capsule (*Caps*) that separates the gland from the surrounding meninges.

Each of the components of the anterior lobe (i.e., the pars distalis, pars tuberalis, and pars intermedia), when examined at higher magnification, exhibit features at the cellular level that aid in their identification. These features are described in the following figures as well as those in Plate 21.2 (page 852).

Pars distalis, pituitary, human, H&E $\times 375$.

This photomicrograph shows a region of the **pars distalis** of the anterior lobe that is rich in **acidophils** (*A*). **Basophils** (*B*) are present in this area in lesser numbers. The acidophils are readily identified by the acidophilic staining of their cytoplasm, in contrast to the basophils whose cytoplasm is clearly basophilic. **Chromophobes** (*C*) are also very numerous in this field. The cytoplasm stains poorly in contrast to that of the acidophils and basophils. The cells are arranged in cords and clumps, between which are capillaries (*Cap*), some of which can be recognized, but most are in a collapsed state and difficult to visualize at this magnification.

Pars distalis, pituitary, human, H&E $\times 375$.

This photomicrograph shows a region of the **pars distalis** of the anterior lobe that is rich in basophils (*B*). At this particular site, there are no recognizable acidophils (at other sites, it is possible to find a more equal distribution of acidophils and basophils, although, typically, one cell type outnumbers the other in a given region). **Chromophobes** (*C*) are also relatively numerous at this site. In this particular region, the chromophobe nuclei are readily apparent, but the cytoplasm of the cells is difficult to discern.

Pars intermedia, pituitary, human, periodic acid-Schiff (PAS)/aniline blue black $\times 380$.

This photomicrograph shows a small portion of the **pars distalis** (*PD*); the remainder reveals the **pars intermedia** (*PI*) of the

anterior lobe. The pars distalis shown here contains numerous capillaries filled with red blood cells, thus producing a bright red appearance. The pars intermedia contains a number of small cysts (*Cy*). The cells that make up the pars intermedia, which is relatively small in humans, consist of small basophils and chromophobes. The basophils have taken up the blue stain, thus making them prominent. To the extreme *right* is a less cellular area, the **pars nervosa** (*PN*).

A, acidophils
B, basophils
C, chromophobes
Cap, capillaries
Caps, capsule
Cl, cleft
Cy, cysts
PD, pars distalis
PI, pars intermedia
PN, pars nervosa
PT, pars tuberalis

PLATE 21.2 ■ PITUITARY II

The parenchyma of the pars distalis consists of two general cell types: chromophobes and chromophils. Chromophobes stain poorly; chromophils

stain well. Chromophils are further subdivided into **acidophils** and **basophils**. Basophils stain with basic dyes or hematoxylin, whereas the cytoplasm of the acidophil stains with acid dyes such as eosin. The cytoplasm of basophils also stains with the periodic acid-Schiff (PAS) reaction because of the glycoprotein in its secretory granules.

Acidophils can be further subdivided into two groups on the basis of special cytochemical and ultrastructural features. One group, called **somatotropes**, produces the growth hormone, *somatotropic hormone* (STH); the other group of acidophils, called **lactotropes**, produces *prolactin* (PRL).

The groups of basophils can also be distinguished with the electron microscope and with special cytochemical procedures. One group of **thyrotropes** produces *thyroid-stimulating hormone* (TSH); another group of **gonadotropes** produces the gonadotropic hormones *follicle-stimulating hormone* (FSH), and *luteinizing hormone* (LH); and a third group of **corticotropes** produces *adrenocorticotrophic hormone* (ACTH) and *lipotropic hormone* (LPH).

Chromophobes are also a heterogeneous group of cells. Many are considered to be depleted acidophils or basophils.

Pars distalis, pituitary, human, Mallory trichrome $\times 360$;
inset $\times 1,200$.

This photomicrograph of the pars distalis is from an area where there is an almost equal distribution of **acidophils** (A) and **basophils** (B). The clumps and cords of cells are delineated by strands of connective tissue (*stained blue*) that surround them. A number of engorged capillaries (Cap) containing red blood cells (*stained yellow*) are also seen. The acidophil's cytoplasm in this preparation stains a reddish or rust color. The basophils stain a *reddish blue to deep blue*, and the **chromophobes** (C) exhibit a *pale blue* color. The *inset* shows the three general cell types at higher magnification. The secretory granules of the acidophils (A) and basophils (B) are just discernible. It is the granules that stain and provide the overall coloration to the two cell types. In contrast, the chromophobe (C) lacks granules and simply reveals a *pale blue* background color.

Pars nervosa, pituitary, human, hematoxylin and eosin (H&E) $\times 325$.

The **pars nervosa** of the posterior lobe seen here contains cells called *pituicytes*, and unmyelinated nerve fibers form the supraoptic and paraventricular nuclei of the hypothalamus. The **pituicytes** (P) are comparable with neuroglial cells of the central nervous system. The nuclei are round to oval; the cytoplasm extends from the nuclear region of the cell as long processes. In H&E preparations such as this, the cytoplasm of the pituicyte cannot be distinguished from the unmyelinated nerve fibers. The hormones of the posterior lobe, oxytocin, and antidiuretic hormone (ADH; also called *vasopressin*) are formed in the hypothalamic nuclei and pass via the fibers of the hypothalamohypophyseal tract to the posterior lobe, where they

are stored in the expanded nerve terminal portion of the nerve fibers. The stored neurosecretory material appears as **Herring bodies** (*HB*). In H&E preparations, the Herring bodies simply appear as small islands of eosin-stained substance. Interspersed among the nerve fibers are capillaries (*Cap*).

Pars nervosa, pituitary, human, periodic acid-Schiff (PAS)/aniline blue black $\times 250$; inset $\times 700$.

In this specimen from the pars nervosa, the *aniline blue* has stained the nuclei of the **pituicytes** (*P*); the nerve fibers have taken up some of the stains to give a *light blue* background. With this staining technique, the **Herring bodies** (*HB*) appear as *dark black islands*. The *inset* shows a Herring body near the *bottom* of the micrograph at high magnification. The granular texture of the Herring body as seen here is a reflection of the accumulated secretory granules in the nerve terminals. Also of note in this specimen are the capillaries (*Cap*), which are prominent as a result of the contrasting red staining of the red blood cells within them.

A, acidophils
B, basophils
C, chromophobes
Cap, capillaries
HB, Herring bodies
P, pituicytes

PLATE 21.3 ■ PINEAL GLAND

The pineal gland (*pineal body*, *epiphysis cerebri*) is located in the brain above the superior colliculi. It develops from neuroectoderm but, in

the adult, bears little resemblance to nerve tissue.

Two cell types have been described within the pineal gland: pinealocytes (parenchymal) cells and glial cells. The full extent of these cells cannot be appreciated without the application of special staining methods. These would show that the glial cells and the pinealocytes have processes that are expanded at their periphery. The pinealocytes are more numerous. In a hematoxylin and eosin (H&E) preparation, the nuclei of the pinealocytes are pale staining. The nuclei of the glial cells, on the other hand, are smaller and stain more intensely.

The secretion of the pineal gland has an antigonadal effect: It decreases the production of gonadal steroids. For example, hypogenitalism has been reported with pineal tumors that consist chiefly of pinealocytes, whereas sexual precocity (puberty that occurs at an unusually early age) is associated with glial cell tumors (presumably, the pinealocytes have been destroyed). In addition, experiments with animals indicate that the pineal gland has a neuroendocrine function, whereby the pineal gland serves as an intermediary that relates endocrine function (particularly gonadal function) to cycles of light and dark. The external photic stimuli reach the pineal gland via optical pathways that connect with the superior cervical ganglion. In turn, the superior cervical ganglion sends postganglionic nerve fibers to the pineal gland. The pineal gland has a role in adjusting to sudden changes in day length, such as those experienced by travelers who suffer from jet lag, and a role in regulating emotional responses to reduced day length during winter in temperate and subarctic zones (seasonal affective disorder [SAD]).

Pineal gland, human, H&E $\times 180$.

The pineal gland is surrounded by a very thin **capsule** (*Cap*) that is formed by the pia mater. Connective tissue trabeculae (*CT*) extend from the capsule into the substance of the gland dividing it into lobules. The **lobules** (*L*) appear often as indistinct groups of cells of varying size surrounded by the connective tissue. Blood vessels, generally small arteries (*A*) and veins (*V*), course through the connective tissue. The arteries give rise to capillaries that surround and penetrate the lobules to supply the parenchyma of the gland. In this specimen and even at this low magnification, the capillaries (*C*) are prominent as a consequence of the red blood cells present in their lumina.

Pineal gland, human, H&E $\times 360$; inset $\times 700$.

This micrograph shows at higher magnification the parenchyma of the pineal gland as well as a component called **brain sand** (*BS*) or **corpora arenacea**. When viewed at even higher magnification, the corpora arenacea are seen to have an indistinct lamellated structure. Typically, they stain heavily with hematoxylin. The presence of these structures is an identifying feature of the pineal gland. A careful examination of the cells within the gland at the light microscopic level reveals two specific cell types. One cell type represents the pinealocytes (or chief cells of the pineal gland), which are by far the most numerous. Pinealocytes are modified neurons. Their nuclei are spherical and are relatively lightly stained because of the amount of euchromatin that they contain. The second cell type is the interstitial cell or glial cell that constitutes a relatively small percentage of the cells in the gland. Their nuclei are smaller and more elongated than those of the pinealocytes. The *inset* reveals several **glial cells** (*G*) that can be identified by their more densely staining nuclei. The majority of the nuclei of the other cells seen here belong to pinealocytes. Also seen in the **inset** are several fibroblasts (*F*) that are present within a trabecula.

A, artery
 BS, brain sand
 C, capillary
 Cap, capsule
 CT, connective tissue
 F, fibroblast
 G, glial cell
 L, lobule
 V, vein

PLATE 21.4 ■ PARATHYROID AND THYROID GLANDS

The **parathyroid glands** are usually four in number. Each is surrounded by a capsule and lies on or is partially embedded in the thyroid gland. Connective tissue trabeculae extend from the capsule into the substance of the gland.

The **parathyroid glands** elaborate a hormone that influences calcium and bone metabolism. Injection of parathyroid hormone into laboratory

animals results in the release of calcium from bone by the action of osteocytes (osteocytic osteolysis) and osteoclasts. Removal of the parathyroid glands results in a rapid drop in blood calcium levels.

The **thyroid gland** is located in the neck in close relation to the upper part of the trachea and the lower part of the larynx. It consists of two lateral lobes that are joined by a narrow isthmus. The follicle, which consists of a single layer of cuboidal or low columnar epithelium surrounding a colloid-filled space, is the functional unit of the thyroid gland. A rich capillary network is present in the connective tissue that separates the follicles. The connective tissue also contains lymphatic capillaries.

Parathyroid gland, human, hematoxylin and eosin (H&E) ×320.

As seen here, the larger blood vessels are associated with the trabeculae (*BV*) and, occasionally, adipose cells (*A*). The parenchyma of the parathyroid glands appears as cords or sheets of cells separated by capillaries and delicate connective tissue septa.

Two parenchymal cell types can be distinguished in routine H&E sections: chief cells (principal cells) and oxyphil cells. The **chief cells** (*CC*) are more numerous. They contain a spherical nucleus surrounded by a small amount of cytoplasm. **Oxyphil cells** (*OC*) are less numerous. They are conspicuously larger than chief cells but have a slightly smaller and more intensely staining nucleus. Their cytoplasm stains with eosin, and the boundaries between the cells are usually well marked. Moreover, the oxyphils are arranged in groups of variable size that appear scattered about in a much larger field of chief cells. Even with low magnification, it is often possible to identify clusters of oxyphil cells because a unit area contains fewer nuclei than a comparable unit area of chief cells, as is clearly evident in this figure. Oxyphil cells appear during the end of the first decade of life and become more numerous around puberty. A subsequent increase may be seen in older individuals.

Thyroid gland, human, H&E ×240.

A histologic section of the thyroid gland is shown here. The **thyroid follicles** (*F*) vary somewhat in size and shape and appear closely packed. The homogeneous mass in the center of each follicle is the colloid. The follicular cells of the gland appear to form a simple cuboidal epithelium enclosing the colloid. Careful examination of the apical surface of follicular cells reveals small vacuoles, an indication of colloid resorption. Although the individual cells are difficult to distinguish at this magnification, the nuclei of the cells serve as an indication of their location and arrangement. The thyroid is well vascularized: Larger **blood vessels** (*BV*) are found in the connective tissue (*CT*), and the capillary network surrounds follicles.

This specimen has few areas of large groups of cells with nuclei that are of the same size, shape, and staining characteristics as follicular cells. These areas represent **tangentially sectioned follicles** (*tsF*).

A, adipose cells
BV, blood vessels
CC, chief cells
CT, connective tissue
F, follicles
OC, oxyphil cells
tsF, tangentially sectioned follicle

PLATE 21.5 ■ ADRENAL GLAND I

There are two adrenal glands, one at the upper pole of each kidney. The gland is a composite of two distinct structural and functional components:

a **cortex** and a **medulla**. The cortex develops from mesoderm and secretes *steroid hormones*; the medulla develops from neuroectoderm of the neural crest and secretes *catecholamines*.

The adrenal cortex is divided into three zones according to the type and arrangement of its parenchymal cells. These are designated as **zona glomerulosa**, **zona fasciculata**, and **zona reticularis**. The zona glomerulosa constitutes 15% of the cortical volume. It secretes *mineralocorticoid* (*aldosterone*). The zona fasciculata constitutes nearly 80% of the cortical volume. It secretes *glucocorticoids* (*cortisol* and *corticosterone*) and a small amount of adrenal androgens. The zona reticularis (5%-7% of cortical volume) produces most of the adrenal androgens.

The zona fasciculata and the zona reticularis are regulated by *adrenocorticotrophic hormone* (ACTH) secreted by the anterior lobe of the pituitary gland in response to *corticotropin-releasing factor* (CRF) produced by the hypothalamus. The zona glomerulosa is not regulated by ACTH but by angiotensin II, which is part of feedback control of the *renin-angiotensin-aldosterone system* that also regulates blood pressure.

Adrenal gland, human, hematoxylin and eosin (H&E) $\times 45$.

This low-magnification micrograph of a section through the partial thickness of an adrenal gland shows the outer capsule (*Cap*), the **cortex** (*Cort*) from one surface of the gland, the underlying **medulla** (*Med*), and a very small portion of the cortex from the other surface of the gland (*Cort, bottom center*). The cortex has a distinctly different appearance in both structural organization and staining characteristics. From the inner portion, the medulla, note the lighter appearance of the medullary tissue. A small amount of adipose tissue (*AT*) in which the gland is partially embedded is seen at the *upper center* of the micrograph. The corticomedullary boundary (*dashed lines*) has a wave-like contour, a reflection of the irregular shape of the gland. Within the medulla are a number of relatively large blood vessels (*BV*). These are the adrenomedullary collecting veins that drain both the cortex and the medulla.

Cortex, adrenal gland, human, H&E $\times 180$.

This is a higher magnification of a portion of the capsule and the full thickness of the **cortex** from an area in the previous figure. The capsule consists of dense connective tissue in which the larger arteries (*A*) travel to give rise to smaller vessels that will supply the cortex and medulla. The **zona glomerulosa** (*ZG*) is located at the outer part of the cortex, immediately under the capsule. The parenchyma of this zone consists of small cells that appear as arching cords or as oval groups of cells.

The **zona fasciculata** (*ZF*) consists of radially oriented cords and sheets of cells, usually two cells in width, that extend toward the medulla. The cells of the outer part of the zona fasciculata are generally larger than those of the inner portion of this zone and typically stain poorly because of the large

number of lipid droplets that they contain. The cells of the **zona reticularis** (*ZR*) are relatively small and contain little or no lipid droplets and, consequently, stain prominently with eosin. Because of their small size, the nuclei are in close proximity to one another, much like the cells of the zona glomerulosa.

Cortex, adrenal gland, human, H&E $\times 245$.

This is a higher magnification of the area inscribed by the *left rectangle* in the previous figure. It shows the **zona glomerulosa** (*ZG*) and the outer portion of the **zona fasciculata** (*ZF*). Note the smaller size of the cells in the zona glomerulosa than those in the zona fasciculata. In addition, cells of the zona glomerulosa contain fewer lipid droplets than those of the zona fasciculata. Typically, the cells in this part of the zona fasciculata are filled with lipid droplets, thus the very poor staining characteristic of their cytoplasm. Delicate connective tissue trabeculae (*arrows*) extend from the capsule to surround the glomerular groups of cells and extend between the cords of cells in the zona fasciculata. Capillaries and arterioles are located within the connective tissue trabeculae. Usually, the capillaries are collapsed and, without the presence of red blood cells in their lumina, are thus difficult to identify.

Cortex, adrenal gland, human, H&E $\times 245$.

This is a higher magnification of the area inscribed by the *right rectangle* in the previous figure. This deep portion of the **zona fasciculata** (*ZF*) reveals smaller cells, although they are still arranged in cords and contain lipid droplets, although in lesser amounts. The cells of the **zona reticularis** (*ZR*) are arranged in irregular anastomosing cords and contain only a small amount of lipid and, consequently, their cytoplasm stains with eosin.

A, arteries
AT, adipose tissue
BV, blood vessels

PLATE 21.6 ■ ADRENAL GLAND II

The cells of the adrenal medulla develop from the same source as the postganglionic cells of the sympathetic nervous system. They are directly innervated by preganglionic cells of the sympathetic system and may be regarded as modified postganglionic cells that are specialized to secrete. These cells produce the catecholamines *epinephrine* and *norepinephrine*.

The adrenal medulla receives its blood supply via two routes: by arterioles that pass through the cortex and by capillaries that continue from the cortex, a type of portal circulation. Thus, some of the blood supplying the medulla contains cortical secretions that regulate medullary function. Blood leaves the medulla via the central adrenomedullary vein. Its structure is unusual in that the tunica media of the vessel contains prominent bundles of longitudinally oriented smooth muscle, the contraction of which facilitates rapid outflow of blood when medullary catecholamines are released.

Medulla, adrenal gland, human, hematoxylin and eosin (H&E) $\times 175$; inset $\times 250$.

This moderately low-power photomicrograph shows the cells of the **adrenal medulla**. The medullary cells are organized in ovoid groups and short interconnecting cords. The cytoplasm of the medullary cells may stain with different intensity. The cytoplasm of some cells is very poorly stained, appearing almost clear, whereas others show greater intensity of eosin staining. In this photomicrograph, a portion of the wall, namely, the tunica media (*TM*) of the central adrenomedullary vein, can be seen. The nature of the central adrenomedullary vein is described in the *lower left* figure. The *inset* shows the ovoid groups of medullary cells at a higher magnification. Between these groups of cells are capillaries (*Cap*) that, as in the cortex, can be identified when they contain red blood cells as shown here.

Medulla, adrenal gland, human, H&E $\times 125$.

This micrograph shows a **central adrenomedullary vein (AMV)** that drains the adrenal medulla. The tunica media (*TM*) is unusually thick. The smooth muscle that constitutes this part of the vessel wall is in the form of bundles that are arranged longitudinally, that is, in the same direction as the vessel. Thus, the muscle seen here is cut in cross section, as is the vein. Whereas the central adrenomedullary vein occupies most of the micrograph, **medullary cells (MC)** can be seen in several locations surrounding the vein. The portion of the figure outlined by the *rectangle* is seen at higher magnification in the *bottom right* figure.

Central adrenomedullary vein, adrenal gland, human, H&E $\times 350$.

This higher magnification view of the *rectangle* in the *bottom left* figure shows part of the lumen (*L*) of the **central adrenomedullary vein (AMV)** at the bottom of the field. The tunica intima (*TI*) of the vessel is relatively thin but may contain a variable amount of connective tissue. The smooth muscle (*SM*) of the tunica media (*TM*) is readily seen here as being arranged in bundles and appears in cross section. There is no discrete tunica adventitia in this vein. Instead, its connective tissue blends in with surrounding structures. **Ganglion cells (GC)** are

frequently found in proximity to the wall of the central adrenomedullary vein. They are large cells with a moderately basophilic cytoplasm. Because of the large size of the cell, the nucleus is often missed in the section, and only the cell cytoplasm is seen.

AMV, central adrenomedullary vein
Cap, capillary
GC, ganglion cells
L, lumen of central adrenomedullary vein
MC, medullary cells
SM, smooth muscle
TI, tunica intima
TM, tunica media

HISTOLOGY

■ OVERVIEW OF THE MALE REPRODUCTIVE SYSTEM

The **male reproductive system** consists of the testes, genital excurrent ducts, accessory sex glands, and external genitalia containing the penis and scrotum (Fig. 22.1). The accessory sex glands include the seminal vesicles, the prostate, and bulbourethral glands. The two primary functions of the testis are **spermatogenesis** (the production of sperm, called *male gametes*) and **steroidogenesis** (synthesis of androgens, also called *sex hormones*). Androgens, mainly testosterone, are essential for spermatogenesis. They also play an important role in embryonic development of the male embryo into the phenotypic male fetus and are responsible for sexual dimorphism (male physical and behavioral characteristics). The events of cell division that occur during the production of male gametes, as well as those of the female (the ova), involve both normal division (mitosis) and reduction division (meiosis).

FIGURE 22.1. Schematic diagram demonstrating the components of the male reproductive system. Midline structures are depicted in sagittal section; bilateral structures, including the testis, epididymis, ductus deferens, and seminal vesicle, are shown intact.

A brief description of mitosis and meiosis is included in Chapter 3, The Cell Nucleus (pages 99–103). A basic understanding of these processes is essential to understanding the production of gametes in both sexes.

■ TESTIS

The adult **testes** are paired ovoid organs that lie within the **scrotum**, located outside the body. Each testis is suspended within the end of an elongated musculofascial pouch, which is continuous with the layers of the anterior abdominal wall that projects into the scrotum. Testes are connected by the spermatic cords to the abdominal wall and tethered to the scrotum by scrotal ligaments, the remnants of the gubernaculum (see discussion later in this chapter).

Sex Determination and Development of the Testis

Sex differentiation is accomplished through a cascade of gene activations.

Genetic sex is determined at fertilization by the presence or absence of the Y chromosome. The testes, however, do not form until the seventh week of development. **Gonadal sex** is determined by the presence of the **SRY gene** located in the **sex-determining region Y** of the short arm of the Y chromosome. SRY gene expression in early embryonic development triggers the differentiation of the gonads into the testis. **Mutations in this gene give rise to XY female embryo with gonadal dysgenesis**, a condition known as **Swyer syndrome**. Females with Swyer syndrome have an X and Y chromosome and functional female genitalia, including the vagina, uterus, and uterine tubes. However, they lack female sex gonads (ovaries). Females with this syndrome do not produce sex hormones. Treatment with hormone therapy is necessary to induce puberty.

The genetic information encoded in the Y chromosome itself is not sufficient to guide the complex development of the male gonads. Instead, the SRY gene operates as a **master switch** that controls the cascade of several gene activations on autosomes 9, 11, 17, and 19 and the X chromosome. A transcription factor called the **testis-determining factor (TDF)**, encoded by the SRY gene, contains a molecular domain that binds to a specific region of DNA and alters its structure. The affected DNA forms a loop that permits binding of other transcription factors. These factors, in turn, cause the expression of other genes that initiate male sex determination (formation of the testes and other male sex organs). These genes include the following:

- **WT-1 gene** (Wilms tumor 1 gene), which is required for the development of the urogenital system and regulation of the SRY transcription. **Mutations of the WT-1 gene are present in children with familial Wilms tumor and in children with accompanied genitourinary malformations.**
- **SOX-9 gene** (SRY [sex-determining region Y]-box 9 gene) activates the **AMH gene** (anti-Müllerian hormone gene) that is responsible for Müllerian-inhibiting factor (MIF) synthesis. **Mutation of the SOX9 gene is linked the formation of ambiguous or female sex organs in a genetically male individual (46,XY).**

- **SF-1 gene** (steroidogenic factor-1 gene) that regulates the expression of a number of steroidogenic genes
- **DAX-1 gene** (dosage-sensitive sex reversal, adrenal hypoplasia critical region, on chromosome X, gene 1) that encodes nuclear receptor DAX-1. Activation of this receptor suppresses the SRY gene during gonadal sex differentiation, and its mutation is responsible for congenital adrenal hypoplasia.

The testes develop on the posterior wall of the abdomen and later descend into the scrotum.

The **testes** develop in close association with the urinary system retroperitoneally on the posterior wall of the abdominal cavity. Testes (like ovaries) are derived from three sources:

- **Intermediate mesoderm** forms the urogenital ridges on the posterior abdominal wall, giving rise to Leydig cells (interstitial cells) and myoid cells (peritubular contractile cells).
- **Mesodermal epithelium (coelomic mesothelium)** lines the urogenital ridges and gives rise to finger-like epithelial cords called *primary sex cords*. These cords grow into the underlying intermediate mesoderm and become colonized by primordial germ cells. The primary sex cords also give rise to Sertoli cells.
- **Primordial germ cells** migrate from the yolk sac into developing gonads, where they are incorporated into the **primary sex cords**. They differentiate into **gonocytes**, which are the precursors of the definitive germ cells called **spermatogonia**. At this stage, the cords are composed of primordial germ cells, pre-Sertoli cells, and a surrounding layer of myoid cells. Later, primary sex cords differentiate into the **seminiferous cords**, which give rise to the seminiferous tubules, straight tubules, and rete testis (Fig. 22.2).

FIGURE 22.2. Schematic diagram of the stages of testicular development. **a.** This diagram shows the 5-week embryo in the stage of

indifferent gonads. The gonadal ridges visible on the posterior abdominal wall are being infiltrated by primordial germ cells (*green*) that migrate from the yolk sac. Most of the developing gonad is formed by mesenchyme derived from the coelomic epithelium. The primordial germ cells become incorporated into the primary sex cords. b. At a later stage, under hormonal influence of testis-determining factor (TDF), the developing gonad initiates the production of testosterone. This is followed by differentiation of the primary sex cords into seminiferous cords. At the same time, the developing gonad produces Müllerian-inhibiting factor (MIF), which causes regression of the paramesonephric duct and those structures derived from it. Note that the mesonephric tubules come in close contact with the developing rete testis. c. Final stages of testicular development. The tunica albuginea surrounding the testis contributes to the development of the testicular septa. The rete testis connects with the seminiferous cords and with the excurrent duct system that develops from the mesonephric duct and tubules.

SRY expression is responsible for the development of male sex organs in the indifferent embryo.

In the first stage of development, the testes develop on the posterior abdominal wall from indifferent primordia of **urogenital ridges** that are identical in both sexes. During this **indifferent stage**, an embryo has the potential to develop into either a male or female. However, expression of the SRY gene, which occurs exclusively in the pre-Sertoli cells, orchestrates male development of the embryo.

Early in male development, mesenchyme separating the seminiferous cords gives rise to **Leydig (interstitial) cells** that produce **testosterone** to stimulate the development of the indifferent primordium into a testis. Testosterone is also responsible for the growth and differentiation of the mesonephric (Wolffian) ducts that develop into the male genital excurrent ducts. Also during this early stage, the **Sertoli (sustentacular) cells** that develop within the seminiferous cords produce another important hormonal substance, called **Müllerian-inhibiting factor (MIF)**. The molecular structure of MIF is similar to that of transforming growth factor- β (TGF- β). It is a large glycoprotein that inhibits cell division of the paramesonephric (Müllerian) ducts, which, in turn, inhibits the development of female reproductive organs (Fig. 22.3).

FIGURE 22.3. Schematic diagram of male sex development and hormonal influence on developing reproductive organs. This diagram

illustrates three levels at which the sex of the developing embryo is determined. Genetic sex is determined at the time of fertilization; gonadal sex is determined by activation of the sex-determining region Y (*SRY*) gene located on the short arm of chromosome Y; and hormonal sex is determined by a hormone secreted by the developing gonad. The diagram shows the influence of Müllerian-inhibiting factor (*MIF*), testosterone, and dihydrotestosterone (*DHT*) on the developing structures. *TDF*, testis-determining factor.

Development and differentiation of the external genitalia (also from the sexually indifferent stage) occur at the same time and result from the action of **dihydrotestosterone (DHT)**, a product of the conversion of testosterone by 5 α -reductase. Without DHT, regardless of the genetic or gonadal sex, the external genitalia will develop along the female template. The appearance of testosterone, MIF, and DHT is the trigger that determines the development of male sex organs in the embryo (Folder 22.1).

FOLDER 22.1

FUNCTIONAL CONSIDERATIONS: HORMONAL REGULATION OF SPERMATOGENESIS

Normal function of the testis is dependent on hormones acting through endocrine and paracrine pathways. The endocrine function of the testis resides primarily in the Leydig cell population that synthesizes and secretes the principal circulating androgen, **testosterone**. Nearly all of the testosterone is produced by the testis; less than 5% is produced by the adrenal glands. It is estimated in humans that the total Leydig cell population produces about 7 mg of testosterone per day. As testosterone leaves the Leydig cells, it enters the bloodstream and lymphatic capillaries and crosses into the peritubular tissue to reach the seminiferous epithelium.

High local levels of testosterone within the testis (estimated to be as much as 200 times the circulating levels) are necessary for the proliferation and differentiation of spermatogenic cells. This high testicular level of testosterone can be significantly decreased by negative feedback from exogenous testosterone. Intensive research in this area has focused on the development of the male testosterone-based contraceptive drugs. In early clinical studies, these drugs have been shown to cause a significant decrease in the testicular testosterone concentration and inhibition of spermatogenesis. Recovery of spermatogenesis occurs after discontinuation of contraceptive use. However, in some individuals, this type of contraceptive does not cause spermatogenic suppression.

It also can cause significant side effects, including acne and depression.

Peripheral testosterone has the following effects:

- Differentiation of the **central nervous system** (CNS) and the genital apparatus and genital excurrent duct system
- Growth and maintenance of **secondary sexual characteristics** (such as the beard, male distribution of pubic hair, and low-pitched voice)
- Growth and maintenance of the **accessory sex glands** (seminal vesicles and prostate and bulbourethral glands), genital excurrent duct system, and the external genitalia (mainly byproducts of testosterone conversion to dihydrotestosterone [DHT])
- **Anabolic and general metabolic processes**, including skeletal growth, skeletal muscle growth, distribution of subcutaneous fat, and kidney function
- **Behavioral effects**, including libido

The steroidogenic and spermatogenic activities of the testis are regulated by hormonal interaction between the hypothalamus, anterior lobe of the pituitary gland, and gonadal cells (i.e., Sertoli, spermatogenic, and Leydig cells). The anterior lobe of the pituitary gland produces three hormones involved in this process: luteinizing hormone (LH), which, in the male, is sometimes referred to as interstitial cell-stimulating hormone (ICSH); follicle-stimulating hormone (FSH); and prolactin (PRL). In response to LH release by the pituitary, Leydig cells produce increasing amounts of testosterone. PRL acts in combination with LH to increase the steroidogenic activity of Leydig cells. Because FSH and testosterone receptors are found in Sertoli cells, these cells are the primary regulators of spermatogenesis.

The testes descend from the abdomen into the scrotum along the inguinal canal at approximately 26 weeks of gestation.

At approximately 26 weeks of gestation, the testes descend from the abdomen into the scrotum. This migration of the testes is caused by differential growth of the abdominal cavity combined with the action of testosterone that causes shortening of the **gubernaculum**, the testosterone-sensitive ligament connecting the inferior pole of each testis to the developing scrotum. The testes descend into the scrotum by passing through the inguinal canal, the narrow passage between the abdominal cavity and the scrotum. During descent, the testes carry their blood vessels, lymphatic vessels, and nerves as well as their principal excurrent duct system, the ductus deferens, with them. [Descent of](#)

the testis is sometimes obstructed, resulting in cryptorchidism, or undescended testes. This condition is common (30%) in premature newborns and approximately 1% of full-term newborns. Cryptorchidism can lead to irreversible histologic changes in the testis and increases the risk of testicular cancer. An undescended testis requires surgical correction. Orchiopexy (placement in the scrotal sac) should preferably be performed before histologic changes become irreversible at approximately 2 years of age.

Spermatogenesis requires that the testes be maintained below normal body temperature.

As the testes descend from the abdominal cavity into the scrotum, they carry blood vessels, lymphatic vessels, autonomic nerves, and an extension of the abdominal peritoneum called the tunica vaginalis, which covers their anterolateral surface. Within the scrotum, the temperature of the testes is 2° C–3° C below body temperature. This lower temperature is essential for spermatogenesis but is not required for hormone production (steroidogenesis), which can occur at normal body temperature. An increase in the testicular temperature of more than 37° C can induce testicular heat stress that alters spermatogenesis, especially the differentiation and maturation of spermatocytes and spermatids. Heat stress decreases DNA synthesis, causes DNA damage, and increases the degradation of messenger RNAs (mRNAs) and denaturation of cytoplasmic proteins in spermatocytes and spermatids, triggering their apoptosis and autophagy. Several factors that increase the temperature of the testis, such as fever, prolonged exposure to high temperatures (e.g., saunas), obesity, varicocele (enlargement of veins within the scrotum), and cryptorchidism (failure of the testis to descend into the scrotum) may lead to infertility.

Each testis receives blood through a testicular artery, a direct branch of the abdominal aorta. It is highly convoluted near the testis, where it is surrounded by the pampiniform venous plexus, which carries blood from the testis to the abdominal veins. This arrangement allows heat exchange between the blood vessels and helps maintain the testes at a lower temperature. The cooler venous blood returning from the testis

cools the arterial blood before it enters the testis through a **countercurrent heat exchange mechanism**. In addition, the **cremaster muscle**, whose fibers originate in the internal abdominal oblique muscle of the anterior abdominal wall, responds to changes in ambient temperature. Its contraction moves the testes closer to the abdominal wall, and its relaxation lowers the testes within the scrotum. Cold temperatures also cause contraction of a thin sheet of smooth muscle (**dartos muscle**) in the superficial fascia of the scrotum. **Contraction of the dartos muscles causes the scrotum to wrinkle when cold to help regulate heat loss (Folder 22.2).**

FOLDER 22.2

CLINICAL CORRELATION: FACTORS AFFECTING SPERMATOGENESIS

Spermatogenic cells are sensitive to noxious agents. Degenerative changes, such as apoptosis, premature sloughing of cells, or formation of multinucleated giant cells, are readily apparent after exposure to such agents. Factors that negatively affect spermatogenesis include the following:

- **Dietary deficiencies.** Reduced dietary intake is known to impair spermatogenesis. Vitamins, coenzymes, and microelements such as vitamin A, vitamin B₁₂, vitamin C, vitamin E, β -carotenes, zinc, and selenium have been shown to affect sperm formation.
- **Environmental/lifestyle factors.** A recent study conducted in Denmark compared the sperm count in two groups of young men from rural and urban populations. A higher median sperm count (24%) was found in the men from the rural group compared with those from the urban group.
- **Developmental disorders.** Cryptorchidism, hypospadias, and factors such as low birth weight have been found to be important risk factors for testicular cancer associated with reduced semen quality and reduced fertility.
- **Systemic diseases or local infections.** Infections involving the testis (orchitis) may have an effect on spermatogenesis. Systemic diseases that can impair spermatogenesis include fever, kidney diseases, HIV and other viral infections, and metabolic disorders.
- **Elevated testicular temperature.** A sedentary lifestyle may impair the ability to maintain the lower temperature in the scrotum necessary for sperm production. A higher-than-average scrotal temperature has been linked to the failure of spermatogenesis.

- **Steroid hormones and related medications.** Exposure to synthetic estrogen (diethylstilbestrol) and other sex steroids can exert negative feedback on follicle-stimulating hormone (FSH) secretion, resulting in decreased spermatogenesis. Prenatal exposure to estrogens can potentially inhibit fetal gonadotropin secretion and inhibit Sertoli cell proliferation.
- **Toxic agents.** Mutagenic agents, antimetabolites, and some pesticides, such as dibromochloropropane (DBCP), can drastically affect spermatogenesis and production of normal sperm. DBCP is a nematocide pesticide that is still used in some developing countries. It has been shown to cause a major decrease in sperm count and infertility after human exposure. Other agents that may affect fertility include chemicals in plastics (e.g., phthalates), pesticides (e.g., DDT), products of combustion (e.g., dioxins), polychlorinated biphenyls (PCBs), and others. Most of these chemicals possess weak estrogen properties and are known as **endocrine-disrupting chemicals (EDCs)**. Direct toxicity to the spermatogonia is linked to changes in sperm quality.
- **Ionizing radiation and alkylating agents.** Nitrogen mustard gas and procarbazine have been found to have toxic effects on spermatogonia. **Electromagnetic and microwave radiation** also affect sperm count and motility.

Proliferating cells are particularly sensitive to mutagenic agents and the absence of essential metabolites. Therefore, nondividing Sertoli cells, Leydig cells, and reserve stem cells, which demonstrate low mitotic activity, are much less vulnerable than actively dividing, differentiating spermatogenic cells.

Structure of the Testis

The testes have an unusually thick connective tissue capsule, the tunica albuginea.

An unusually thick, dense connective tissue capsule, the **tunica albuginea**, covers each testis (Fig. 22.4). The inner part of this capsule, the **tunica vasculosa**, is a loose connective tissue layer that contains blood and lymphatic vessels. Each testis is divided into approximately 250 lobules by incomplete **connective tissue septa** that project from the capsule. Along the posterior surface of the testis, the tunica albuginea thickens and projects inward as the mediastinum testis. Blood vessels, lymphatic vessels, and the genital excurrent ducts pass through the mediastinum as they enter or leave the testis.

FIGURE 22.4. Sagittal section of the human testis. **a.** This schematic diagram shows a midsagittal section of the human testis. The genital duct system, which includes the tubuli recti, rete testis, efferent ducts, duct of the epididymis, and ductus deferens, is also shown. Note the thick connective tissue covering, the tunica albuginea, and the surrounding tunica vaginalis. (Modified from Dym M. In: Weiss L, ed. *Cell and Tissue Biology: A Textbook of Histology*. 6th ed. Urban & Schwarzenberg; 1988.) **b.** Sagittal section of a hematoxylin and eosin (H&E)-stained section of the testis and the head and body of the epididymis. Again, note the surrounding tunica albuginea and tunica vaginalis. Only a small portion of the rete testis is visible in this section. Its connection with the excurrent duct system is not evident in the plane of this section. $\times 3$.

Each lobule consists of several highly convoluted seminiferous tubules.

Each lobule of the testis consists of one to four **seminiferous tubules**, in which sperm are produced, and a connective tissue stroma, in which testosterone-producing **Leydig (interstitial) cells** are contained (Fig. 22.5 and Plate 22.1, page 896). Each tubule within the lobule forms a loop and, because of its considerable length, is highly convoluted, actually folding on itself within the lobule. The ends of the loop are located near the **mediastinum** of the testis, where they assume a short

straight course. This part of the seminiferous tubule is called the **straight tubule (tubulus rectus)**. It becomes continuous with the **rete testis**, an anastomosing channel system within the mediastinum.

FIGURE 22.5. Photomicrographs of human testis. a. This low-magnification photomicrograph of a hematoxylin and eosin (H&E)-stained section of human testis shows seminiferous tubules and the tunica albuginea. The larger blood vessels are present in the inner aspect of the tunica albuginea. The seminiferous tubules are highly convoluted; thus, the profiles that they present in the section are variable in appearance. $\times 30$. b. A higher magnification of the previous specimen shows several seminiferous tubules. Note the population of Leydig (interstitial) cells that occur in small clusters in the space between adjoining tubules. $\times 250$.

The seminiferous tubules consist of a seminiferous epithelium surrounded by a tunica propria.

Each **seminiferous tubule** is approximately 50 cm long (range, 30–80 cm) and 150–250 μm in diameter. The seminiferous epithelium is an unusual and complex stratified epithelium composed of two basic cell populations:

- **Sertoli cells**, also known as *supporting*, or *sustentacular*, *cells*. These cells do not replicate after puberty. Sertoli cells are columnar cells with extensive apical and lateral processes that surround the adjacent spermatogenic cells and occupy the spaces between them. However, this elaborate configuration of the Sertoli cells cannot be seen distinctly in routine hematoxylin and eosin (H&E) preparations. Sertoli cells give structural organization to the tubules as they extend through the full thickness of the seminiferous epithelium.
- **Spermatogenic cells**, which regularly replicate and differentiate into mature sperm. These cells are derived from primordial germ cells originating in the yolk sac that colonize the gonadal ridges during the early development of the testis. Spermatogenic cells are organized in poorly defined layers of progressive development between adjacent Sertoli cells (Fig. 22.6). The most immature spermatogenic cells, called **spermatogonia**, rest on the basal lamina. The most mature cells, called **spermatids**, are attached to the apical portion of the Sertoli cell, where they border the lumen of the tubule.

FIGURE 22.6. Schematic drawing of human seminiferous epithelium. This drawing shows the relationship of the Sertoli cells to the spermatogenic cells. The seminiferous epithelium rests on a basal lamina, and a layer of peritubular cells surrounds the seminiferous tubule. The spermatogonia—type A pale, type A dark, and type B—and preleptotene spermatocytes are located in the basal compartment of the seminiferous epithelium below the junctional complex, between adjacent Sertoli cells. Pachytene primary spermatocytes, early spermatids, and late spermatids, with partitioning residual cytoplasm that becomes the residual body, are seen above the junctional complex in the abluminal compartment. (Redrawn from Clermont Y. The cycle of the seminiferous epithelium in man. *Am J Anat.* 1963;112:35.)

The **tunica (lamina) propria**, also called *peritubular tissue*, is a multilayered connective tissue that lacks typical fibroblasts. In humans, it consists of three to five layers of **myoid cells** (peritubular contractile cells) and collagen fibrils, external to the basal lamina of the seminiferous epithelium (see Fig. 22.6). At the ultrastructural level, myoid cells demonstrate features associated with smooth muscle cells, including a basal lamina and large numbers of actin filaments. They also exhibit a significant amount of rough endoplasmic reticulum (rER), a feature indicating their role in collagen synthesis in the absence of typical fibroblasts. Rhythmic contractions of the myoid cells create peristaltic waves that help move spermatozoa and testicular fluid through the seminiferous tubules to the excurrent duct system. Blood vessels and extensive lymphatic vasculature as well as Leydig cells are present external to the myoid layer.

As a normal consequence of aging, the tunica propria increases in thickness. This thickening is accompanied by a decreased rate of sperm production and an overall reduction in the size of the seminiferous tubules. Excessive thickening of the tunica propria earlier in life is associated with infertility.

Leydig Cells

Leydig cells (interstitial cells) are large, polygonal, eosinophilic cells that typically contain lipid droplets (Fig. 22.7). Lipofuscin pigment is also frequently present in these cells as well as distinctive, rod-shaped cytoplasmic crystals, the **crystals of Reinke** (Fig. 22.8). In routine histologic

preparations, these crystals are refractile and measure approximately $3 \times 20 \text{ }\mu\text{m}$. Although their exact nature and function remain unknown, they probably represent a protein product of the cell.

FIGURE 22.7. Electron micrograph of Leydig cells. This electron micrograph shows portions of several Leydig cells. The cytoplasm

contains an abundance of smooth endoplasmic reticulum (sER), a characteristic of Leydig cells. Other features characteristic of the Leydig cell seen in the lower power micrograph are the numerous lipid droplets (*L*), the segmented profiles of the Golgi apparatus (*G*), and the presence of variable numbers of lysosomes (*Ly*). Occasional profiles of rough endoplasmic reticulum (*rER*) are also seen. Note also the microvilli along portions of the cell surface (*arrows*). *M*, cytoplasm of adjacent macrophage. $\times 10,000$. Inset. sER at higher magnification. The very dense particles are glycogen. $\times 60,000$.

FIGURE 22.8. Electron micrograph of a Reinke crystal. This electron micrograph shows the internal structure of a Reinke crystal in

the cytoplasm of a human Leydig cell. Also note the smooth endoplasmic reticulum (sER) (*arrows*) and a lipid droplet (*L*) in the cytoplasm. $\times 16,000$. (Courtesy of Dr. Don F. Cameron.)

Like other steroid-secreting cells, Leydig cells have an elaborate smooth endoplasmic reticulum (sER), a feature that accounts for their eosinophilia (see Fig. 22.7). The enzymes necessary for the synthesis of testosterone from cholesterol are associated with the sER. Mitochondria with tubulovesicular cristae, another characteristic of steroid-secreting cells, are also present in Leydig cells.

Leydig cells differentiate and secrete **testosterone** during early fetal life. Secretion of testosterone is required during embryonic development, sexual maturation, and reproductive function:

- In the **embryo**, secretion of testosterone and other androgens is essential for the normal development of the gonads in the male fetus. In addition to testosterone, Leydig cells secrete **insulin-like protein 3 (INSL3)** that stimulates the descent of the testis during development.
- At **puberty**, secretion of testosterone is responsible for the initiation of sperm production, accessory sex gland secretion, and development of secondary sex characteristics. Secretion of INSL3 also promotes meiotic divisions in the seminiferous tubules.
- In the **adult**, secretion of testosterone is essential for the maintenance of spermatogenesis and secondary sex characteristics, genital excurrent ducts, and accessory sex glands. **Leydig cells in the adult testes are the chief source of circulating insulin-like factor-3 (INSL3) protein.** Measurement of INSL3 is utilized in clinical tests to establish the **Leydig cell steroidogenetic capacity index**. In addition to the secretion of INSL3, Leydig cells produce and secrete **oxytocin**. Testicular oxytocin stimulates contraction of myoid cells that surround the seminiferous tubules, moving the spermatozoa toward the efferent ductules.

The Leydig cells are active in the early differentiation of the male fetus and then undergo a period of inactivity beginning

at about 5 months of fetal life. Inactive Leydig cells are difficult to distinguish from fibroblasts. When Leydig cells are exposed to gonadotropic stimulation at puberty, they again become androgen-secreting cells and remain active throughout life.

Leydig cell tumors are usually benign tumors and occur during two distinct periods (in childhood and adults between 20 and 60 years old). They are hormonally active and secrete androgens or a combination of androgens and estrogens. Commonly, they are composed of uniform cells that have all of the characteristics of steroid hormone-secreting cells, including Reinke crystals. Initial symptoms of these benign tumors, besides testicular enlargement, are usually related to an abnormal level of hormone production. In prepubertal individuals, this leads to **sexual precocity** (unexpected pubertal changes in early age), whereas in adults, it may be observed as **feminization** (development of female sexual characteristics) and **gynecomastia** (development of breast in males).

■ SPERMATOGENESIS

Spermatogenesis is the process by which spermatogonia develop into sperm.

Spermatogenesis, the process by which sperm are produced, involves a complex and unique series of events. It begins shortly before puberty, under the influence of rising levels of pituitary gonadotropins, and continues throughout life. For descriptive purposes, spermatogenesis is divided into three distinct phases:

- **Spermatogonial phase**, in which spermatogonia divide by mitosis to replace themselves as well as provide a population of committed spermatogonia that will eventually give rise to primary spermatocytes
- **Spermatocyte phase (meiosis)**, in which primary spermatocytes undergo two meiotic divisions to reduce both the chromosome number and amount of DNA to produce haploid cells called *spermatids*
- **Spermatid phase (spermiogenesis)**, in which spermatids differentiate into mature sperm cells

At the conclusion of spermatogenesis, spermatids undergo their final maturation and are released during a process called **spermiation** from the supporting Sertoli cells into the lumen of the seminiferous tubule.

Spermatogonial Phase

In the spermatogonial phase, stem cells divide to replace themselves and provide a population of committed spermatogonia.

Spermatogonial stem cells undergo multiple divisions and produce **spermatogonia** that can be differentiated into three types based on the appearance of their nuclei in routine H&E preparations:

- **Type A dark (Ad) spermatogonia** have ovoid nuclei with intensely basophilic, finely granular chromatin. These spermatogonia are thought to be the stem cells of the seminiferous epithelium. They divide at irregular intervals to give rise to either a pair of type Ad spermatogonia that remain as **reserve stem cells** or to a pair of type Ap spermatogonia.
- **Type A pale (Ap) spermatogonia** have ovoid nuclei with lightly staining, finely granular chromatin. Ap spermatogonia are committed to the differentiation process that produces the sperm. They undergo several successive mitotic divisions, thereby increasing their number. Type Ap spermatogonia are also called **renewing stem cells**.
- **Type B spermatogonia** have generally spherical nuclei with chromatin that is condensed into large clumps along the nuclear envelope and around a central nucleolus (see Fig. 22.6).

An unusual feature of the division of an Ad spermatogonium into two types Ap spermatogonia is that the daughter cells remain connected by a thin cytoplasmic bridge. This same phenomenon occurs with each subsequent mitotic and meiotic division of the progeny of the original pair of Ap spermatogonia (Fig. 22.9). Thus, all of the progeny of an initial pair of Ap spermatogonia are connected, much like a strand of pearls. These cytoplasmic connections remain intact until the last stages of spermatid maturation and are essential for the synchronous development of each clone from an original pair of Ap cells.

FIGURE 22.9. Schematic diagram illustrating the generations of spermatogenic cells. This diagram shows the clonal nature of the successive generations of spermatogenic cells. Type A dark spermatogonia are recognized as the reserve stem cells in the testis, whereas type A pale spermatogonia are the renewing stem cells. Type A pale spermatogonia undergo a series of synchronized cell divisions to either produce new type A pale cells or form more differentiated type B

spermatogonia that undergo further divisions into primary spermatocytes. Note that cytoplasmic division is complete only in the type A dark spermatogonia. All other spermatogenic cells remain connected by intercellular bridges as they undergo mitotic and meiotic division and differentiation of the spermatids. Note also that primary spermatocytes undergo meiosis I and secondary spermatocytes undergo meiosis II. The cells separate into individual spermatozoa as they are released from the seminiferous epithelium. The residual bodies remain connected and are phagocytosed by the Sertoli cells. (Based on Dym M, Fawcett DW. Further observations on the numbers of spermatogonia, spermatocytes, and spermatids connected by intercellular bridges in the mammalian testis. *Biol Reprod.* 1971;4:195 - 215.)

After several divisions, type A spermatogonia differentiate into type B spermatogonia. The appearance of type B spermatogonia represents the last event in the spermatogonial phase.

Spermatocyte Phase (Meiosis)

In the spermatocyte phase, primary spermatocytes undergo meiosis to reduce both the chromosome number and the amount of DNA.

The mitotic division of type B spermatogonia produces **primary spermatocytes**. They replicate their DNA shortly after they form and before meiosis begins so that each primary spermatocyte contains the normal chromosomal number ($2n$). Because each chromosome consists of two sister chromatids, primary spermatocytes contain double the amount of DNA ($4d$).

Meiosis I results in reduction of both the number of chromosomes (from $2n$ to $1n$) and the amount of DNA to the haploid number (from $4d$ to $2d$); thus, secondary spermatocytes have a haploid number of chromosomes ($1n$) and $2d$ amount of DNA. Because no DNA replication precedes **meiosis II**, the spermatids, which are formed after this division, will also have the haploid ($1n$) number of chromosomes, each containing a single chromatid ($1d$). Meiosis is described in detail in Chapter 3, The Cell Nucleus (pages 102-103); a brief description of spermatocyte meiosis follows.

Each spermatocyte undergoes meiosis to form four haploid spermatids.

Prophase of the first meiotic division, during which the chromatin condenses into visible chromosomes, lasts up to 22 days in human primary spermatocytes. At the end of prophase, 44 autosomes and an X and a Y chromosome, each having two chromatin strands (chromatids), can be identified. Homologous chromosomes are paired as they line up on the metaphase plate.

The **paired homologous chromosomes**, called **tetrads** because they consist of four chromatids, exchange genetic material in a process called **crossing-over**. During this exchange, the four chromatids rearrange into a tripartite structure called a **synaptonemal complex**. This process ensures genetic diversity. Through genetic exchange, the four spermatids produced from each spermatocyte differ from each other and from every other spermatid.

After crossing-over is complete, the homologous chromosomes separate and move to the opposite poles of the meiotic spindle. Thus, the tetrads, which have been modified by crossing-over, separate and become dyads again. The two chromatids of each original chromosome (although modified by crossing-over) remain together.

The movement of a particular chromosome of a homologous pair to either pole of the spindle is random (i.e., maternally derived chromosomes and paternally derived chromosomes do not sort themselves out at the metaphase plate). This random sorting is another source of genetic diversity in the resulting sperm.

The cells derived from the first meiotic division are called **secondary spermatocytes**. These cells immediately enter the prophase of the second meiotic division *without synthesizing new DNA* (i.e., without passing through an S phase; see pages 102–103). The second meiotic division is short and lasts only several hours. Each secondary spermatocyte has a reduced number of chromosomes ($1n$), which is represented by 22 autosomes, and an X or a Y chromosome. Each of these chromosomes consists of two sister chromatids. The secondary spermatocyte has the (2d) diploid amount of DNA. During the metaphase of the second meiotic division, the chromosomes line up at the metaphase plate, and the sister chromatids separate and move to opposite poles of the spindle. As the second meiotic division is completed and the nuclear membranes reform, two haploid **spermatids**, each

containing 23 single-stranded chromosomes ($1n$) and the $1d$ amount of DNA, are formed from each secondary spermatocyte (Fig. 22.10).

FIGURE 22.10. Comparison of mitosis and meiosis in spermatogenesis and oogenesis. The two pairs of chromosomes ($2n$) of

maternal and paternal origin are depicted in *red* and *blue*, respectively. Mitotic division produces daughter cells that are genetically identical to the parental ($2n$) cell. Meiotic division, which has two components, a reductional division and an equatorial division, produces a cell that has only half the number of chromosomes (n). In addition, during the chromosome pairing in prophase I of meiosis, chromosome segments are exchanged, a process called *crossing-over*, creating genetic diversity. In humans, the first polar body does not divide, but it does so in other species.

Spermatid Phase (Spermiogenesis)

In the spermatid phase, spermatids undergo extensive cell remodeling as they differentiate into mature sperm.

Each **spermatid** that results from the second meiotic division is haploid in DNA content (**1d**) and chromosome number (**1n**) represented by 22 autosomes and an X or Y chromosome. No further division occurs. The haploid spermatids undergo a differentiation process that produces mature sperm, which are also haploid. The $2d$ condition is restored when a sperm fertilizes an oocyte.

The extensive cell remodeling that occurs during differentiation of the spermatid population into mature sperm (spermiogenesis) consists of four phases: the Golgi phase, cap phase, acrosome phase, and maturation phase. These phases occur while the spermatids are physically attached to the Sertoli cell's plasma membrane by specialized junctions. The morphologic changes in all four phases that occur during spermiogenesis are described here and summarized in Figure 22.11.

FIGURE 22.11. Schematic diagram of spermiogenesis in the human. The basic changes in the structure of the key organelles of the spermatid are illustrated (see text for detailed explanation). (Modified from Dym M. In: Weiss L, ed. *Cell and Tissue Biology: A Textbook of Histology*. 6th ed. Urban & Schwarzenberg; 1988.)

Golgi phase

This phase is characterized by the presence of periodic acid-Schiff (PAS)-positive granules that accumulate in the numerous Golgi complexes of the spermatid. These **proacrosomal granules**,

rich in glycoproteins, coalesce into a membrane-bound vesicle, the **acrosomal vesicle**, adjacent to the nuclear envelope. The vesicle enlarges and its contents increase during this phase. The position of the acrosomal vesicle determines the anterior pole of the developing sperm. Also during this phase, the centrioles migrate from the juxtannuclear region to the posterior pole of the spermatid, where the mature centriole aligns at right angles to the plasma membrane. The centriole initiates the assembly of the nine peripheral microtubule doublets and two central microtubules that constitute the **axoneme** of the sperm tail.

Cap phase

In this phase, the acrosomal vesicle spreads over the anterior half of the nucleus. This reshaped structure is called the **acrosomal cap**. The portion of the nuclear envelope beneath the acrosomal cap loses its pores and becomes thicker. The nuclear content also condenses. DNA in the spermatid is about 6 times smaller than the DNA in mitotic chromosomes. This high condensation of nuclear DNA is achieved by the presence of small, highly basic proteins called **protamines** that become incorporated into the chromatin during spermiogenesis, replacing the core histones.

Acrosome phase

In this phase, the spermatid reorients itself so that the head becomes deeply embedded in the Sertoli cell and points toward the basal lamina. The developing flagellum extends into the lumen of the seminiferous tubule. The condensed nucleus of the spermatid flattens and elongates, the nucleus and its overlying acrosome also move to a position immediately adjacent to the anterior plasma membrane, and the cytoplasm is displaced posteriorly. The cytoplasmic microtubules become organized into a cylindrical sheath, the **manchette**, which extends from the posterior rim of the acrosome toward the posterior pole of the spermatid.

The **centrioles**, which had earlier initiated the development of the flagellum, now move back to the posterior surface of the nucleus where the immature centriole becomes attached to a shallow groove in the nucleus. They are then modified to form the connecting piece, or neck region, of the developing sperm. Nine coarse fibers develop from the centrioles attached to the nucleus

and extend into the tail, becoming the outer dense fibers peripheral to the microtubules of the axoneme. These fibers unite the nucleus with the flagellum; hence, the name **connecting piece**.

As the plasma membrane moves posteriorly to cover the growing **flagellum**, the manchette disappears, and the mitochondria migrate from the rest of the cytoplasm to form a tight, helically wrapped sheath around the coarse fibers in the neck region and its immediate posterior extension (Fig. 22.12). This region is the **middle piece** of the tail of the sperm. Distal to the middle piece, a **fibrous sheath** consisting of two longitudinal columns and numerous connecting ribs surrounds the nine longitudinal fibers of the **principal piece** and extends nearly to the end of the flagellum. This short segment of the tail distal to the fibrous sheath is called the **end piece**.

HEAD AND NECK REGION

MIDDLE PIECE

PRINCIPAL PIECE

FIGURE 22.12. Diagram of a human spermatozoon. Regions of the spermatozoon are indicated on the *top*. Key structural features of the

head (viewed in frontal and sagittal planes), the middle piece, and the principal piece of the spermatozoon are illustrated on the *bottom*. (Modified from Pederson PL, Fawcett DW. In: Hafez ESE, ed. *Human Semen and Fertility Regulation in the Male*. CV Mosby; 1976.)

Maturation phase

This last phase of spermatid remodeling reduces excess cytoplasm from around the flagella to form mature **spermatozoon**. The Sertoli cells then phagocytose this excess cytoplasm, also termed the **residual body**. The intercellular bridges have characterized the developing gametes because the prespermatocyte stages remain with the residual bodies. Spermatids are no longer attached to each other and are released from the Sertoli cells.

Spermatids are released into the lumen of the seminiferous tubules during the process called spermiation.

Toward the end of the maturation phase of spermatogenesis, elongated spermatids are released from Sertoli cells into the lumen of seminiferous tubule. This complex process called **spermiation** involves the progressive removal of specialized Sertoli-to-spermatid junctional complexes and disengagement of spermatids from the Sertoli cell. The presence of $\beta 1$ -integrins in the Sertoli-to-spermatid junctions, as well as increased activity of integrin-linked kinase at the time of spermiation, suggests enzymatic control of spermatid release. The rate of spermiation in the testis determines the number of sperm cells in the ejaculate of semen. Various pharmacologic treatments, toxic agents, and gonadotropin suppression result in spermiation failure, in which spermatids are not released but instead are retained and phagocytosed by the Sertoli cell.

Structure of the Mature Sperm

The events of spermiogenesis result in a structurally unique cell.

The **mature human sperm** is about 60 μm long. The **sperm head** is flattened and pointed and measures 4.5 μm long by 3 μm wide by 1 μm thick (see Fig. 22.12). The **acrosomal cap** that covers the anterior two-thirds of the nucleus contains **hyaluronidase**,

neuraminidase, acid phosphatase, and a trypsin-like protease called **acrosin**. These acrosomal enzymes are essential for penetration of the zona pellucida of the ovum. The release of acrosomal enzymes as the sperm makes contact with the egg is the first step in the **acrosome reaction**. This complex process facilitates sperm penetration and subsequent fertilization and prevents the entry of additional sperm into the ovum.

The **sperm tail** is subdivided into the neck, middle piece, principal piece, and end piece. The short neck contains the centrioles and the origin of the coarse fibers. The middle piece is approximately 7 μm long and contains mitochondria, helically wrapped around the coarse fibers and the axonemal complex. These mitochondria provide the energy for movement of the tail and thus are responsible for the motility of the sperm. The principal piece is approximately 40 μm long and contains the fibrous sheath external to the coarse fibers and the axonemal complex. The end piece, approximately the last 5 μm of the flagellum in the mature sperm, contains only the axonemal complex.

Newly released sperm cells are processed in the epididymis where they acquire motility and undergo further maturation.

Newly released sperm cells are **nonmotile** and are transported from the seminiferous tubules in a fluid secreted by the Sertoli cells. The fluid and sperm flow through the **seminiferous tubules**, facilitated by peristaltic contractions of the peritubular contractile cells of the lamina propria. They then enter the **straight tubules**, a short segment of the seminiferous tubule where the epithelium consists only of Sertoli cells. At the mediastinum testis, the fluid and sperm enter the **rete testis**, an anastomosing system of ducts lined by simple cuboidal epithelium (Plate 22.2, page 898). From the rete testis, they move into the extratesticular portion of the **efferent ductules** (ductuli efferentes), the first part of the excurrent duct system, and then into the proximal portion of the **duct of the epididymis** (ductus epididymis). As the sperm cells move through 4–5 m of the highly coiled duct of the epididymis, they acquire motility and undergo several maturational changes. These changes include the following:

- Further condensation of nuclear DNA due to a series of chromatin remodeling events, leading to replacement of histones by protamines. The head of the sperm decreases in size.
- Additional reduction of cytoplasm. The sperm cells become more slender.
- Changes in plasma membrane lipids, proteins, and glycosylation
- Alterations in the outer acrosomal membrane (decapacitation). The surface-associated decapacitation factor is added to inhibit the fertilizing ability of the sperm cells (page 883).

Initiation of sperm cell motility during cell transit through the epididymis is most likely related to changes in the intracellular levels of cyclic adenosine monophosphate (cAMP), calcium ions (Ca^{2+}), and intracellular pH. These factors regulate flagellar activity through changes in **protein phosphorylation**, resulting from activities of **protein kinases** and **protein phosphatases**. For instance, pharmacologic stimulation of **protein kinase A** activity increases motility of sperm cells, whereas inhibition of **protein phosphatase** activity may initiate or stimulate such motility. This suggests that phosphatases have an important role in the regulation of sperm kinetic activity.

Contractions of the smooth muscle that surrounds the progressively distal and larger ducts continue to move the sperm by peristaltic action until they reach the distal portion of the duct of the epididymis, where they are stored before ejaculation.

Sperm can *live* for several weeks in the male excurrent duct system, but they will *survive* only 2–3 days in the female reproductive tract. They acquire the ability to fertilize the ovum only after some time in the female tract. This process, which involves removal and replacement of glycocalyx components (glycoconjugates) on the sperm membrane, is called **capacitation**. Capacitation of spermatozoa is described in detail in Chapter 23, The Female Reproductive System (pages 919–920).

■ SEMINIFEROUS TUBULES

Cycle of the Seminiferous Epithelium

Differentiating spermatogenic cells are not arranged at random in the seminiferous epithelium; specific cell types are grouped together. These groupings or associations occur because intercellular bridges are present between the progeny of each pair of **type Ap spermatogonia** and because the synchronized cells spend specific amounts of time in each stage of maturation. All phases of differentiation occur sequentially at any given site in a seminiferous tubule as the progeny of stem cells remain connected by cytoplasmic bridges and undergo synchronous mitotic and meiotic divisions and maturation (see Fig. 22.10).

Each recognizable grouping, or **cell association**, is considered a **stage** in a cyclic process. The series of stages that appears between two successive occurrences of the same cell association pattern at any given site in the seminiferous tubule constitutes a **cycle of the seminiferous epithelium**. The cycle of the seminiferous epithelium has been most thoroughly studied in rats, in which 14 successive stages occur in a linear sequence along the tubule. In humans, six stages or cell associations are defined in the cycle of the seminiferous epithelium (Fig. 22.13). These stages are not as clearly delineated as those in rodents because in humans, the cellular associations occur in irregular patches that form a mosaic pattern.

FIGURE 22.13. Schematic drawing of the stages of the human seminiferous epithelium. This diagram shows each of the six recognizable cell associations (stages) that occur in the cycle of the human seminiferous epithelium. These stages of spermatogenesis are artificially defined according to changes observed in the spermatids during their various steps of differentiation. In 1952, six stages of human seminiferous epithelium were first described by Leblond and Clermont and, since then, have been adopted by most researchers. Stages are labeled with Roman numerals I to VI. (Cell associations depicted in this drawing are based on Clermont Y. The cycle of the seminiferous epithelium in man. *Am J Anat.* 1963;112:35 - 51.)

Duration of spermatogenesis in humans is approximately 74 days.

After injecting a pulse of tritiated thymidine, a specific generation of cells can be followed by sequential biopsies of the seminiferous tubules. In this way, the time required for the labeled cells to go through the various stages can be determined. Several generations of developing cells may be present in the

thickness of the seminiferous epithelium at any given site and at any given time, which produces the characteristic cell associations. Autoradiographic studies have revealed that the duration of the **cycle of the seminiferous epithelium** is constant, lasting about 16 days in humans. In humans, it would require about 4.6 cycles (each 16 days long), or **approximately 74 days**, for a spermatogonium produced by a stem cell to complete the process of spermatogenesis. It would then require approximately **12 days** for the spermatozoon to **pass through the epididymis**. Approximately 300 million sperm cells are produced daily in the human testis. The length of the cycle and the time required for spermatogenesis are constant and specific in each species. **Therefore, in any pharmacologic intervention (e.g., therapy for male infertility), if a drug is given that affects the initial phases of spermatogenesis, approximately 86 days are required to see the effect of that compound on sperm production.**

Waves of the Seminiferous Epithelium

As indicated earlier, the cycle of the seminiferous epithelium describes changes that occur with time at any given site in the tubule. In addition, the **wave of the seminiferous epithelium** describes the distribution of patterns of cellular association (**spermatogenic stages**) along the length of the tubule. In rodents and other mammals that have been studied, including subhuman primates, each stage occupies a significant length of the seminiferous tubule, and the stages appear to occur sequentially along the length of the tubule. In the rat, there are approximately 12 waves in each tubule. A transverse section through the tubule usually reveals only one pattern of cell associations. There are no waves in the human seminiferous epithelium, and the arrangement of spermatogenic stages along the seminiferous tubule is random. Each pattern of cellular associations (spermatogenic stage) has a **patch-like distribution in the human** seminiferous tubule (Fig. 22.14). Patches do not extend around the circumference of the tubule, nor are they in sequence. Therefore, a transverse section through a human seminiferous tubule may reveal as many as six different stages of the cycle arranged in a pie-wedge manner around the circumference of the tubule.

FIGURE 22.14. Diagram of organization of seminiferous epithelium in humans and other species. a. In mice and other rodent species, a specific cellular association occupies varying lengths along the tubule. Therefore, in a typical cross section, only a single cellular association is observed. b. In humans, cellular associations occur in irregularly shaped areas along the tubule, and therefore, a cross section typically shows two or more cellular associations.

Sertoli Cells

Sertoli cells constitute the true epithelium of the seminiferous epithelium.

Sertoli cells (sustentacular cells) are tall, columnar, nonreplicating epithelial cells that rest on the thick, multilayered basal lamina of the seminiferous epithelium (Fig. 22.15). They are the supporting cells for the developing spermatozoa that attach to their surface after meiosis. Sertoli cells contain an extensive sER, a well-developed rER, and stacks of annulate lamellae. They have numerous spherical and elongated mitochondria, a well-developed Golgi apparatus, and varying numbers of lysosomes, lipid droplets, vesicles, and glycogen granules.

FIGURE 22.15. Electron micrograph of a human Sertoli cell. This electron micrograph shows characteristic crystalloid inclusion bodies of

Charcot-Böttcher in the basal cytoplasm of the Sertoli cell. The basal lamina (*BL*) is indicated for orientation. $\times 9,000$. Inset. This higher magnification shows filaments of the crystalloid. $\times 27,000$. (Courtesy of Dr. Don F. Cameron.)

The cytoskeleton of the Sertoli cell is one of the most elaborate in the human body and contains the following components:

- **Microtubules** that are abundant and predominately oriented parallel to the long axis of the cell. Unlike in many other cells, microtubules are nucleated at the periphery of the Sertoli cell and not from the microtubule-organizing center (MTOC). They are all oriented with their minus (–) ends toward the apex and plus (+) ends toward the base of the cell. In addition to their role in vesicular transport, recent evidence suggests that microtubules and microtubule-associated motor proteins are responsible for repositioning of the embedded elongated spermatids in the Sertoli cell's cytoplasm.
- **Intermediate filaments** that are a major component of the Sertoli cell's cytoskeleton and consist mainly of **vimentin** (class III of intermediate filament proteins). They form a perinuclear sheath that surrounds and separates the nucleus from other cytoplasmic organelles. Intermediate filaments extend from the perinuclear sheath to the desmosome-like junctions between the adjacent Sertoli cells and the hemidesmosomes.
- **Actin filaments** that are concentrated beneath the plasma membrane near the intercellular junctions. Actin filaments reinforce and stabilize the Sertoli intercellular junction specializations of plasma membrane.

The euchromatic Sertoli cell nucleus, a reflection of this very active cell, is generally ovoid or triangular and may have one or more deep infoldings. Its shape and location vary. It may be flattened, lying in the basal portion of the cell near and parallel to the base of the cell, or it may be triangular or ovoid, lying near or some distance from the base of the cell. In some species, the Sertoli cell's nucleus contains a unique tripartite structure that consists of an RNA-containing nucleolus

flanked by a pair of DNA-containing bodies called **karyosomes** (Fig. 22.16).

FIGURE 22.16. Schematic drawing of the Sertoli cell and its relationship to adjacent spermatogenic cells. This drawing shows the Sertoli-to-Sertoli junctional specialization between adjacent Sertoli cells and the Sertoli-to-spermatid junctional specialization between the Sertoli cell and late spermatids. The Sertoli-to-Sertoli junctional complex is an adhesion device that includes a tight junction that contributes to the blood-testis barrier. The junctional specialization between the Sertoli cell and late spermatids residing in deep recesses within the apical cytoplasm is an adhesion device only. Lateral processes of the Sertoli cells extend over the surface of the spermatocytes and spermatids. Note the ultrastructural features of the Sertoli cell, including the microtubule arrays and characteristic shape of the nucleus and its karyosome. *rER*, rough endoplasmic reticulum; *sER*, smooth endoplasmic reticulum. (Reprinted with permission from Bloom W, Fawcett DW. *A Textbook of Histology*. WB Saunders; 1975.)

In humans, characteristic **inclusion bodies of Charcot-Böttcher** are found in the basal cytoplasm. These slender fusiform crystalloids measure 10–25 μm long by 1 μm wide and are visible in routine histologic preparations. With transmission electron microscopy, they are resolved as bundles of poorly ordered, parallel or converging, straight, dense 15-nm-diameter filaments (see Fig. 22.15). Their chemical composition and function are unknown; however, recent studies detect an accumulation of lipoprotein receptor (CLA-1) proteins. This

suggests that inclusion bodies may be involved in lipid transport and their utilization by the Sertoli cells.

The Sertoli cell-to-Sertoli cell junctional complex consists of a structurally unique combination of membrane and cytoplasmic specializations.

Sertoli cells are bound to one another by an unusual **Sertoli cell-to-Sertoli cell junctional complex** (Fig. 22.17). This complex is characterized, in part, by an exceedingly tight junction (zonula occludens) that includes more than 50 parallel fusion lines in the adjacent membranes. In addition, two cytoplasmic components characterize this unique junctional complex:

FIGURE 22.17. Electron micrograph of Sertoli cell junctions. This electron micrograph demonstrates a Sertoli-to-Sertoli junctional complex and, in close proximity, a Sertoli-to-spermatid junctional specialization. Condensation and shaping of the spermatid nucleus (*N*) are well advanced. The acrosome (*A*) of the spermatid appears as a V-shaped profile, and in close association with it is the Sertoli cell

junctional specialization characterized by bundles of microfilaments that are cut in cross section (*arrows*). The associated profile of endoplasmic reticulum resides immediately adjacent to the microfilament bundles. The Sertoli-to-Sertoli junction lies below, joining one Sertoli cell (S^1) to the adjacent Sertoli cell (S^2). The *arrowheads* indicate the limits of the junction. Note that the junction here reveals the same elements, the microfilament bundles (*arrows*) and a profile of endoplasmic reticulum, as are seen in the Sertoli-to-spermatid junctional specialization. Not evident at this magnification is the tight junction associated with the Sertoli-to-Sertoli junctional complex. $\times 30,000$.

- A **flattened cisterna of sER** lies parallel to the plasma membrane in the region of the junction in each cell.
- **Actin filament bundles**, hexagonally packed, are interposed between the sER cisternae and the plasma membranes.

A similar-appearing junctional complex in the Sertoli cell is also present at the site where the spermatids are attached. However, no tight junction is present, and the spermatid lacks flattened cisternae of sER and actin filament bundles (see Figs. 22.16 and 22.17). Other junctional specializations of the Sertoli cells include gap junctions between Sertoli cells, desmosome-like junctions between Sertoli cells and early-stage spermatogenic cells, and hemidesmosomes at the Sertoli cell-basal lamina interface.

The Sertoli cell-to-Sertoli cell junctional complex divides the seminiferous epithelium into basal and luminal compartments, segregating postmeiotic germ cell development and differentiation from the systemic circulation.

The Sertoli cell-to-Sertoli cell junctions establish two epithelial compartments, a **basal epithelial compartment** and a **luminal compartment** (see Fig. 22.16). Spermatogonia and early primary spermatocytes are restricted to the basal compartment (i.e., between the Sertoli cell-to-Sertoli cell junctions and the basal lamina). More mature spermatocytes and spermatids are restricted to the luminal side of the Sertoli cell-to-Sertoli cell junctions. **Early spermatocytes** produced by mitotic division of type B spermatogonia **must pass through the junctional complex** to move from the basal compartment to the luminal compartment. This movement occurs via the formation of a new junctional

complex between Sertoli cell processes that extends beneath the newly formed spermatocytes, followed by the breakdown of the junction above them. Thus, in the differentiation of the spermatogenic cells, meiosis and spermiogenesis take place in the luminal compartment.

In both compartments, spermatogenic cells are surrounded by complex processes of the Sertoli cells. Because of the unusually close relationships between Sertoli cells and differentiating spermatogenic cells, it has been suggested that Sertoli cells serve as “nurse,” or supporting, cells (i.e., they function in the exchange of metabolic substrates and wastes between the developing spermatogenic cells and the circulatory system).

In addition, Sertoli cells phagocytose and break down the residual bodies formed in the last stage of spermiogenesis. They also phagocytose any spermatogenic cells that fail to differentiate completely.

The Sertoli cell-to-Sertoli cell junctional complex is the site of the blood-testis barrier.

In addition to the physical compartmentalization described earlier, the Sertoli cell-to-Sertoli cell junctional complex also creates a permeability barrier called the **blood-testis barrier**. This barrier is essential in creating a physiologic compartmentalization within the seminiferous epithelium with respect to ionic, amino acid, carbohydrate, and protein composition. Therefore, the composition of the fluid in the seminiferous tubules and excurrent ducts differs considerably from the composition of the blood plasma and testicular lymph.

Plasma proteins and circulating antibodies are excluded from the lumen of the seminiferous tubules. The exocrine secretory products of the Sertoli cells (particularly **androgen-binding protein [ABP]**, which has a high binding affinity for testosterone and DHT) are highly concentrated in the lumen of the seminiferous tubules and maintain a high concentration of testosterone, which provides a favorable microenvironment for the differentiating spermatogenic cells.

Most importantly, the blood-testis barrier isolates the genetically different and, therefore, antigenic haploid germ cells (secondary spermatocytes, spermatids, and sperm) from the

immune system of the adult male. Antigens produced by, or specific to, the sperm are prevented from reaching the systemic circulation. Conversely, γ -globulins and specific sperm antibodies found in some individuals are prevented from reaching the developing spermatogenic cells in the seminiferous tubule (Folder 22.3). Therefore, the **blood-testis barrier** serves an essential role in isolating the spermatogenic cells from the immune system.

FOLDER 22.3

CLINICAL CORRELATION: SPERM-SPECIFIC ANTIGENS AND THE IMMUNE RESPONSE

Two basic facts are well established about the immunologic importance of the **blood-testis barrier**:

- Spermatozoa and spermatogenic cells possess molecules that are unique to these cells and are recognized as “foreign” (not self) by the immune system.
- Spermatozoa are first produced at puberty, long after the individual has become immunocompetent (i.e., capable of recognizing foreign molecules and producing antibodies against them).

Failure of the spermatogenic cells and spermatozoa to remain isolated results in the production of sperm-specific antibodies. Such an immune response is sometimes seen after **vasectomy** and in some cases of **infertility**. After vasectomy, sperm-specific antibodies are produced as the cells of the immune system are exposed to the spermatozoa that may leak from the severed ductus deferens. Thus, sperm no longer remain isolated from the immune system within the reproductive tract. In some cases of infertility, sperm-specific antibodies have been found in the semen. These antibodies cause the sperm to agglutinate, preventing movement and interaction with the ovum.

Sertoli cells have both exocrine and endocrine secretory functions.

In addition to secreting fluid that facilitates passage of the maturing sperm along the seminiferous tubules to the intratesticular ducts, **Sertoli cells** produce critical factors necessary for the successful progression of spermatogonia into spermatozoa. They secrete a 90-kDa **androgen-binding protein (ABP)**. ABP concentrates testosterone in the luminal compartment

of the seminiferous tubule, where high concentrations of testosterone are essential for the normal maturation of the developing sperm.

Follicle-stimulating hormone (FSH) receptors and testosterone receptors are present in Sertoli cells; therefore, their secretory function is regulated by both FSH and testosterone (Fig. 22.18). Sertoli cells secrete several endocrine substances, such as **inhibin**, a 32-kDa glycoprotein hormone involved in the feedback loop that inhibits FSH release from the anterior pituitary gland. In addition, Sertoli cells synthesize **plasminogen activator**, which converts plasminogen to the active proteolytic hormone plasmin, **transferrin** (an iron-transporting protein), and **ceruloplasmin** (a copper-transporting protein). Furthermore, the Sertoli cells secrete other glycoproteins that function as growth factors or paracrine factors, such as MIF, stem cell factor (SCF), and glial cell line-derived neurotrophic factor (GDNF).

See text for explanation. *CNS*, central nervous system; *DHT*, dihydrotestosterone; *FSH*, follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone.

■ INTRATESTICULAR DUCTS

At the end of each seminiferous tubule, there is an abrupt transition to the **straight tubules**, or **tubuli recti**. This short terminal section of the seminiferous tubule is lined only by Sertoli cells (Plate 22.2, page 898). Near their termination, the straight tubules narrow, and their lining changes to a simple cuboidal epithelium.

The straight tubules empty into the **rete testis**, a complex series of interconnecting channels within the highly vascular connective tissue of the mediastinum (Fig. 22.19). A simple cuboidal or low columnar epithelium lines the channels of the rete testis. These cells have a single apical cilium and relatively few short apical microvilli.

FIGURE 22.19. Photomicrograph of human testis. a. This hematoxylin and eosin (H&E)-stained specimen shows the site that includes the mediastinum of the testis. On the *right* are seminiferous tubules, and on the *left* are the anastomosing channels of the rete testis. The *arrow* indicates termination of a straight tubule that is lined only by Sertoli cells. It is at this site that the tubule contents enter the rete testis and the channels are then lined by a simple cuboidal epithelium. $\times 70$. b. This higher magnification from a slightly deeper section of the same specimen shows the rete testis (*left*), a cross section of a seminiferous tubule (*upper right*), and a terminating straight tubule (*asterisk*) where it is entering the rete testis. Note the abrupt change in the epithelial lining at this site. As noted, the lining epithelium of the rete testis is simple cuboidal. $\times 275$.

■ EXCURRENT DUCT SYSTEM

The excurrent duct system develops from the mesonephric (Wolffian) duct and mesonephric tubules.

The initial development of Leydig cells and initiation of testosterone secretion stimulate the mesonephric (Wolffian) duct to differentiate into the excretory duct system for the developing testis (Fig. 22.20). The portion of the mesonephric duct adjacent to the developing testis becomes convoluted and differentiates into the **duct of the epididymis**. In addition, a number (about 20) of the remaining mesonephric tubules in this region make contact with the developing seminiferous cords and finally develop into the **efferent ductules** (Fig. 22.21 and Plate 22.3, page 900). They connect the developing rete testis with the duct of the epididymis. The distal part of the mesonephric duct acquires a thick, smooth muscle coat and becomes the **ductus deferens**. The end of the distal mesonephric duct gives rise to the **ejaculatory duct** and **seminal vesicles**.

FIGURE 22.20. Schematic diagram of development of intratesticular and excurrent duct systems. a. This diagram shows the testis in the seventh week of development before it descends into the scrotal sac.

Note that the mesonephric duct and its tubules give rise to the excurrent duct system for the developing testis. b. Sagittal section of a fully developed testis positioned within the scrotum. Note that the seminal vesicles, ejaculatory ducts, ductus deferens, and epididymis are all developed from the mesonephric duct. Efferent ductules originated from mesonephric tubules. The seminiferous tubules, straight tubules, and rete testis develop from the indifferent gonads. The prostate gland develops from the multiple outgrowths that originate from the pelvic urethra (a urogenital sinus derivative).

FIGURE 22.21. Photomicrograph of efferent ductules. The specimen in this photomicrograph was stained with picric acid and hematoxylin to better visualize the epithelial components of the efferent ductules. The efferent ductules are lined by pseudostratified columnar epithelium. The luminal surface has an uneven or wavy appearance because of the presence of alternating groups of tall columnar cells and cuboidal cells. The ductules are surrounded by several layers of circularly arranged smooth

muscle (*SM*). Within the ductule lumina are clumped spermatozoa (*asterisks*). Connective tissue (*CT*) makes up the stroma of the organ and contains blood vessels (*BV*) of various sizes. $\times 120$. Inset. This higher magnification of the pseudostratified epithelium shows columnar and cuboidal cells that contain sparse cilia. $\times 500$.

The efferent ductules are lined with pseudostratified columnar epithelium.

In humans, approximately 20 efferent ductules connect the channels of the rete testis at the superior end of the mediastinum to the proximal portion of the duct of the epididymis. As the efferent ductules exit the testis, they become highly coiled and form 6-10 conical masses, the conivasculosi, whose bases form part of the head of the epididymis. The conivasculosi, each about 10 mm in length, contain highly convoluted ducts that measure 15-20 cm in length. At the base of the cones, the efferent ductules open into a single channel, the duct of the epididymis (see Fig. 22.4).

The efferent ductules are lined with a pseudostratified columnar epithelium that contains clumps of tall and short cells, giving the luminal surface a saw-tooth appearance (see Fig. 22.21). Interspersed among the columnar cells are occasional basal cells that serve as epithelial stem cells. The tall columnar cells are ciliated. The short nonciliated cells have numerous microvilli and canalicular invaginations of the apical surface as well as numerous pinocytotic vesicles, membrane-bound dense bodies, lysosomes, and other cytoplasmic structures associated with endocytic activity. Most of the fluid secreted in the seminiferous tubules is reabsorbed in the efferent ductules.

A smooth muscle layer in the excurrent ducts first appears at the beginning of the efferent ductules. The smooth muscle cells form a layer of several cells thick in which the cells are arrayed as a circular sheath in the wall of the ductule. Interspersed among the muscle cells are elastic fibers. Transport of the sperm in the efferent ductules is affected largely by both ciliary action and contraction of this fibromuscular layer.

Epididymis

The epididymis is an organ that contains the efferent ductules and the duct of the epididymis.

The **epididymis** is a crescent-shaped structure that lies along the superior and posterior surfaces of the testis. It measures about 7.5 cm in length and consists of the **efferent ductules** and the **duct of the epididymis** and associated vessels, smooth muscles, and connective tissue coverings (Fig. 22.22 and Plate 22.3, page 900). The duct of the epididymis is a highly coiled tube measuring 4–6 m in length. The epididymis is divided into a **head**, a **body**, and a **tail** (see Fig. 22.4). The efferent ductules occupy the head, and the duct of the epididymis occupies the body and tail. Newly produced sperm, which enter the epididymis from the testis, mature during their passage through the duct of the epididymis, acquiring motility and the ability to fertilize an oocyte. During this androgen-dependent maturation process, the head of the sperm is modified by the addition of **surface-associated decapacitation factor** containing epididymal fluid glycoconjugates. This process, called **decapacitation**, inhibits the fertilizing ability of the sperm in a reversible manner. The surface-associated decapacitation factor is later released during **capacitation** that occurs in the female reproductive tract just before fertilization. After maturation in the epididymis, sperm can transport their haploid content of DNA to the ovum, and after capacitation, they can bind to sperm receptors on the zona pellucida of the ovum. This binding triggers the acrosome reaction in which the sperm uses its acrosomal enzymes to penetrate the outer covering of the oocyte.

FIGURE 22.22. Photomicrograph of human epididymis. This photomicrograph of a hematoxylin and eosin (H&E)-stained section shows the highly coiled ductus epididymis. Its coiled nature is reflected in the variously shaped profiles of the duct. Within the connective tissue are numerous profiles of blood vessels (*BV*). The vessels tend to follow the duct; thus, they too reflect multiple profiles of several vessels.

The section of the duct within the *rectangle* is shown at higher magnification in Figure 22.23. $\times 30$.

The principal cells in the pseudostratified epithelium of the epididymis are characterized by stereocilia.

Like most of the excurrent duct system, the duct of the epididymis is also lined with a pseudostratified columnar epithelium (Fig. 22.23). In general, it contains two types of cells:

FIGURE 22.23. Photomicrograph of human ductus epididymis. This higher magnification of the *rectangular area* in Figure 22.22 reveals the two cell types of the epididymal epithelium, the principal cells and the basal cells. Stereocilia (*arrows*) extend from the apical surface of the principal cells. The nuclei of the basal cells are spherical and are located in close proximity to the basement membrane, whereas the nuclei of the principal cells are cylindrical and conform to the columnar shape

of the cell. Surrounding the duct epithelium is a layer of circularly arranged smooth muscle cells. The duct lumen contains numerous sperm. $\times 250$.

- **Principal cells** that vary from approximately 80 μm in height in the head of the epididymis to approximately 40 μm in height in the tail. Numerous long, modified microvilli called **stereocilia** extend from the luminal surface of the principal cells (Plate 22.3, page 900). The stereocilia vary in height from 25 μm in the head to approximately 10 μm in the tail.
- **Basal cells** that represent small, round cells resting on the basal lamina. They are the stem cells of the duct epithelium.

In addition, **migrating lymphocytes** called **halo cells** are often found within the epithelium. Under normal conditions, the epithelium of the epididymis represents the most proximal level of the excurrent duct system in which lymphocytes are present.

Epididymal cells function in both absorption and secretion.

Most of the fluid that is not reabsorbed by the efferent ductules is reabsorbed in the proximal portion of the epididymis. The epithelial cells also phagocytose any residual bodies not removed by the Sertoli cells as well as sperm that degenerate in the duct. The apical cytoplasm of the principal cells contains numerous invaginations at the bases of the stereocilia, along with coated vesicles, multivesicular bodies, and lysosomes (Fig. 22.24).

FIGURE 22.24. Electron micrograph of epididymis. a. Electron micrograph of the epididymal epithelium showing principal cells (PC) extending to the lumen and a basal cell (BC) limited to the basal portion of the epithelium. Profiles of sperm (S) are seen in the lumen. The apical cytoplasm of the principal cells exhibits numerous long microvilli (stereocilia). $\times 3,000$. b. Apical surface of the epithelial cell with its numerous long microvilli (stereocilia). The middle piece of a sperm (S) is evident in the lumen. The small, light circular profiles (arrowheads) are endocytotic vesicles. $\times 13,000$.

The principal cells secrete glycerophosphocholine, sialic acid, and glycoproteins, which, in addition to the glycocalyx and steroids, aid in the **maturation of the sperm**. They have numerous cisternae of rER surrounding the basally located nucleus and a remarkably large supranuclear Golgi apparatus. Profiles of sER and rER are also present in the apical cytoplasm.

The smooth muscle coat of the duct of the epididymis gradually increases in thickness to become three layered in the tail.

In the head of the epididymis and most of the body, the smooth muscle coat consists of a thin layer of circular smooth muscle, resembling that of the efferent ductules. In the tail, inner and outer longitudinal layers are added. These three layers are then continuous with the three smooth muscle layers of the ductus

deferens, the next component of the excurrent duct system (Plate 22.4, page 902).

Differences in smooth muscle function parallel these morphologic differences. In the head and body of the epididymis, spontaneous, rhythmic peristaltic contractions serve to move the sperm along the duct. Few peristaltic contractions occur in the tail of the epididymis, which serves as the principal reservoir for mature sperm. These sperm are forced into the ductus deferens by intense contractions of the three smooth muscle layers after appropriate neural stimulation associated with ejaculation.

Ductus Deferens

The ductus deferens is the longest part of the excurrent duct system.

The **ductus deferens (vas deferens)** is a direct continuation of the tail of the epididymis (see Fig. 22.1). In the scrotum, the ductus deferens ascends along the posterior border of the testis, close to the testicular vessels and nerves. It then enters the abdomen as a component of the spermatic cord by passing through the inguinal canal. The **spermatic cord** contains all of the structures that pass to and from the testis. In addition to the ductus deferens, the spermatic cord contains the testicular artery, small arteries to the ductus deferens and cremaster muscle, the pampiniform plexus, lymphatic vessels, sympathetic nerve fibers, and the genital branch of the genitofemoral nerve. All of these structures are surrounded by fascial coverings derived from the anterior abdominal wall. After leaving the spermatic cord, the ductus deferens descends into the pelvis to the level of the bladder, where its distal end enlarges to form the **ampulla of ductus deferens**. The ampulla is joined there by the **duct of the seminal vesicle** and continues through the prostate gland to the prostatic urethra as the **ejaculatory duct**.

The ductus deferens is lined with a pseudostratified columnar epithelium that closely resembles that of the epididymis (Plate 22.4, page 902). The tall columnar cells also have stereocilia that extend into the lumen. The rounded basal cells rest on the basal lamina. Unlike the epididymis, however, the lumen of the duct does not appear smooth. In histologic preparations (Fig.

22.25), it appears to be thrown into deep longitudinal folds throughout most of its length, probably because of the contraction of the thick (1–1.5 mm) muscular coat of the duct during fixation.

FIGURE 22.25. Photomicrograph of human spermatic cord. **a.** This low-magnification photomicrograph shows a cross section of the spermatic cord containing several structures. These include the ductus deferens, the accompanying testicular artery and vein, and veins of the pampiniform plexus. $\times 15$. Inset. A higher magnification of a pampiniform vein. Note the bundles of longitudinal smooth muscles (cut in cross section) in the tunica adventitia and tunica intima. $\times 55$. **b.** This cross section of the ductus deferens shows the thick muscular wall organized in three distinct smooth muscle layers: an inner longitudinal ($SM[L]$), middle circular ($SM[C]$), and outer longitudinal ($SM[L]$). $\times 100$. Inset. A higher magnification shows the pseudostratified epithelium lining the ductus deferens. The tall principal cells possess long microvilli (stereocilia; *arrows*). The basal cells are in close proximity to the basement membrane and possess spherical nuclei. $\times 215$.

As the vas deferens passes through the spermatic cord, it can be easily palpable during physical examination of the scrotum. The easy access to this structure is advantageous during vasectomy, a male option for sterilization. Vasectomy is a safe and relatively simple method of sterilization and has lower rates of morbidity and mortality than female sterilization (uterine

tube occlusion). During a vasectomy, small incisions in the skin of the scrotum are made and the vas deferens from each testis is exposed, clamped, and severed, preventing passage of the sperm cells into the ejaculatory duct and prostatic urethra. Following vasectomy, both testes continue to produce sperm cells. In 10%–30% of vasectomy cases, increased intraluminal pressure causes distension of the epididymis and pressure-mediated damage to the seminiferous epithelium, followed by **sperm granuloma** formation at the vasectomy site, epididymis, or rete testis. A sperm granuloma is a site of spermatozoa phagocytosis by large, activated macrophages. Degradation products of macrophages are absorbed by the epididymal epithelium. Sperm granulomas are rarely symptomatic. In addition, owing to the constant leak of spermatozoal antigens into the tissues, mechanisms of humoral immunity may be activated, resulting in the production of IgA **antisperm antibodies**. Although these antibodies develop in a significant proportion of patients postvasectomy, they do not increase the risk of immune complex or atherosclerotic heart disease. About 500,000 vasectomies are performed each year in the United States, with up to 6% of patients requesting **vasectomy reversal** in the form of vasovasostomy or vasoepididymostomy for various reasons. Research indicates that after vasectomy reversal microsurgery, the patency of vas deference can be achieved at about 89% and successful pregnancy rates follow at approximately 73%.

The **ampulla of ductus deferens** has taller, branched mucosal folds that often show glandular diverticula. The muscle coat surrounding the ampulla is thinner than that of the rest of the ductus deferens, and the longitudinal layers disappear near the origin of the ejaculatory duct. The epithelium of the ampulla and ejaculatory duct appears to have a secretory function. The cells contain large numbers of yellow pigment granules. The wall of the ejaculatory duct does not have a muscularis layer; the fibromuscular tissue of the prostate substitutes for it.

■ ACCESSORY SEX GLANDS

The paired seminal vesicles secrete a fluid rich in fructose.

The **seminal vesicles** are paired, elongated, and highly folded tubular glands located on the posterior wall of the urinary bladder, parallel to the ampulla of the ductus deferens. A short excretory duct from each seminal vesicle combines with the ampulla of the ductus deferens to form the **ejaculatory duct**. Seminal vesicles develop as evaginations of the mesonephric (Wolffian) ducts in the region of future ampullae. The wall of the seminal vesicles contains a mucosa, a thin layer of smooth muscle, and a fibrous coat (Fig. 22.26). The mucosa is thrown into numerous primary, secondary, and tertiary folds that increase the secretory surface area (Plate 22.6, page 906). All of the irregular spaces thus formed, however, communicate with the lumen.

FIGURE 22.26. Photomicrograph of human seminal vesicle. **a.** This low-magnification photomicrograph shows part of a hematoxylin and eosin (H&E)-stained section of a human seminal vesicle. This gland is a tortuous tubular structure and in a section exhibits what appear to be a number of isolated lumina. In actuality, there is only one lumen. The mucosa is characterized by extensive folding (*arrows*). It rests on a thick smooth muscle (*SM*) investment that is organized in two layers: an inner circular layer and an outer longitudinal layer. $\times 20$. **b.** This higher magnification shows the mucosal folds surfaced by a pseudostratified epithelium. *Arrows* indicate the basal cells. $\times 500$.

The pseudostratified columnar epithelium contains tall, nonciliated columnar cells and short, round cells that rest on the basal lamina. The short cells appear identical to those of the rest of the excurrent duct system. They are the stem cells from which the columnar cells are derived. The columnar cells have the morphology of protein-secreting cells, with a well-developed rER and large secretory vacuoles in the apical cytoplasm.

The **secretion of the seminal vesicles** is a whitish yellow, viscous material. It contains fructose, which is the principal metabolic substrate for sperm, along with other simple sugars, amino acids, ascorbic acid, and prostaglandins. Although prostaglandins were first isolated from the prostate gland (hence the name), they are actually synthesized in large amounts in the seminal vesicles. Contraction of the smooth muscle coat of the seminal vesicles during ejaculation discharges their secretion into the ejaculatory ducts and helps to flush sperm out of the urethra. The secretory function and morphology of the seminal vesicles are under the control of testosterone.

■ PROSTATE GLAND

The prostate, the largest accessory sex gland, is divided into several morphologic and functional zones.

The **prostate** is the largest **accessory sex gland** of the male reproductive system. Its size and shape are commonly compared to those of a walnut. The main function of the prostate gland is to secrete a clear, slightly alkaline (pH 7.29) fluid that contributes to the formation of seminal fluid. The gland is located in the pelvis, inferior to the bladder, where it surrounds the prostatic part of the urethra. It consists of 30-50 tubuloalveolar glands arranged in three concentric layers: an inner **mucosal layer**, an intermediate submucosal layer, and a peripheral layer containing the main prostatic glands (Fig. 22.27). The glands of the mucosal layer secrete directly into the urethra; the other two layers have ducts that open into the prostatic sinuses located on either side of the urethral crest on the posterior wall of the urethra.

FIGURE 22.27. Schematic drawing of the zones of the human prostate gland. This drawing illustrates the relative location, by color, of the four zones of the prostate gland and anterior fibromuscular stroma of the gland.

The **adult prostatic parenchyma** is divided into four anatomically and clinically distinct zones:

- The **central zone** surrounds the ejaculatory ducts as they pierce the prostate gland. This zone comprises approximately 25% of the glandular tissue of the prostate gland and is resistant to both carcinoma and inflammation. In comparison to the other zones, cells in the central zone have distinctive morphologic features (a more prominent and slightly basophilic cytoplasm and larger nuclei displaced at different levels in adjacent cells). Recent findings suggest that this zone originates embryologically from the inclusion of mesonephric duct cells into the developing prostate.
- The **peripheral zone** comprises 70% of the glandular tissue of the prostate. It surrounds the central zone and occupies the

posterior and lateral parts of the gland. Most prostatic carcinomas arise from the peripheral zone of the prostate gland. The peripheral zone is palpable during digital examination of the rectum. This zone is also the most susceptible to inflammation.

- The transitional zone surrounds the prostatic urethra; it comprises about 5% of the prostatic glandular tissue and contains the mucosal glands. In older individuals, the parenchymal cells of this zone frequently undergo extensive division (hyperplasia) and form nodular masses of epithelial cells. Because the transitional zone is proximate to the prostatic urethra, these nodules can compress the prostatic urethra, causing difficult urination. This condition is known as benign prostatic hyperplasia (BPH) and is discussed in Folder 22.4 (pages 887 - 888).

FOLDER 22.4

CLINICAL CORRELATION: BENIGN PROSTATIC HYPERTROPHY AND CANCER OF THE PROSTATE

Benign prostatic hypertrophy (nodular hyperplasia, BPH) occurs almost exclusively in the transitional and periurethral zones, leading to partial or total obstruction of the urethra (Fig. F22.4.1a). A widely accepted theory of the pathogenesis of BPH is related to the action of dihydrotestosterone (DHT). DHT is synthesized in the stromal cells by conversion from circulating testosterone in the presence of 5α -reductase. Once synthesized, DHT acts as an autocrine agent on the stromal cells and as a paracrine hormone on the glandular epithelial cells, causing them to proliferate (Fig. F22.4.1b). BPH is believed to occur to some extent in all male individuals by age 80.

FIGURE F22.4.1. Benign prostatic hyperplasia (BPH). a. This photograph shows a cross section of the prostate gland surgically removed from an individual with BPH. The cut section shows an enlarged transitional zone with numerous well-defined hyperplastic nodules that compress the prostatic urethra. Note the normal appearance of tissue in the peripheral zone. (Courtesy of Jodi L. Hilderbrand, PA.) b. Photomicrograph of prostatic glands shows the hypertrophy of epithelium lining the glands. Note that the cells form folds that protrude into the lumen of the glands. $\times 200$. (Reprinted with permission from Rubin E, Gorstein F, Schwartz R, et al. *Rubin's Pathology*. 4th ed. Lippincott Williams & Wilkins; 2004; Fig. 17 - 40.)

Several options are available to treat BHP. **Noninvasive treatment** includes medications (α -receptor blockers) to relax the prostate smooth muscles and relieve pressure on the compressed urethra. Clinical trials have shown that inhibitors of 5α -reductase reduce the DHT concentration and thus decrease the size of the prostate and reduce urethral obstruction.

Minimally invasive treatment options use laser, microwave, or radiofrequency energy to destroy the prostate tissue causing urethral obstruction. These include interstitial laser coagulation (ILC), microwave hyperthermia, and transurethral needle ablation (TUNA). Finally, a variety of **surgical procedures** are used to

remove hypertrophied regions of the prostate gland. They include transurethral incision of the prostate (TUIP), a more extensive transurethral resection of the prostate (TURP), and most recently, a modification of the TURP procedure that uses laser energy to vaporize the prostate tissue called Greenlight PVP.

Cancer of the prostate is one of the most common cancers in the male: The lifetime risk of developing prostate cancer is 16.7% (one in six men). The incidence of prostatic cancer increases with age, and it is estimated that 70% of men between the ages of 70 and 80 years will develop this disease. Tumors usually develop in the peripheral zone of the gland. In the past, early detection was uncommon because the abnormal growth of the tumor did not impinge on the urethra to produce symptoms that demanded prompt attention. Therefore, prostatic cancer was often inoperable by the time it was discovered. In the late 1980s, universal screening for prostate-specific antigen (PSA) for prostate cancer was introduced. Its use with annual digital rectal examination in prostate cancer screening programs has significantly increased the early detection of the disease.

Screening with PSA to detect prostate cancer is debatable. Recently, large epidemiologic studies revealed that the proportion of men who are diagnosed with prostate cancer but never develop associated clinical problems may range from 23% to 66%. The current view is that the value of screening for prostate cancer in most cases is low because in most cases, the chances of harm from screening (repeated testing, aggressive therapy, and patient anxiety) outweigh the chances of benefit. Therefore, screening for prostate cancer using the PSA test is **currently regarded as controversial** among health professionals and organizations who publish screening guidelines and recommendations for health care professionals.

The most common prostate cancer grading system known as the **Gleason score** is used to predict tumor behavior and patient survival rate. Tissue obtained from two biopsies from the largest areas of prostate cancer is evaluated and grades ranging from 1 to 5 are assigned. A ranking of 1 indicates well-differentiated cells, which form the slowest growing and the least aggressive form of cancer. The ranking 5 is given to poorly differentiated cells characteristic of the fastest growing cancers. These grades, when added together, represent a Gleason score or sum between 2 and 10. The higher the score, the more likely the cancer will grow and spread rapidly.

Treatment of the cancer is by surgery, radiotherapy, or both for patients with localized disease. Hormonal therapy is the treatment of choice for advanced cancer with metastases. Because prostatic cancer cells depend on androgens, the goal of therapy is to deprive the cells of testosterone by performing orchiectomy (removal of the testis) or by administration of estrogens or gonadotropin-releasing hormone (GnRH) agonists to suppress

testosterone production. Despite treatment, patients with metastasis have a poor prognosis.

- The **periurethral zone** contains mucosal and submucosal glands. In the later stages of BPH, this zone may undergo pathologic growth but mainly from the stromal components. Together with the glandular nodules of the transitional zone, this growth causes increased **urethral compression** and further retention of urine in the bladder.

In addition, **fibromuscular stroma** occupies the anterior surface of the prostate gland anterior to the urethra and is composed of dense irregular connective tissue with a large amount of smooth muscle fibers.

The growth of the prostatic glandular epithelium is regulated by the hormone dihydrotestosterone.

Within each prostate zone, the **glandular epithelium** is generally simple columnar, but there may be patches that are simple cuboidal, squamous, or occasionally pseudostratified (Fig. 22.28). The alveoli of the prostatic glands, especially those in older individuals, often contain **prostatic concretions (corpora amylacea)** of varied shape and size, often up to 2 mm in diameter (see Fig. 22.28 and Plate 22.5, page 904). They appear in sections as concentric lamellated bodies and are believed to be formed by precipitation of secretory material around cell fragments. They may become partially calcified.

FIGURE 22.28. Photomicrograph of human prostate gland. **a.** This Mallory-Azan-stained specimen shows the tubuloalveolar glands (*GI*) and the fibromuscular tissue that forms the septa between glandular tissues. Within the lumina, various-sized prostatic concretions can be seen. The stain used for this specimen readily distinguishes the smooth muscle component (stained *red*) from the dense connective tissue component (stained *blue*) of the stroma. $\times 60$. **b.** This higher magnification shows an area where the glandular epithelium is pseudostratified. The round nuclei adjacent to the connective tissue (*arrowheads*) belong to the basal cells. Those nuclei that are more elongated and further removed from the base of the epithelium belong to the secretory cells. Note the terminal bars (*arrows*) that are evident at the apical region of these cells. The red-stained sites within the dense connective tissue represent smooth muscle cells. $\times 635$.

The **glandular epithelium** is influenced by sex hormones, such as testosterone and adrenal androgens. These hormones enter the secretory cells of the glandular epithelium and are converted to **dihydrotestosterone (DHT)** by the enzyme **5 α -reductase**. DHT is approximately 30 times more potent than testosterone. Binding of DHT to the **androgen receptor (AR)** results in a conformational

change of the receptor and its relocation from the cytosol to the cell nucleus. Here, the phosphorylated dimers of the AR complex bind to a specific sequence of DNA known as a **hormone-response element** residing in the promoter regions of target genes. The primary function of AR is direct upregulation or downregulation of specific genes. **DHT stimulation is a factor in both proliferation and growth of BPH and androgen-dependent prostate cancer.**

The prostate gland secretes prostatic acid phosphatase (PAP), fibrinolysin, citric acid, and prostate-specific antigen (PSA).

The epithelial cells in the prostate gland produce several enzymes, particularly prostate-specific antigen (PSA), prostatic acid phosphatase (PAP), fibrinolysin, and citric acid.

- **Prostate-specific antigen (PSA)**, a 33-kDa serine protease, is one of the most clinically important tumor markers. In normal conditions, PSA is secreted into prostatic gland alveoli and ultimately incorporated into seminal fluid. The alveolar secretion from the prostate gland is pumped into the prostatic urethra during ejaculation by contraction of the fibromuscular tissue of the prostate. Because PSA is predominately released into the prostatic secretion, only a very small amount of PSA (usually <4 ng/mL) normally circulates in the blood of a healthy individual. **However, in prostate cancer, serum concentration of PSA increases; large amounts of PSA are produced and misdirected into the circulation by the transformed prostatic epithelium. An increased PSA serum level is used as a clinical marker for progression of the disease. Recently, it has become widely accepted that small amounts of PSA are also present in many nonprostatic tissues, including breast, ovary, salivary gland, and liver tissue, and in various tumors. In addition, high circulating levels of PSA are also associated with benign (noncancerous) conditions such as prostatitis (infection of the prostate gland), interrupted blood flow to the prostate, or BPH (for more details on PSA screening, see Folder 22.4).**
- **Prostatic acid phosphatase (PAP)** (100 kDa) regulates cell growth and metabolism of the prostate glandular epithelium. **Because elevated serum levels of PAP are found in patients**

with metastatic prostate cancer, this enzyme is routinely used as an alternate marker to PSA for prostatic tumors. Measurements of PAP and PSA are useful in assessing the prognosis of prostate cancer.

- **Fibrinolysin**, secreted from the prostate gland, liquefies semen.

Bulbourethral Glands

The bulbourethral glands secrete preseminal fluid.

The paired **bulbourethral glands (Cowper glands)** are pea-sized structures located in the urogenital diaphragm (see Fig. 22.1). The duct of each gland passes through the inferior fascia of the urogenital diaphragm and joins the initial portion of the penile urethra. The glands are compound tubuloalveolar glands that structurally resemble mucus-secreting glands (Fig. 22.29). The simple columnar epithelium, which varies considerably in height depending on the functional state of the gland, is under the control of testosterone.

FIGURE 22.29. Photomicrograph of human bulbourethral gland. This photomicrograph shows a hematoxylin and eosin (H&E)-stained section of

the compound tubuloalveolar bulbourethral gland. The epithelium consists of columnar mucus-secreting cells. The nuclei are displaced to the base of the cells by the accumulated secretory material that they contain. The cytoplasm has an appearance similar to typical mucus-secreting cells. Note several ducts (*D*) lined by a simple columnar epithelium. The ducts will merge to form a single excretory duct. In some sites, the ducts contain mucus-secreting cells (*arrows*). $\times 40$.

The clear, mucus-like glandular secretion contains considerable amounts of galactose, galactosamine, galacturonic acid, sialic acid, and methylpentose. Sexual stimulation causes the release of this secretion, which constitutes the major portion of the preseminal fluid and serves to lubricate the penile urethra, neutralizing any traces of acidic urine.

■ SEMEN

Semen contains fluids and sperm cells from the testis and secretory products from the epididymis, ductus deferens, prostate, seminal vesicles, and bulbourethral glands. The seminal fluid provides nutrients (e.g., amino acids, citrates, and fructose) and protection for the sperm cells during their passage through the excurrent duct system. Semen is alkaline (pH 7.7) and helps to neutralize the acid environment of the urethra and vagina. The major components of semen can be traced to the secretion from the seminal vesicles (65%–75%) and prostate gland (25%–30%). Additional components include testicular fluid (2%–5%) that was not completely absorbed in the straight tubules as well as secretions from the bulbourethral (Cowper) glands that account for less than 1%. Semen also contains prostaglandins (produced by seminal vesicles) that may influence sperm transit in both the male and female reproductive tracts and may have a role in implantation of a fertilized ovum.

The average ejaculate of semen has a volume of about 3 mL and normally contains up to 100 million sperm cells per milliliter. It is estimated that 20% of the sperm in any ejaculate are morphologically abnormal and nearly 25% are immotile.

■ PENIS AND SCROTUM

Erection of the penis involves filling of the vascular spaces of the corpora cavernosa and corpus spongiosum.

The **penis** consists principally of two dorsal masses of erectile tissue, the **corpora cavernosa**, and a ventral mass of erectile tissue, the **corpus spongiosum**, in which the spongy part of the urethra is embedded. A dense, fibroelastic layer, the **tunica albuginea**, binds the three together and forms a capsule around each (Fig. 22.30). The corpora cavernosa contain numerous wide, irregularly shaped vascular spaces lined with vascular endothelium. These spaces are surrounded by a thin layer of smooth muscle that forms trabeculae within the tunica albuginea interconnecting and crisscrossing the corpus cavernosum. Irregular smooth muscle bundles are observed frequently as “subendothelial cushions” surrounding irregular vascular spaces (Fig. 22.31).

FIGURE 22.30. Transverse section of the penis. **a.** This diagram shows a cross section of the penis with the location of major vessels and nerves and their relationships to the fascial layers and erectile tissues. **b.** This photomicrograph shows a hematoxylin and eosin (H&E)-stained specimen of a cross section of the penis near the base of the organ. Note the arrangement of the corpora cavernosa and corpus spongiosum; the latter contains the urethra. $\times 3$.

FIGURE 22.31. Photomicrograph of corpus spongiosum. **a.** This photomicrograph of a hematoxylin and eosin (H&E)-stained section shows the corpus spongiosum and urethra. $\times 20$. **b.** This higher magnification of the corpus spongiosum shows the numerous irregularly shaped vascular spaces. Note the surrounding layer of smooth muscle (*SM*) forming the “subendothelial cushions.” $\times 135$.

The interstitial connective tissue contains many nerve endings and lymphatic vessels. The vascular spaces increase in size and rigidity by filling with blood, principally derived from the **deep artery of the penis** that divides into branches called the **helicine arteries**. These arteries dilate during erection (Folder 22.5) to increase blood flow to the penis. An arteriovenous (AV) anastomosis exists between the deep artery of the penis and the peripheral venous system (see Folder 22.5).

FOLDER 22.5

CLINICAL CORRELATION: MECHANISM OF ERECTION AND ERECTILE DYSFUNCTION

Erection of the penis is a vascular event initiated by the central nervous system (CNS) and maintained by complex interactions between vascular and neurologic events. The CNS responds to external or internal stimuli (sensory impulses, perception, desire, etc.) that involve the sympathetic and parasympathetic innervation of the penis.

Parasympathetic stimulation initiates erection by relaxation of the trabecular smooth muscle cells and dilation of the helicine arteries. This leads to expansion of the corpora cavernosa and, to a lesser degree, the corpus spongiosum. Arterial blood accumulates in these erectile tissues by compression of the venules against the nondistensible tunica albuginea. This process is referred to as the **corporal veno-occlusive mechanism**. The tunica albuginea also compresses the larger veins that drain blood from the corpora cavernosa so that venous outflow is also blocked, resulting in tumescence and rigidity of the penis.

Two neuromediators, acetylcholine and nitric oxide, are involved in the relaxation of smooth muscle during the initiation and maintenance of penile erection.

- **Acetylcholine** is released by the parasympathetic nerve endings and acts primarily on the endothelial cells that line the vascular spaces of the corpora cavernosa. This causes the release of vasoactive intestinal peptide (VIP) and, more importantly, nitric oxide.
- **Nitric oxide (NO)** activates guanylate cyclase in the trabecular smooth muscle cells to produce cyclic guanosine monophosphate (cGMP). cGMP causes the smooth muscle cells to relax.

Sympathetic stimulation terminates penile erection by causing contraction of the trabecular smooth muscle cells of the helicine arteries. These events decrease the flow of blood to the corpora cavernosa, reducing blood pressure in the erectile tissue to normal venous pressure. The lower pressure within the corpus cavernosum allows the veins leading from the corpora cavernosa to open and drain the excess blood.

Erectile dysfunction (ED) is an inability to achieve and maintain sufficient penile erection to complete satisfactory intercourse. Adequate arterial blood supply is critical for erection; therefore, any disorder that decreases blood flow into the corpora cavernosa may cause erectile failure.

Many cases of ED that do not involve parasympathetic nerve damage can now be treated effectively with drugs known as phosphodiesterase inhibitors (i.e., sildenafil citrate [Viagra], tadalafil [Cialis], vardenafil [Levitra], and others). These compounds enhance the relaxing effect of NO on smooth muscle cells of the corpora cavernosa by inhibiting phosphodiesterase, which is responsible for degradation of cGMP. As noted earlier, cGMP causes smooth muscle relaxation, which, in turn, allows inflow of blood into the corpus cavernosum to initiate erection.

However, when parasympathetic nerve damage has occurred (e.g., as a complication of prostatic surgery), phosphodiesterase inhibitors have no effect because the event involving parasympathetic stimulation and release of acetylcholine cannot occur. Without acetylcholine, NO cannot produce cGMP, and without cGMP, smooth muscle cells cannot relax to allow inflow of blood to fill the

erectile tissue. In these cases of ED, **prostaglandin E1 (PGE1)** (alprostadil) can be used in a direct intracavernous injection (or as intraurethral suppository). PGE1 is produced endogenously to relax vascular smooth muscle and cause vasodilation. In adult males, after injections into erectile tissue, the PGE1 causes relaxation of smooth muscles of the helicine arteries and the trabecular smooth muscles, resulting in rapid inflow of blood and expansion of the vascular spaces within the corpora cavernosa. As the pressure within the corpora cavernosa is increasing, the venous outflow through the subtunical vessels is compressed (the corporal veno-occlusive mechanism) and penile rigidity develops. The alternative option in the treatment of ED is the use of special pumps that draw blood into the erectile tissues using negative pressure.

Skin of the penis shows a thin epidermis with minimal keratinization.

The **skin of the penis** is thin and loosely attached to the underlying connective tissue, except at the **glans penis**, where it is very thin and tightly attached. The skin of the glans is so thin that blood within its large, muscular anastomosing veins that drain the corpus spongiosum may give it a bluish color. The epithelium of the glans penis in uncircumcised individuals is stratified squamous nonkeratinized; however, after circumcision, the epithelium becomes keratinized. There is no adipose tissue in the subcutaneous tissue. There is, however, a thin layer of smooth muscle that is continuous with the dartos layer of the scrotum. The **dartos layer** in the skin of the penis is composed of smooth muscle fibers arranged in superficial (longitudinal) and deep (transverse) layers. These two layers are separated by the dense irregular connective tissue and are comparable to the hypodermis of the skin but without adipose tissue. In uncircumcised males, the glans is covered with a fold of skin, the **prepuce**, which resembles a mucous membrane on its inner aspect and the skin of the penis on the outer aspect. Numerous sebaceous glands not related to hair follicles are present in the skin of the penis just proximal to the glans. The **deep fascia of the penis (Buck fascia)** is visible underneath the dartos layer. It is composed of a continuous fibroelastic membrane that encircles both the corpora cavernosa and the corpus spongiosum.

The penis is innervated by somatic and visceral motor (sympathetic and parasympathetic) fibers. Many sensory nerve

endings are distributed throughout the tissue of the penis. The visceral motor fibers innervate the smooth muscle of the trabeculae of the tunica albuginea and the blood vessels. Both sensory and visceral motor fibers play essential roles in erectile and ejaculatory responses. **Parasympathetic stimulation** initiates **erection**, whereas **sympathetic stimulation** terminates erection and causes **ejaculation**, a rhythmic contraction of smooth muscle that ejects semen from the spongy urethra (see Folder 22.5).

The wall of the scrotum reflects the layers of the abdominal wall that were pulled into the developing scrotum during the descent of the testis.

The **scrotum** represents a musculocutaneous pigmented pouch located inferior to the shaft of the penis and pubic symphysis. The scrotum is embryologically derived from the fusion of the labioscrotal folds and is homologous to the labia majora in the female. The **median raphe** (and the septum inside the scrotum) divides the left and right parts of the scrotum and extends from the ventral surface of the penis anteriorly to the anus posteriorly. Each part of the scrotum contains a testis, epididymis, and proximal part of the spermatic cord.

The wall of the scrotum is complex and contains several layers that are extensions of the anterior abdominal wall layers. This arrangement can be traced to the descent of the testis in fetal life. The descending testes travel into the developing scrotum taking with them the blood and lymphatic vessels, nerves, attached peritoneum, and the muscular and aponeurotic layers of the abdominal wall. As discussed earlier, the temperature within the scrotum is about 2° C–3° C lower than body temperature, creating an optimal environment for the thermosensitive testes to maintain spermatogenesis.

The **wall of the scrotum** consists of the following layers, starting from the most superficial:

- **Skin of the scrotum.** The skin is thin, corrugated (wrinkled), and darker than the skin of neighboring regions. It consists of an epidermis made of the keratinized stratified squamous epithelium. The basal layer of the epidermis contains a high concentration of melanocytes (about one melanocyte to four

basal cells). Most of the pigment resides in the stratum basale but is also present in cells progressing toward the surface. The dermis comprises a papillary layer (loose connective tissue) and a reticular layer (dense irregular connective tissue). It contains small, smooth muscle fibers and myofibroblasts embedded in the extracellular matrix that is rich in elastic fibers. The dermis also contains hair follicles, apocrine and eccrine sweat glands, and sebaceous glands. The subcutaneous adipose tissue is absent in the hypodermis and is replaced by the dartos layer of smooth muscles (Fig 22.32).

FIGURE 22.32. Photomicrograph of the wall of the scrotum. a. This photomicrograph of a hematoxylin and eosin (H&E)-stained specimen shows the superficial layers of the scrotum. Note the wrinkled appearance of the skin that shows the stratified squamous keratinized epithelium (*Epi*) on the surface. The underlying dermis (*Derm*) contains a few small smooth muscle fibers and myofibroblasts embedded in the elastic-rich extracellular matrix. These structures are not visible at this magnification. The subcutaneous adipose tissue is absent in the hypodermis and is replaced by the two layers of dartos smooth muscle: the superficial layer (*DMSL*) and deep layer (*DMDL*). The apocrine and eccrine sweat glands as well as roots of hair follicles (*HF*) are often visible between these two layers. Deep to the dartos muscle is a layer of the external spermatic fascia (*ESF*), which is an extension of the external abdominal oblique aponeurosis. $\times 55$. b. A higher magnification of the epidermis (*Epi*) taken from the *left rectangular area* shows loose connective tissue in the papillary layer (*PL*) and reticular layer (*RL*) of dense irregular connective tissue with rich

elastic fiber content. Note the dark brown appearance of the basal layer of the epithelium, which gives the skin of the scrotum its dark appearance. $\times 150$. c. A higher magnification view of glandular tissue from the *center rectangular box*. Note both the apocrine (*ASG*) and eccrine (*ESG*) sweat glands surrounded by layers of dartos smooth muscle (*SM*). Large blood vessels (*BV*) also pass between these layers. $\times 220$. d. A higher magnification photomicrograph of smooth muscle bundles from the *right rectangular area* that form an interlocking network of the dartos layer. $\times 320$. (Courtesy of Dr. Robert A. Bloodgood, University of Virginia School of Medicine.)

- **Dartos layer.** This smooth muscle layer replaces the hypodermis and is firmly attached to the dermis. There are two distinct perpendicularly arranged layers of the dartos muscle, the superficial (longitudinal) and deep (transverse), as shown in Figure 22.32. As the layers contract, this crisscrossing organization of the dartos layer is responsible for the reduction of the scrotal skin surface, giving the scrotum a wrinkled appearance. Apocrine and eccrine sweat glands, as well as roots of hair follicles, are often visible between these two layers. The dartos muscle contracts in response to cold, exercise, and sexual stimulation. In a cold environment, the contraction of the dartos layer causes elevation (retraction) of the testes, bringing them toward the abdominal wall. In a hot environment, the dartos layer relaxes, providing a larger skin surface for heat dissipation and preventing testicular hyperthermia.
- **External spermatic fascia.** This extension of the external abdominal oblique aponeurosis is thin and more organized than the typical irregular connective tissue layer. Thick bundles of collagen fibers, nerve fibers, and blood vessels are clearly visible; a few smooth muscle fibers on the outer surface are also detectable.
- **Cremaster muscle and cremasteric fasciae.** The cremaster muscle (*Gr. Kρ ε μ α σ τ η ' ρ, suspender*) is an elongation of the internal oblique muscle into the scrotal wall. It consists of loosely arranged striated muscle fascicles surrounded by cremasteric fascia. They are predominately type I fibers (slow oxidative fibers) that contract slowly but are fatigue resistant. They differ from skeletal muscle by having multiple motor end plates and several nerve endings that terminate on a single muscle fiber. A few smooth muscle fibers,

nerve cells, and nerve plexuses can be found between skeletal fibers in this layer. Because the muscle has a weak somatic innervation (by the genital branch of the genitofemoral nerve), these plexuses provide autonomic innervations, leading to involuntary contraction of the cremaster muscle. The cremaster muscle reflex can be elicited to assess spinal cord injury at levels L1 and L2 and provide evidence of successful spinal anesthesia. It is also used to assess scrotal pain in testicular torsion, which is unilateral and absent on the side of the torsion.

- **Internal spermatic fascia.** This layer is positioned between the parietal layer of the tunica vaginalis and the cremaster muscle. It originates from and represents the elongation of the transversalis fascia, which resides deep into the transversus abdominis muscle. This layer is mostly composed of dense irregular connective tissue containing nerves and blood and lymphatic vessels.
- **Parietal layer of tunica vaginalis.** This layer of the serous membrane forms the inner surface of the scrotal wall. It represents the mesothelial layer that originated from the parietal peritoneum of the abdominal cavity. A thin, submesothelial layer of connective tissue supports the simple squamous epithelium lining its surface. The parietal layer, together with the visceral layer (which is attached to the testis), defines the cavity of the tunica vaginalis. A small amount of a lubricating fluid essential for the smooth movement of the testis is found in the cavity of the tunica vaginalis. An abnormal collection of peritoneal fluid in the cavity of the tunica vaginalis is referred as a hydrocele. Hydrocele can either be congenital (processus vaginalis is patent and communicates with the peritoneal cavity) or acquired (i.e., infections, injury, and malignancy). Hydrocele is caused by an imbalance between secretion and reabsorption of peritoneal fluid by the tunica vaginalis.

The scrotum receives its main blood supply from the anterior scrotal arteries (branches of external pudendal arteries) and posterior scrotal arteries (branches of internal pudendal arteries). The additional blood supply of the scrotum comes from small branches of the cremasteric and testicular arteries that

traverse the spermatic cords. Venous drainage accompanies the arteries. Lymphatic drainage of the scrotum is to the superficial inguinal nodes. The ilioinguinal and genitofemoral nerves provide the innervation of the skin of the anterior part of the scrotum. Posterior scrotal nerves (branches of the pudendal nerve) supply innervation to the posterior part of the scrotum.

MALE REPRODUCTIVE SYSTEM

OVERVIEW OF THE MALE REPRODUCTIVE SYSTEM

- The **male reproductive system** consists of the testes, genital excurrent ducts, accessory sex glands, and external genitalia containing the penis and scrotum.
- Testes lie within the scrotum and are responsible for **spermatogenesis** (production of sperm) and **steroidogenesis** (synthesis of steroid hormones called *androgens*).

TESTIS

- Development of the male reproductive system is guided by a cascade of gene activations triggered in response to the presence of the **Y chromosome** (chromosome-determining genetic sex).
- Activation of the **SRY gene** in the sex-determining region of the Y chromosome results in the production of **testis-determining factor (TDF)**, which activates several other genes required for the development of the male reproductive organs (**region-determining gonadal sex**).
- Hormonal secretion from the developing testis allows for the growth and differentiation of the male reproductive organs (**secretion-determining hormonal sex**).

- The testes develop on the posterior abdominal wall from three sources: **intermediate mesoderm** (which forms urogenital ridges), **mesodermal epithelium** (which gives rise to primary sex cords), and **primordial germ cells** (which migrate from the yolk sac).
- Under the influence of **testosterone** and **Müllerian-inhibiting factor (MIF)**, the testes develop from indifferent gonads to fully developed organs that descend into the scrotum during fetal development.
- **Dihydrotestosterone (DHT)** is responsible for the development of the external genitalia and accessory sex glands.
- Scrotal position of the testes allows for spermatogenesis to occur. This process requires lower-than-normal body temperature.
- Each testis has approximately 250 lobules containing one to four highly convoluted **seminiferous tubules**, which are surrounded by a lamina propria containing blood, lymphatic vessels, and Leydig (interstitial) cells.
- **Leydig (interstitial) cells** produce testosterone and other hormones (e.g., androgens, insulin-like protein 3) that guide the development and descent of the testis.
- The seminiferous tubules consist of a **seminiferous epithelium** that contains **Sertoli cells** and **spermatogenic cells**. The walls of the tubules consist of connective tissue that contains **myoid cells** (peritubular contractile cells).

SPERMATOGENESIS

- **Spermatogenesis** is the process by which spermatogonia develop into sperm. It begins before puberty and continues throughout life.
- Spermatogenesis occurs in the seminiferous tubules in two compartments established by Sertoli cells: a **basal compartment** containing diploid (2d) cells (i.e., spermatogonia) and a **luminal compartment** containing haploid (1d) cells (i.e., spermatocytes and spermatids).

- These compartments are separated by Sertoli cell-to-Sertoli cell junctional complexes that represent the site of the blood-testis barrier.
- Spermatogenesis in humans lasts approximately 74 days and is divided into three distinct phases.
- During the spermatogonial phase, spermatogonia (stem cells) undergo mitosis to replace themselves and provide a population of committed cells that eventually give rise to primary spermatocytes.
- During the spermatocyte phase, primary spermatocytes undergo a first meiotic division (lasts up to 22 days) to produce secondary spermatocytes. Then they undergo a second meiotic division (only a few hours long) to produce haploid cells called spermatids that have a reduced number of chromosomes (1n) and amount of DNA (1d).
- During the spermatid phase (spermiogenesis), spermatids undergo extensive cell remodeling in association with Sertoli cells, including condensation of DNA content in the nucleus, formation of an acrosomal cap, and development of a long flagellum.
- Spermatids then differentiate into spermatozoa, which are released during spermiation into the lumen of the seminiferous tubule.
- The mature sperm cell contains a flattened head covered by the acrosomal cap (contains hydrolytic enzymes for penetration of the ovum) and an axonemal complex in the sperm tail that is helically wrapped by mitochondria.
- Newly released sperm cells are nonmotile. Their travel from the seminiferous tubules is facilitated by myoid cell contractions. Sperm cells first enter the short straight tubules and then the rete testis, which is connected via efferent ductules to the head of the epididymis.

EXCURRENT DUCT SYSTEM

- The excurrent duct system develops from the mesonephric (Wolffian) duct (epididymis, ductus deferens, ejaculatory duct) and mesonephric tubules (efferent ductules).

- Efferent ductules connect the rete testis with the duct of the epididymis, which forms the head, body, and tail of the epididymis. Sperm cells acquire motility, undergo further maturation, and are stored in the epididymis before ejaculation.
- The duct of the epididymis is lined with a pseudostratified columnar epithelium containing stereocilia and is surrounded by a smooth muscle coat that gradually increases in thickness.
- The ductus (vas) deferens is a direct continuation of the tail of the epididymis. It is lined with a pseudostratified columnar epithelium with stereocilia that is surrounded by a thick (1–1.5 mm) muscular coat.
- During ejaculation, sperm cells are forcefully squeezed from the epididymis to the ductus deferens and are propelled into the ejaculatory duct.

ACCESSORY SEX GLANDS

- The seminal vesicles are lined by a mucosa that forms numerous thin folds. They produce a fluid rich in fructose that becomes a constituent of semen.
- The excretory duct of each seminal vesicle unites with the ampulla of the ductus deferens to form the ejaculatory duct, which pierces the prostate to enter the prostatic urethra.
- The prostate is a tubuloalveolar gland that lies beneath the bladder and surrounds the prostatic urethra. Parenchyma of the prostate is divided into several distinct anatomic and clinical zones.
- Glandular epithelium of prostatic alveoli is simple columnar with characteristic prostatic concretions that are often located within the lumen of the glands.
- The prostate gland secretes several enzymes, including prostatic acid phosphatase (PAP) and prostate-specific antigen (PSA).
- Bulbourethral (Cowper) glands are located within the urogenital diaphragm and discharge their secretion

directly to the penile urethra. They lubricate and protect the urethra.

- **Semen** contains fluids and sperm cells from the testis and secretory products from the epididymis, ductus deferens, prostate, seminal vesicles, and bulbourethral glands.

PENIS AND SCROTUM

- The **penis** consists of three erectile tissues: two **corpora cavernosa** at the dorsum of the penis and the **corpus spongiosum** that contains the spongy part of the urethra.
- **Erectile tissues** contain vascular spaces that increase in size and rigidity by filling with blood during erection.
- The wall of the **scrotum** reflects the layers of the abdominal wall that were pulled into the developing scrotum during the descent of the testis.
- The **temperature** within the scrotum is about 2°C – 3°C lower than body temperature, creating an optimal environment for **spermatogenesis**.
- Layers of the scrotum include **skin** of the scrotum, **dartos** layer, **external spermatic fascia**, **cremaster muscle**, and **cremasteric fasciae**, **internal spermatic fascia**, and **parietal layer of tunica vaginalis**.

PLATE 22.1 ■ TESTIS I

The male reproductive system consists of the paired testes, epididymides, and genital ducts as well as accessory reproductive glands and the penis. The functions of the testis are the production of **sperm** and the synthesis and secretion of **androgens**, especially **testosterone**. The events of cell division that lead to the production of mature sperm involve both normal cell division, **mitosis**, and reduction division, **meiosis**, to yield a haploid chromosome number and haploid DNA content. Androgen secretion by the testis begins early in fetal development and is essential for the continued normal development of the male fetus. At puberty, androgen production resumes and is responsible for initiation and maintenance of sperm production (**spermatogenesis**),

secretion by accessory sex glands (e.g., prostate and seminal vesicles), and development of secondary sex characteristics.

Testis, monkey, hematoxylin and eosin (H&E) $\times 65$.

This section of the testis shows the **seminiferous tubules** and the **tunica albuginea** (*TA*), the capsule of the organ. Extending from the very thick capsule are connective tissue septa (*S*) that divide the organ into compartments. Each compartment contains several seminiferous tubules and represents a lobule (*L*). Blood vessels (*BV*) are present within the inner portion of the capsule, the part referred to as the *tunica vasculosa*, and in the connective tissue septa.

The seminiferous tubules are convoluted; thus, the profiles they present in a section are variable in appearance. Not infrequently, the wall of a tubule is sectioned tangentially, thus obscuring the lumen and revealing what appears to be a solid mass of cells (*X*).

Seminiferous tubules, testis, monkey, H&E $\times 400$.

Examination at higher magnification, as in this figure, reveals a population of interstitial cells that occur in small clusters and lie in the space between adjoining tubules. They consist mostly of **Leydig cells** (*LC*), the chief source of testosterone in male. They are readily identified by virtue of their location and by their small round nucleus and eosinophilic cytoplasm. Macrophages are also found, in close association with the Leydig cells, but in lesser numbers. They are, however, difficult to identify in H&E sections.

A layer of closely apposed squamous cells forms a sheath-like investment around the **tubule epithelium** of each seminiferous tubule. In humans, several layers of cells invest the tubule epithelium. The cells of this peritubular investment exhibit myoid features and account for the slow peristaltic activity of the tubules. Peripheral to the myoid layer is a broad lymphatic channel that occupies an extensive space between the tubules. In routine histologic sections, however, the lymphatic channels are usually collapsed and thus unrecognizable. The cellular elements that surround the tubule epithelium are generally referred to as a **lamina propria** (*LP*) or a *boundary tissue*. As a lamina propria, it is atypical. It is not a loose connective tissue. Indeed, under normal circumstances, lymphocytes and other cell types related to the immune system are conspicuously absent.

Examination of the tubule epithelium reveals two kinds of cells: a proliferating population of spermatogenic cells and a nonproliferating population, the sustentacular, or Sertoli, cells. The Sertoli cells are considerably fewer and can be recognized by their elongated, pale-staining nuclei (*Sn*) and conspicuous nucleolus. The Sertoli cell cytoplasm extends from the periphery of the tubule to the lumen.

The **spermatogenic cells** consist of successive generations arranged in concentric layers. Thus, the **spermatogonia** (*Sg*) are found at the periphery. The **spermatocytes** (*Sc*), most of which have large round nuclei with visible chromatin arranged in a distinctive pattern, lie above the spermatogonia. The spermatid population (*Sp*) consists of one or two generations and occupies the site closest to the lumen. The tubules in this figure have been identified according to their stage of development. The tubule at the *upper right* can be identified as stage *VI*. At this stage, the mature population of **spermatids** (identified by their dark blue heads and eosinophilic thread-like flagella protruding into the lumen) are in the process of being released (spermiogenesis). The younger generation of spermatids is composed of round cells and exhibits round nuclei. Moving clockwise, the tubule indicated as stage *VII* is slightly more advanced. The mature spermatids are now gone. Progressing to stage *VIII*, the tubule at the *bottom* of the micrograph reveals that the spermatid population is undergoing a change in nuclear shape. Note the tapered nuclei (*arrows*). Further maturation of the spermatids is reflected in the tubule at the *top* of the micrograph, stage *XI*. Finally, the tubule marked stage *II*, on the *left*, reveals slightly greater maturation of the luminal spermatids, and with the start of the new cycle (stage *I*), a newly formed spermatid population is now present. By examining the spermatid population and assessing the number of generations present (i.e., one or two) and the degree of maturation, it is possible to approximate the stage of a tubule (see Fig. 22.14).

BV, blood vessels
L, lobule

PLATE 22.2 ■ Testis II

Although the mature testis is characterized by seminiferous tubules, the immature testis is characterized by cords of cells consisting of an epithelium of sustentacular (Sertoli) cells surrounding occasional gonocytes, precursors of spermatogonia that are derived from the primordial germ cells that invaded the developing gonad in the embryo. At puberty, these cords become canalized, and the gonocytes begin the multiple divisions that give rise to the spermatogonia that, in turn, will divide and differentiate into mature sperm. The seminiferous tubules terminate as straight tubules (tubuli recti) that are lined only by Sertoli cells. The tubuli recti lead to the rete testis, a complex series of anastomosing channels in the mediastinum testis that signifies the termination of the intratesticular tubule system.

Prepubertal testis, newborn human, hematoxylin and eosin (H&E) $\times 180$; inset $\times 360$.

The various germ cell types representative of spermatogenesis in the mature seminiferous tubules is not present in the testis before puberty or in the postpubertal undescended testis. Instead, the “tubules” are represented by cords of cells in which a lumen is lacking. The **seminiferous cords** display the same tortuosity as in the adult; the tunica albuginea (*TA*) of the testis, although thinner, is of the same relative thickness.

The seminiferous cords are of considerably smaller diameter than the tubules of the adult and are composed of two cell types: the gonocyte, or first-generation spermatogonium, derived from the primordial germ cell that migrates from the yolk sac to the developing gonad in the embryo, and a cell that resembles the Sertoli cell of the adult. The latter cell type predominates and constitutes the bulk of the cord. The cells are columnar, and their nuclei are close to the basement membrane. The **gonocytes** (*G*, *inset*) are the precursors of the definitive germ cells, or spermatogonia. They are round cells that have a centrally placed, spherical nucleus. The cytoplasm takes little stain and usually appears as a light ring around the nucleus. This gives the gonocyte a distinctive appearance in histologic sections. Generally, the gonocytes are found at the periphery of the cord, but many are also found more centrally. The gonocytes give rise to spermatogonia that begin to proliferate in males between the ages of 10 and 13 years. The seminiferous epithelium then becomes populated with cells at various stages of spermatogenesis, as seen in the adult.

The seminiferous cords are surrounded by one or two layers of cells with long processes and flat nuclei. They resemble fibroblasts at the

ultrastructural level and give rise to the myoid peritubular cells of the adult.

The interstitial cells (of Leydig) are conspicuous in the newborn, a reflection of the residual effects of maternal hormones. Leydig cells, however, regress and do not become conspicuous again until puberty. In this preparation, the **Leydig cells** (*LC, inset*) can be seen between the cords. They are ovoid or polygonal and are closely grouped so that adjacent cells are in contact with each other. Overall, they have the same appearance as the Leydig cells of the adult.

Mediastinum testis, testis, monkey, H&E $\times 65$.

In the posterior portion of the testis, the connective tissue of the tunica albuginea extends more deeply into the organ. This inward extension of connective tissue is called the **mediastinum testis**. It contains a network of anastomosing channels called the **rete testis**. Only a small portion of the mediastinum testis (*MT*) is evident in the figure. The area includes, however, a few seminiferous tubules (*ST*) in the *upper portion* of the micrograph and, fortuitously, the site where one of the seminiferous tubules terminates and joins the rete testis (*RT*). This can be recognized in the area delineated by the *rectangle*, which is shown at higher magnification in the next figure. As noted earlier, the seminiferous tubules are arranged in the form of a loop, with each end joining the rete testis. The seminiferous tubules open into the rete testis by way of a straight tubule. Straight tubules are very short and are lined by Sertoli-like cells; no germ cell component is present. The connective tissue of the mediastinum is very dense but exhibits no other special features, nor is smooth muscle present. Adipose cells (*AC*) and blood vessels (*BV*), particularly veins of varying size, are present within the connective tissue.

Straight tubule, testis, monkey, H&E $\times 400$.

This photomicrograph is a higher magnification of the *boxed* area on the image immediately above. The **seminiferous tubule** (*ST*) is seen in continuity with a **straight tubule** or tubulus rectus (*TR*). Straight tubule is relatively short and terminates at the point where it enters a channel of the **rete testis** (*RT*). The rete testis is identified by its simple cuboidal epithelium. Note that because of the angle at which the straight tubule was sectioned, it appears that the cuboidal epithelium characterizing the rete testis begins on the upper side of the tubule before it is seen on the lower side of the tubule. The rete testis (*RT*) constitutes an anastomosing system of channels that lead to the efferent ductules. The epithelial

cells lining the rete testis are sometimes more squamous than cuboidal or, occasionally, may be low columnar in appearance. Typically, they possess a single (primary) cilium; however, this is difficult to see in routine H&E preparations.

TR, tubulus rectus

PLATE 22.3 ■ EFFERENT DUCTULES AND EPIDIDYMIS

The rete testis is connected via ~20 efferent ductules (*ductuli efferentes*; remnants of nephrons of the fetal mesonephric kidney) to the ductus epididymis. These are the first elements of the excurrent duct system of the male genital system. Most of the fluid secreted in the seminiferous tubules is reabsorbed in the efferent ductules. The muscular coat characteristic of the excurrent duct system first appears at the beginning of the efferent ductules. The ductus epididymis is a highly coiled tube, 4-6 m long; sperm mature during their passage along its length, acquiring motility as well as the ability to fertilize an egg. This maturation is also androgen dependent and involves changes in the sperm plasma membrane and addition to the glycocalyx of glycoproteins secreted by the epididymal epithelial cells.

Efferent ductules, testis-epididymis, monkey, hematoxylin and eosin (H&E) $\times 60$; inset $\times 360$.

About 12-20 efferent ductules leave the testis and serve as channels from the rete testis to the ductus epididymis. Each of the efferent ductules undergoes numerous spiral windings and convolutions to form a group of conical structures; together, they constitute the initial part of the head of the epididymis. When examined in a tissue section, the ductules exhibit a variety of irregular profiles owing to their twisting and turning. This is evident on the *right side* of this micrograph.

The epithelium that lines the efferent ductules is distinctive in that groups of tall columnar cells alternate with groups of cuboidal cells, giving the luminal surface an unevenly contoured appearance. Thus, small cup-like depressions are created where the epithelium contains groups of cuboidal or low columnar cells. Typically, these shorter cells exhibit a brush border-like apical surface because of the microvilli that they possess (*arrowhead, inset*). The basal surface of the ductule, in contrast, has a smooth contour (see next figure and *inset*). Some of the cells, generally the tall columnar cells, possess cilia (*C, inset*). Whereas the ciliated cells aid in moving the contents of the tubule toward the epididymis, the cells with the microvilli are largely responsible for absorbing fluid from the lumen. In addition to the columnar and cuboidal cells, basal cells are also present; thus, the epithelium is designated pseudostratified columnar. The basal cells possess little cytoplasm and presumably serve as stem cells.

The efferent ductules possess a thin layer of circularly arranged smooth muscle cells (*SM, inset*). The muscle is close to the basal

surface of the epithelial cells, being separated from it by only a small amount of connective tissue (*CT*, *inset*). Because of this close association, the smooth muscle may be overlooked or misidentified as connective tissue. Smooth muscle facilitates the movement of luminal contents of the ductule to the ductus epididymis.

Epididymis, monkey, H&E $\times 180$.

The **epididymis**, by virtue of its shape, is divided into a head, body, and tail. The initial part of the head contains the **ductus epididymis**, a single convoluted duct into which the efferent ductules open. The duct is, at first, highly convoluted but becomes less tortuous in the body and tail. A section through the **head of the epididymis**, as shown in the previous figure, cuts the ductus epididymis in numerous places, and as in the efferent ductules, different-shaped profiles are observed.

The epithelium contains two distinguishable cell types: tall columnar cells and basal cells similar to those of the efferent ductules. The epithelium is, therefore, also pseudostratified columnar. The columnar cells are tallest in the head of the epididymis and diminish in height as the tail is reached. The free surface of the cell possesses **stereocilia** (*SC*). These are extremely long, branching microvilli. They evidently adhere to each other during the preparation of the tissue to form the fine tapering structures that are characteristically seen with the light microscope. The nuclei of the **columnar cells** are elongated and are located a moderate distance from the base of the cell. They are readily distinguished from the spherical nuclei of the **basal cells** that lie close to the basement membrane. Other conspicuous features of the columnar cells include a very large supranuclear Golgi apparatus (not seen at the magnification offered here), pigment accumulations (*P*), and numerous lysosomes, demonstrable with appropriate techniques.

Because of the unusual height of the columnar cells and the tortuosity of the duct, an uneven lumen appears in some sites; indeed, even “islands” of epithelium can be encountered in the lumen (see *arrows*, previous figure). Such profiles are accounted for by sharp turns in the duct where the epithelial wall on one side of the duct is partially cut. For example, a cut in the plane of the *double-headed arrow* indicated in this figure would create such an isolated epithelial island.

A thin layer of smooth muscle circumscribes the duct and appears similar to that associated with the efferent ductules. In the terminal portion of the epididymis, however, the smooth muscle acquires a greater thickness, and longitudinal fibers are also present. Beyond the smooth muscle coat, there is a small amount of connective tissue (*CT*) that binds the loops of the duct together and carries the blood vessels (*BV*) and nerves.

PLATE 22.4 ■ SPERMATIC CORD AND DUCTUS DEFERENS

The ductus (vas) deferens continues from the duct of the epididymis as a thick-walled muscular tube that leaves the scrotum and passes through the inguinal canal as a component of the spermatic cord. At the deep inguinal ring, it continues into the pelvis and, behind the urinary bladder, joins with the excretory duct from the seminal vesicle to form the ejaculatory duct. The ejaculatory duct then pierces the prostate gland and opens into the urethra.

Mature sperm are stored in the terminal portion (tail) of the ductus epididymis. These sperm are forced into the ductus deferens by intense contractions of the three smooth muscle layers of the ductus deferens following appropriate neural stimulation. Contraction of the smooth muscle of the ductus deferens continues the movement of the sperm through the ejaculatory duct into the urethra during the ejaculatory reflex. The seminal vesicles (see Plate 22.6, page 906) are not storage sites for sperm but, rather, secrete a fructose-rich fluid that becomes part of the ejaculated semen. Fructose is the principal metabolic substrate for sperm.

Spermatic cord, human, hematoxylin and eosin (H&E) ×80.

A cross section through the ductus deferens and some of the vessels and nerves that accompany the duct in the spermatic cord is shown in this figure. The wall of the ductus deferens is extremely thick, mostly because of the presence of a large amount of smooth muscle. The muscle contracts when the tissue is removed, causing the mucosa to form longitudinal folds. For this reason, in histologic sections, the lumen (*L*) usually appears irregular in cross section.

The smooth muscle of the ductus deferens is arranged as a thick outer longitudinal layer (*SM[L]*), a thick middle circular layer (*SM[C]*), and a thinner inner longitudinal layer (*SM[L]*). Between the epithelium and the inner longitudinal smooth muscle layer, there is a moderately thick cellular layer of loose connective tissue, the lamina propria (*LP*). The connective tissue immediately surrounding the ductus deferens contains nerves and some of the smaller blood vessels that supply the duct. In fact, some of these vessels can be seen penetrating the outer longitudinal smooth muscle layer (*asterisks*).

A unique feature of the spermatic cord is the presence of a plexus of atypical veins (**pampiniform plexus**) that arise from the spermatic veins. These vessels receive the blood from the testis. (The pampiniform

plexus also receives tributaries from the epididymis.) The plexus is an anastomosing vascular network that constitutes the bulk of the spermatic cord. Portions of several of these veins (*BV*) are evident in the *upper right* of the previous figure along with a number of nerves (*N*). The unusual feature of the veins is their thick muscular wall that, at a glance, gives the appearance of an artery rather than a vein. Careful examination of these vessels (*inset*) shows that the bulk of the vessel wall is composed of two layers of smooth muscle—an outer circular layer *SM(C)* and an inner longitudinal layer *SM(L)*.

Ductus deferens, human, H&E $\times 320$; inset $\times 250$.

The epithelial lining of the **ductus deferens** consists of pseudostratified columnar epithelium with stereocilia (*arrowheads*). It resembles the epithelium of the epididymis, but the cells are not as tall. The elongated nuclei of the columnar cells are readily distinguished from the spherical nuclei of the **basal cells** (*arrows*).

The epithelium rests on a loose connective tissue known as the lamina propria (*LP*) that extends to the smooth muscle; no submucosa is described.

PLATE 22.5 ■ PROSTATE GLAND

The prostate gland is the largest accessory sex gland. It consists of 30–50 tubuloalveolar glands that surround the proximal urethra. Because of this relationship, a common condition in later life, benign prostatic hyperplasia, can result in partial or total obstruction of the urethra.

The prostatic glands are arranged in three concentric layers: a mucosal layer, a submucosal layer, and a peripheral layer containing the main prostatic glands. The mucosal glands secrete directly into the urethra; the other two sets of glands deliver their secretions through ducts that open into the prostatic sinuses on the posterior wall of the urethra. All of the glands are made up of a pseudostratified columnar epithelium that secretes several components of the semen, including acid phosphatase, citric acid (a nutrient for sperm), and fibrinolysin (which keeps the semen liquified). Aggregations of dead epithelial cells and precipitated secretory products form **prostatic concretions** in the alveoli of the glands; these are a characteristic feature that aids in recognition of the prostate.

The stroma is characterized by numerous small bundles of smooth muscle so that it can also be described as a **fibromuscular stroma**. Contraction of this muscle occurs at ejaculation, forcing the secretion into the urethra. Surrounding the gland is a fibroelastic capsule that also contains small bundles of smooth muscle.

Prostate gland, human, hematoxylin and eosin (H&E) ×47.

A portion of the **prostate gland** is shown in this low-magnification micrograph. A small section of the capsule (*Cap*) of the gland is seen in the *upper left* corner. The rest of the field is filled with the glandular and stromal components of the prostate. The secretory tubuloalveoli of the prostate gland vary greatly in form, as is evident in the figure. They may appear as tubes, as isolated alveoli, as alveoli with branches, or as tubes with branches. Tangential sections through alveoli may even produce the appearance of “epithelial islands” (*arrowheads*) in the lumen of the alveoli. This is due to the extremely uneven contour of the epithelial surface. It should also be noted that many of the alveoli may appear rudimentary in structure (*arrows*). These are simply in an inactive state and are increasingly observed in older individuals. As noted earlier, aggregations of dead epithelial cells and precipitated

secretions form **prostatic concretions** (*C*) in the lumina of the alveoli; these gradually increase in number and size with age. The concretions stain with eosin and may have a concentric lamellar appearance, as is clearly shown in the concretion in the *lower right*. With time, they may become impregnated with calcium salts and can thus be easily recognized in x-rays of the lower abdomen.

Glands and fibromuscular stroma, prostate, human, H&E $\times 178$; upper inset $\times 350$; lower inset $\times 650$.

In this higher magnification view of a portion of the prostate gland, the **fibromuscular stroma** is clearly seen both immediately subtending the secretory epithelium of the tubuloalveoli as well as in deeper, nonsecretory areas. In the *upper inset*, corresponding to the *larger rectangle*, the intensity of the staining of the **smooth muscle** (*SM*) clearly distinguishes it from the fibrous stromal connective tissue with which it is intimately intermingled. There are no clearly outlined bundles or layers of smooth muscle in the prostate; rather, it is randomly arrayed throughout the stroma. **Prostatic concretions** (*C*) are again evident in the lumina of alveoli, in one instance compressing the epithelium to a degree that makes it nearly unrecognizable. The *lower inset*, corresponding to the *smaller rectangle*, clearly demonstrates the pseudostratified columnar nature of the prostatic epithelium (*Ep*). Well-delineated basal cells (*arrowheads*) are seen along with the taller columnar secretory cells. A small blood vessel (*BV*) immediately subtending the epithelium is recognizable by the red blood cells in its lumen. A lymphocytic infiltration (*L*) appears to fill the stroma along the *lower border* of this image, suggesting an inflammatory process occurring in the prostate gland.

arrows, inactive alveoli

arrowheads, top figure, "epithelial islands;" lower inset figure, basal cells

PLATE 22.6 ■ SEMINAL VESICLE

The **seminal vesicles** are evaginations from the end of each ductus deferens that form tightly coiled tubes. Although sections through this structure may show many lumina, they are all profiles of a single continuous tubular lumen. The seminal vesicles are lined with a pseudostratified columnar epithelium that closely resembles that of the prostate gland.

The secretion of the seminal vesicles is a whitish yellow viscous material that contains fructose, other simple sugars, amino acids, ascorbic acid, and prostaglandins. Although prostaglandins were first isolated from the prostate gland (hence the name), they are synthesized in large amounts in the seminal vesicles. Fructose is the primary nutrient source for the sperm in the semen.

The **mucosa** rests on a thick layer of smooth muscle that is directly continuous with that of the ductus deferens, from which the seminal vesicle evaginates. The smooth muscle consists of an indistinct inner circular layer and an outer longitudinal layer (compare with the three layers of the ductus epididymis and the ductus deferens; Plate 22.3, page 900), which are difficult to distinguish. Contraction of the smooth muscle coat during ejaculation forces the secretions of the seminal vesicles into the ejaculatory ducts. Beyond the smooth muscle is the connective tissue of the adventitia.

Seminal vesicle, human, hematoxylin and eosin (H&E) $\times 30$.

This figure shows a cross section of a **seminal vesicle**. Because of the coiled nature of the vesicle, two almost distinct lumina, lying side by side, appear to be present. They are, however, connected so that, in effect, all of the internal spaces are continuous and what is seen here is actually a two-dimensional configuration reflecting the coiling of the tube.

The **mucosa** of the seminal vesicles is characterized by extensive folds or ridges. The ridges vary in size and typically branch and interconnect with one another. The larger ridges may form recesses that contain smaller ridges, and when cut obliquely, these appear as mucosal arches that enclose the smaller folds (*arrows*). When the plane of section is normal to the surface, the mucosal ridges appear as “villi.” In some areas, particularly the peripheral region of the lumen, the interconnecting folds of the mucosa appear as alveoli. Each of these chambers is, however, simply a pocket-like structure that is open and continuous with the lumen. The mucosa is subtended by a very cellular loose connective tissue (*CT*) that, in turn, is surrounded by smooth muscle (*SM*).

The seminal vesicles are paired, elongated sacs. Each vesicle consists of a single tube folded and coiled on itself with occasional diverticula in its wall. The upper extremity ends as a cul-de-sac; the lower extremity is constricted into a narrow straight excretory duct that joins and empties into its corresponding ductus deferens.

Mucosal folds, seminal vesicle, human, H&E ×220.

This higher magnification of the mucosal folds reveals the **epithelium** (*Ep*) and the underlying loose connective tissue or **lamina propria** (*LP*). The epithelium is described as pseudostratified. It is composed of low columnar or cuboidal cells and small, round basal cells. The latter are randomly interspersed between the larger principal cells, but they are relatively sparse. For this reason, the epithelium may not be readily recognized as pseudostratified. In some areas, the epithelium appears thick (*arrowhead*) and, based on the disposition of the nuclei, would seem to be multilayered. This is due to a tangential section of the epithelium and is not a true stratification. The lamina propria of the mucosa is composed of a very cellular connective tissue containing some smooth muscle cells and is rich in elastic fibers.

HISTOLOGY

■ OVERVIEW OF THE FEMALE REPRODUCTIVE SYSTEM

The female reproductive system consists of internal sex organs and external genital structures.

The internal female reproductive organs are located in the pelvis, and the external genital structures (external genitalia) are situated in the anterior part of the perineum known as the **vulva**.

- The **internal female reproductive organs** are the ovaries, uterine tubes, uterus, and vagina (Fig. 23.1). They are contained mainly within the pelvic cavity and in the perineum.

FIGURE 23.1. Schematic drawing of female internal sex organs. This drawing shows the posterior view of the female internal sex organs. Part of the wall of the uterus, uterine tube, and vagina has been removed to reveal their internal structure. Note the three distinct layers of the uterine wall: the inner layer, the endometrium lining the uterine cavity; the middle and thickest layer, the myometrium; and the outer layer, the perimetrium, which is the peritoneal covering of the uterus.

- The **external genitalia** include the mons pubis, labia majora and minora, clitoris, vestibule and opening of the vagina, hymen, and external urethral orifice.

The mammary glands are included in this chapter because their development and functional state are directly related to the hormonal activity of the female reproductive system. Similarly, the placenta is included because of its functional and physical relationship to the uterus in pregnancy.

Female reproductive organs undergo regular cyclical changes from puberty to menopause.

The **ovaries**, **uterine tubes**, and **uterus** of the sexually mature female undergo marked structural and functional changes related to neural activity and changes in hormone levels during each **menstrual cycle** and during **pregnancy**. These mechanisms also regulate the early development of the female reproductive system. The initiation of menstruation, referred to as **menarche**, occurs in females between 9 and 14 years of age (the mean age of menarche is 12.4 years) and marks the beginning of the reproductive life span. During this phase of life, the menstrual cycle averages 21–34 days in length. Between 45 and 55 years of age (the mean age is 51.4 years), the menstrual cycle becomes irregular and eventually ceases. This change in reproductive function is referred to as **menopause** or *climacteric*. The ovaries cease their reproductive function of producing oocytes and their endocrine function of producing hormones that regulate reproductive activity. Other organs (e.g., the vagina and mammary glands) show varying degrees of reduced function, particularly secretory activity.

■ OVARY

Production of gametes and steroid hormones are the two major functions of the ovary.

The **ovaries** have two interrelated functions: **gametogenesis** (the production of gametes; oocytes for fertilization and successful propagation of the species) and **steroidogenesis** (the production of steroids that allow the development of female secondary sexual characteristics and support of oocyte development and pregnancy). The production of female gametes is called **oogenesis**. Developing gametes are called **oocytes**; mature gametes are called **ova**.

Two major groups of **steroid hormones**—estrogens and progestogens—are secreted by the ovaries.

- **Estrogens** promote the growth and maturation of internal and external sex organs and are responsible for the female sex characteristics that develop at puberty. Estrogens also act on mammary glands to promote breast development by stimulating ductal and stromal growth and accumulation of adipose tissue.
- **Progestogens** prepare the internal sex organs, mainly the uterus, for pregnancy by promoting secretory changes in the endometrium (discussed in the section on cyclical changes in the endometrium). Progestogens also prepare the mammary gland for lactation by promoting lobular proliferation.

Both hormones play an important role in the menstrual cycle by preparing the uterus for implantation of a fertilized ovum. If implantation does not occur, the endometrium of the uterus degenerates and menstruation follows.

Ovarian Structure

In nulliparous female (individuals who have not given birth), the **ovaries** are paired, almond-shaped, pinkish white structures measuring about 3 cm in length, 1.5 cm in width, and 1 cm in thickness. Each ovary is attached to the posterior surface of the **broad ligament** by a peritoneal fold, the **mesovarium** (see Fig. 23.1). The superior (or tubal) pole of the ovary is attached to the pelvic wall by the **suspensory ligament of the ovary**, which carries the ovarian vessels and nerves. The inferior (or uterine) pole is attached to the uterus by the **ovarian ligament**. This ligament is a remnant of the **gubernaculum**, the embryonic fibrous cord that attaches the developing gonad to the floor of the pelvis. Before puberty, the surface of the ovary is smooth, but during reproductive life, it becomes progressively scarred and irregular because of repeated ovulation. After menopause, the ovaries are about one-fourth the size observed during the reproductive period.

The ovary is composed of a cortex and a medulla.

A section through the ovary reveals two distinct regions:

- The **medulla** or **medullary region** is located in the central portion of the ovary and contains loose connective tissue, a mass of relatively large contorted blood vessels, lymphatic vessels, and nerves (Fig. 23.2).

FIGURE 23.2. Schematic drawing of a section through the ovary. This drawing shows stages of follicular development from the early primary follicle to the mature (Graafian) follicle. The maturation of the follicles occurs in the direction of the *arrow*. Changes in the follicle after ovulation lead to the development of the corpus luteum and eventually the corpus albicans. Note the highly coiled blood vessels in the hilum and medulla of the ovary.

- The **cortex** or **cortical region** is found in the peripheral portion of the ovary surrounding the medulla. The cortex contains the **ovarian follicles** embedded in a richly cellular connective tissue (Plate 23.1, page 956). Scattered smooth muscle fibers are present in the stroma around the follicles. The boundary between the medulla and the cortex is indistinct.

“Germinal epithelium” instead of mesothelium covers the ovary.

The **surface of the ovary** is covered by a single layer of cuboidal and, in some parts, almost squamous cells. This cellular layer, known as the **germinal epithelium**, is continuous with the mesothelium that covers the mesovarium. The term *germinal epithelium* is a carryover from the past when it was incorrectly thought to be the site of germ cell formation during embryonic development. It is now known that the **primordial germ cells** (both male and female) are of extragonadal origin and that they migrate from the embryonic yolk sac into the cortex of the embryonic gonad, where they differentiate and induce differentiation of the ovary. A dense connective tissue layer, the **tunica albuginea**, lies between the germinal epithelium and the underlying cortex (Plate 23.1, page 956). **Tumors that arise from the epithelial surface of the ovary account for more than 70% of ovarian cancers. The origin of surface epithelial tumors may be related to repeated disruption and repair of the germinal epithelium that occurs during ovulation.**

Ovarian follicles provide the microenvironment for the developing oocyte.

Ovarian follicles of various sizes, each containing a single oocyte, are distributed in the stroma of the cortex. The size of a follicle indicates the developmental state of the oocyte. Early stages of oogenesis occur during fetal life when mitotic divisions massively increase the number of oogonia (see the section on oogenesis). The oocytes present at birth remain arrested in development in the diplotene stage of prophase of the first meiotic division (see page 917). During puberty, small groups of follicles undergo **cyclic growth and maturation**. Ovulation may occur irregularly throughout adolescence. Usually by the third year after menarche, a regular, cyclic pattern of follicular maturation and ovulation is established.

Normally, only one oocyte reaches full maturity and is released from the ovary during each menstrual cycle. Obviously,

the maturation and release of more than one egg at ovulation may lead to multiple zygotes. During the reproductive life span, only about 400 mature ova are produced. Most of the estimated 600,000–800,000 primary oocytes present at birth do not complete maturation and are gradually lost through atresia, spontaneous death, and subsequent resorption of immature oocytes. This process begins as early as the fifth month of fetal life and is mediated by apoptosis of cells surrounding the oocyte. Atresia reduces the number of primary oocytes in a logarithmic manner throughout life from as many as 5 million in the fetus to less than 20% of that number at birth. The oocytes that remain at menopause degenerate within a few years.

Follicle Development

Histologically, three basic types of ovarian follicles can be identified on the basis of developmental state:

- Primordial follicles
- Growing follicles, which are further subcategorized as primary and secondary (or antral) follicles
- Mature follicle or Graafian follicles

Some histologists and clinicians identify additional stages in the continuum of follicular development. In the ovary, follicles are found at all stages of development, but primordial follicles predominate. The fate of each follicle is controlled by endocrine as well as paracrine factors.

The primordial follicle is the earliest stage of follicular development.

Primordial follicles first appear in the ovaries during the third month of fetal development. Early growth of the primordial follicles is independent of gonadotropin stimulation. The primordial follicles do not express follicle-stimulating hormone (FSH) receptors. In the mature ovary, primordial follicles are found in the stroma of the cortex just beneath the tunica albuginea. A single layer of squamous follicle cells surrounds the oocyte (Fig. 23.3 and Plate 23.1,

page 956). The outer surface of the follicle cells is bounded by a basal lamina. At this stage, the oocyte and the surrounding follicle cells are closely apposed to one another. The oocyte in the follicle measures about 30 μm in diameter and has a large, eccentric nucleus that contains finely dispersed chromatin and one or more large nucleoli. The cytoplasm of the oocyte, referred to as *ooplasm*, contains a **Balbiani body** (Fig. 23.3a). At the ultrastructural level, the Balbiani body is revealed as a localized accumulation of Golgi membranes and vesicles, endoplasmic reticulum, centrioles, numerous mitochondria, and lysosomes. In addition, human oocytes contain **annulate lamellae**, and numerous small vesicles are scattered throughout the cytoplasm along with small, spherical mitochondria. Annulate lamellae resemble a stack of nuclear envelope profiles. Each layer of the stack includes pore structures that are morphologically identical to nuclear pores.

PRIMORDIAL FOLLICLE

FIGURE 23.3. Primordial follicle. **a.** Schematic drawing of a primordial follicle shows the oocyte arrested in prophase of the first meiotic division. The oocyte is closely surrounded by a single layer of squamous follicle cells. The outer surface of these cells is separated from the connective tissue by a basal lamina. The ooplasm contains characteristic organelles, as seen with the electron microscope, including a Balbiani body, annulate lamellae, and small spherical mitochondria. *rER*, rough-surfaced endoplasmic reticulum. **b.** This photomicrograph of primordial follicles shows the oocytes surrounded by a single layer of flattened follicle cells (*FC*).

Usually, the nucleus (*N*) of the oocyte is in an eccentric position. Two oocytes in which the nucleus is not included in the plane of section are indicated (*X*). Similarly, there are two follicles (*arrows*) in which the follicle cells are revealed en face or tangential view and the enclosed oocytes are not included in the section. $\times 640$.

The primary follicle is the first stage in the development of the growing follicle.

As a **primordial follicle** develops into a **growing follicle**, changes occur in the oocyte, follicle cells, and adjacent stroma. Initially, the oocyte enlarges, and the surrounding flattened follicle cells proliferate and become cuboidal. At this stage—that is, when the follicle cells become cuboidal—the follicle is identified as a **primary follicle**. As the oocyte grows, it secretes specific proteins that are assembled into an extracellular coat called the **zona pellucida**.

The zona pellucida is composed of glycoproteins that bind to the capacitated spermatozoa and induce the acrosome reaction.

The **zona pellucida (ZP)** appears between the oocyte and the adjacent follicle cells (Fig. 23.4). In humans, it is composed of four classes of sulfated acidic **zona pellucida (ZP) glycoproteins** termed **ZP-1** (638 amino acids), **ZP-2** (745 aa), **ZP-3** (424 aa), and **ZP-4** (540 aa). Human glycoproteins of zona pellucida are heavily glycosylated. ZP-3 and ZP-4 function as the primary spermatozoa-binding receptors. Their binding is detected in the acrosomal cap of the spermatozoon. ZP-1 and ZP-2 act as secondary spermatozoa-binding proteins that interact mainly with the equatorial segment of the spermatozoon head. In addition, ZP-1, ZP-3, and ZP-4 are responsible for the induction of the **acrosome reaction** in capacitated spermatozoa (see page 920). Subsequent to the fusion of the spermatozoon membrane with the plasma membrane of the oocyte (oolemma), zona pellucida glycoproteins are cleaved by metalloendoproteases, which are released from cortical granules, thus making zona pellucida proteins nonrecognizable for binding with other spermatozoa.

FIGURE 23.4. Early primary follicle. **a.** Schematic drawing of a primary follicle in an early stage of development. Note the formation of the zona pellucida between the oocyte and the adjacent follicle cells. A single layer of cuboidal follicle cells surrounds the growing oocyte. **b.** Photomicrograph of a primary follicle. Note the distinct layer of follicle cells (*FC*) surrounding the oocyte. $\times 640$.

In the light microscope, the zona pellucida is clearly visible as a homogeneous and refractile layer that stains deeply with acidophilic stains and with the periodic acid-Schiff (PAS) reagents (Plate 23.1, page 956). It is first apparent when the oocyte, surrounded by a single layer of cuboidal or columnar follicle cells, has grown to a diameter of 50 – 80 μm .

Follicle cells undergo stratification to form the granulosa layer of the primary follicle.

Through rapid mitotic proliferation, the single layer of follicle cells gives rise to a stratified epithelium, the **membrana granulosa (stratum granulosum)**, surrounding the oocyte. The follicle cells are now identified as **granulosa cells**. The basal lamina retains its position between the outermost layer of the follicle cells, which become columnar, and the connective tissue stroma.

During follicular growth, extensive gap junctions develop between granulosa cells. Unlike Sertoli cells in the testis, however, the basal layer of the granulosa cells does not

possess elaborate tight junctions (zonulae occludentes), indicating the absence of a blood-follicle barrier. Movement of nutrients and small informational macromolecules from the blood into the follicular fluid is essential for the normal development of the ovum and follicle.

Connective tissue cells form the theca layers of the primary follicle.

As the granulosa cells proliferate, **stromal cells** immediately surrounding the follicle form a sheath of connective tissue cells, known as the **theca folliculi**, just external to the basal lamina (Fig. 23.5). The theca folliculi further differentiates into two layers:

LATE PRIMARY FOLLICLE

FIGURE 23.5. Late primary follicle. **a.** Schematic drawing of a late primary follicle shows a multilayered mass of granulosa cells (differentiated from follicle cells) surrounding the oocyte. Note that the innermost layer of granulosa cells is adjacent to the zona pellucida, and the outermost layer of these cells rests on the basal lamina, which is adjacent to the stromal cells now called the *theca folliculi*. The Balbiani body at this stage reorganizes into multiple Golgi units, and cortical granules appear in the cytoplasm. The

circle-shaped enlargement depicts the ultrastructure of an oocyte and adjacent follicle cells. Numerous microvilli from the oocyte and slender processes from the granulosa cells extend into the zona pellucida that surrounds the oocyte. Processes of the granulosa cells contact the plasma membrane of the oocyte. b. Photomicrograph of a late primary follicle (monkey). Multiple layers of granulosa cells (GC) can be seen surrounding the primary oocyte. The zona pellucida (ZP) is present between the oocyte and follicle cells. ×640.

- The **theca interna** is the inner, highly vascularized layer of cuboidal secretory cells (Plate 23.2, page 958). The fully differentiated cells of the theca interna possess ultrastructural features characteristic of steroid-producing cells. Cells of the theca interna possess a large number of **luteinizing hormone (LH) receptors**. In response to LH stimulation, they synthesize and secrete the androgens that are the precursors of estrogens. In addition to secretory cells, the theca interna contains fibroblasts, collagen bundles, and a rich network of small vessels typical of endocrine organs.
- The **theca externa** is the outer layer of connective tissue cells. It contains mainly smooth muscle cells and bundles of collagen fibers.

Boundaries between the thecal layers and between the theca externa and surrounding stroma are not distinct. However, the **basal lamina** between the granulosa layer and the theca interna establishes a distinct boundary between these layers. It separates the rich capillary bed of the theca interna from the granulosa layer, which is avascular during the period of follicular growth. The basal lamina boundary between granulosa layer and the theca interna restricts the entry of leukocytes and high-molecular-weight substances (such as low-density lipoproteins) into the follicle.

Maturation of the oocyte occurs in the primary follicle.

The distribution of organelles changes as the oocyte matures. Multiple, dispersed Golgi elements derived from the single Balbiani body of the primordial oocyte become scattered in the cytoplasm. The number of free ribosomes, mitochondria, small

vesicles, and multivesicular bodies and the amount of rough-surfaced endoplasmic reticulum (rER) increase. Occasional lipid droplets and masses of lipochrome pigment may also be seen. The oocytes of many species, including mammals, exhibit specialized secretory vesicles known as **cortical granules** (see Fig. 23.5a). They are located just beneath the **oolemma**. The granules contain proteases that are released by exocytosis when the ovum is activated by the sperm (discussed in the section on fertilization).

Numerous irregular microvilli project from the oocyte into the **perivitelline space** between the oocyte and the surrounding granulosa cells as the zona pellucida is deposited (see Fig. 23.5). At the same time, slender processes from the granulosa cells develop and project toward the oocyte, intermingling with oocyte microvilli and, occasionally, invaginating into the oocyte plasma membrane. They form gap junctions with the plasma membrane of the oocyte. **Cyclic guanosine monophosphate (cGMP)** that is produced by granulosa cells enters the oocyte via gap junctions and **maintains maturational arrest** of oocytes in the first meiotic division by inhibiting hydrolysis of **cyclic adenosine monophosphate (cAMP)** by phosphodiesterase (PDE3A). This inhibition maintains a high concentration of cAMP in the oocyte and thus blocks meiotic progression.

The secondary follicle is characterized by a fluid-containing antrum.

The primary follicle initially moves deeper into the cortical stroma as it increases in size, mostly through proliferation of the granulosa cells. Several factors are required for oocyte and follicular growth:

- **Follicle-stimulating hormone (FSH)**
- **Growth factors** (e.g., epidermal growth factor [EGF], insulin-like growth factor I [IGF-I])
- **Calcium ions (Ca^{2+})**

When the stratum granulosum reaches a thickness of 6–12 cell layers, **fluid-filled cavities** appear among the granulosa cells (Fig. 23.6). As the hyaluronan-rich fluid called **liquor**

folliculi continues to accumulate among the granulosa cells, the cavities begin to coalesce, eventually forming a single, crescent-shaped cavity called the **antrum**. The follicle is now identified as a **secondary follicle** or **antral follicle** (Plate 23.2, page 958). The eccentrically positioned oocyte, which has attained a diameter of about 125 μm , undergoes no further growth. At the secondary follicle stage, most follicles undergo atresia, whereas only a few follicles, under the cyclic gonadotropin stimulation, reach the stage of readiness for ovulation.

FIGURE 23.6. Secondary follicle. a. Schematic drawing of a secondary follicle showing the fluid-filled antrum, which arises by the coalescence of small fluid-filled cavities among the granulosa cells. Note that this actively growing follicle has many dividing granulosa cells. Call-Exner bodies appear at this stage. The *circle-shaped enlargement* depicts the relationship of the granulosa cells, basal lamina, and the theca interna and theca externa. The theca interna cells differentiate into highly vascularized, steroid-producing cells. The theca interna is surrounded by an outer layer of stromal cells called the *theca externa*. The basal lamina separates the

granulosa cells from the theca interna. b. Photomicrograph of a secondary follicle. The antrum (*A*), filled with follicular fluid, is visible within the stratum granulosum (*GC*). Multiple layers of theca interna cells (*TI*) and theca externa cells (*TE*) can be seen outside the basal lamina of the secondary follicle. $\times 85$.

Cyclic nucleotides play a key role in maintaining meiotic arrest of the oocyte during follicle growth and maturation.

The cyclic nucleotides **cGMP** and **cAMP**, produced in the granulosa and oocyte, are the principal molecules responsible for **maintaining oocyte meiotic arrest**. In addition, the inhibition of growth and maturation of the oocyte is also controlled by the natriuretic peptide family. Its representative, a small molecular weight peptide called **C-type natriuretic peptide (CNP)**, is secreted by the granulosa cells into the antral fluid and functions as **oocyte maturation inhibitor**. A direct correlation is observed between the size of the secondary follicle and CNP concentration. The concentration is highest in small follicles and lowest in mature follicles. The follicle, which was 0.2 mm in diameter as an early secondary follicle when the fluid first appeared, continues to grow and reaches 10 mm or more in diameter.

Cells of the cumulus oophorus form a corona radiata around the secretory follicle oocyte.

As the **secondary follicle** increases in size, the antrum, lined by several layers of granulosa cells, also enlarges (Fig. 23.7). The stratum granulosum has a relatively uniform thickness, except for the region associated with the oocyte. Here, the granulosa cells form a thickened mound, the **cumulus oophorus**, which projects into the antrum. The cells of the cumulus oophorus that immediately surround the oocyte and remain with it at ovulation are referred to as the **corona radiata**. The corona radiata is composed of cumulus cells that send penetrating microvilli throughout the zona pellucida to communicate via gap junctions with microvilli of the oocyte. During follicular maturation, the number of surface microvilli of granulosa cells increases and is correlated with an increased number of LH receptors on the free antral surface.

Extracellular, densely staining, PAS-positive material called **Call-Exner bodies** (see Fig. 23.6a) may be seen between the granulosa cells. These bodies are secreted by granulosa cells and contain hyaluronan and proteoglycans.

FIGURE 23.7. Secondary follicle in a late stage of development. a. Schematic drawing of a mature (Graafian) follicle with a large antrum containing an oocyte embedded within the cumulus oophorus. The cells of the cumulus oophorus immediately surrounding the oocyte remain with it after ovulation and are referred to as the *corona radiata*. b. Photomicrograph of a mature secondary follicle. Note the large fluid-filled antrum (A) and the cumulus oophorus (CO) containing the oocyte. The remaining cells that surround the lumen of the antrum make up the membrana granulosa (stratum granulosum, SG). The surface of the ovary is visible on the right. Note the presence of two primary follicles (upper right). TI, theca interna. ×45.

The mature or Graafian follicle contains the mature secondary oocyte.

The **mature follicle**, also known as a **Graafian follicle**, has a diameter of 10 mm or more. Because of its large size, it extends through the full thickness of the ovarian cortex and causes a bulge on the surface of the ovary. As the follicle nears its maximum size, the mitotic activity of the granulosa cells decreases. The stratum granulosum appears to become

thinner as the antrum increases in size. As the spaces between the granulosa cells continue to enlarge, the oocyte and cumulus cells are gradually loosened from the rest of the granulosa cells in preparation for ovulation. The cumulus cells immediately surrounding the oocyte now form a single layer of cells of the corona radiata. These cells and loosely attached cumulus cells remain with the oocyte at ovulation.

During this period of follicle maturation, the thecal layers become more prominent. Lipid droplets appear in the cytoplasm of the theca interna cells, and the cells demonstrate ultrastructural features associated with steroid-producing cells.

The synthesis of estrogens in the ovary requires a collaborative relationship between theca interna and granulosa cells.

Cooperative interaction of both **theca interna cells** and **granulosa cells** is required for estrogen (i.e., estrone, estradiol) production in the developing follicles. Neither granulosa nor theca cells express the full complement of enzymes needed for synthesis of estradiol, the primary female sex hormone. Theca interna cells reside in a highly vascularized layer of the follicle and express both LH and low-density lipoprotein (LDL) receptors on their surface. LDL receptors in these cells expedite the uptake of LDL molecules from which cholesterol is liberated and becomes the main substrate in steroid hormone synthesis (Fig. 23.8).

FIGURE 23.8. Synthesis of estrogens in the ovarian follicle. Synthesis of estrogens in the ovary requires collaboration between theca interna and granulosa cells. Theca interna cells express both luteinizing hormone (*LH*) and low-density lipoprotein (*LDL*) receptors on their surface. *LH* stimulation of theca interna cells facilitates conversion of cholesterol (liberated from lactate dehydrogenase [*LDH*]) to pregnenolone (*P5*) and then via further intermediates into androgens (androstenedione and testosterone). These androgens diffuse into neighboring granulosa cells where they are converted to estrogens by the enzyme P450 aromatase. Granulosa cells express follicle-stimulating hormone (*FSH*) receptors and their activation by *FSH* is a primary stimulator of P450 aromatase activity. *FSH* also promotes the conversion of estrone to 17β-estradiol. *ATP*, adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate.

When stimulated by *LH*, theca interna cells facilitate conversion of **cholesterol** to pregnenolone and then via further intermediates to **androgens** (i.e., dehydroepiandrosterone [*DHEA*], androstenediol, androstenedione, testosterone) (see Fig. 23.8). Owing to the lack of the enzyme **P450 aromatase**, the

theca interna cells are not able to produce estrogens. In contrast, neighboring granulosa cells are equipped with P450 aromatase. Thus, androgens secreted by theca interna cells enter granulosa cells where they are converted in the cells' smooth-surfaced endoplasmic reticulum (sER) by P450 aromatase to **estrogens** in response to FSH stimulation (see Fig. 23.8).

FSH is the primary stimulator of P450 aromatase gene expression in granulosa cells. However, not all granulosa cells have the same capacity to produce estrogens. The highest levels of aromatase activity are found in the peripheral cells near the theca interna, whereas the lowest levels are in the cells bordering the antrum. Almost all (99%) of the aromatization capacity (conversion of androgens to estrogens) in the developing follicles occur in granulosa cells and are thus the only source of estradiol in the follicular phase of the ovarian cycle. Estrogens secreted by granulosa cells stimulate their own proliferation and thereby increase the size of the follicle.

Aromatase inhibitors (AIs) are a class of drug used in the treatment of estrogen-sensitive breast cancer. This type of breast cancer grows in response to estrogen. AIs bind to different sites on the aromatase enzyme and prevent the conversion of androgens to estrogens, thus lowering the level of estrogen in the body and decreasing the potential for growth of cancer cells.

Increased estrogen levels from both follicular and systemic sources are correlated with increased sensitization of gonadotropes to gonadotropin-releasing hormone. A surge in the release of LH (and a smaller surge of FSH) is induced in the adenohypophysis approximately 24 hours before ovulation. In response to the LH surge, LH receptors are downregulated (desensitized), and granulosa cells no longer produce estrogens. Triggered by this surge, the first meiotic division of the primary oocyte resumes. This event occurs between 12 and 24 hours after the LH surge, resulting in the formation of the secondary oocyte and the first polar body. Both the granulosa and thecal cells then undergo luteinization and produce progesterone (see pages 918–919, section on the corpus luteum).

CLINICAL CORRELATION: POLYCYSTIC OVARY DISEASE

Polycystic ovary disease is a syndrome characterized by a variety of clinical signs and symptoms, including bilaterally enlarged ovaries with numerous follicular cysts, irregular menstrual periods, anovulation that may lead to infertility, obesity, and excess hair growth on the face, acne, and oily skin. Morphologically, the ovaries resemble a small, white balloon filled with tightly packed marbles. Affected ovaries, often called *oyster ovaries*, have a smooth, pearl-white surface but do not show surface scarring because no ovulations have occurred. Their appearance is attributable to the large number of fluid-filled follicular cysts and atrophic secondary follicles that lie beneath an unusually thick tunica albuginea.

Although the pathogenesis of polycystic ovary syndrome (PCOS) is not clear, it may be related to a defect in the regulation of androgen biosynthesis that causes production of excessive amounts of androgens, which inhibits ovulation and causes abnormal hair growth and acne that are often associated with PCOS. Insulin resistance also appears to play a role in PCOS.

Treatments of PCOS are individualized based on a patient's desire for childbearing. For those wishing to have children, drugs that sensitize the body to insulin and promote weight loss may reduce insulin resistance and result in the resumption of ovulation. If these measures fail, ovulation-stimulating drugs and laparoscopic surgical procedures are implemented. In vitro fertilization may also be an option. For those who do not wish to have children, combined contraception (containing both estrogen and progesterone) may regulate the menstrual cycle and reduce acne and abnormal hair growth (Fig. F23.1.1).

FIGURE F23.1.1. Polycystic ovary disease. This photomicrograph shows a section through the cortex of the ovary from an individual with polycystic ovary disease. Note the unusually thick tunica albuginea (*TA*) that overlies numerous follicles. The thickness of the tunica albuginea prevents ovulation of the mature (Graafian) follicles. Note that one of the follicles has developed to the primary follicle stage. $\times 45$.

Ovulation

Ovulation is a hormone-mediated process resulting in the release of the secondary oocyte.

Ovulation is the process by which a **secondary oocyte** is released from the Graafian follicle. The follicle destined to ovulate in any menstrual cycle is recruited from a cohort of

several primary follicles in the first few days of the cycle. During ovulation, the oocyte traverses the entire follicular wall, including the germinal epithelium.

A combination of hormonal changes and enzymatic effects is responsible for the actual release of the **secondary oocyte**, which occurs 14 days before the start of the next menstrual cycle (i.e., on the 14th day of a 28-day cycle). These factors include

- increase in the volume and pressure of the follicular fluid;
- enzymatic proteolysis of the follicular wall by activated plasminogen;
- hormonally directed deposition of glycosaminoglycans between the oocyte - cumulus complex and the stratum granulosum; and
- contraction of the smooth muscle fibers in the theca externa layer, triggered by prostaglandins.

Just before ovulation, blood flow stops in a small area of the ovarian surface overlying the bulging follicle. This area of the germinal epithelium, known as the **macula pellucida** or **follicular stigma**, becomes elevated and then ruptures (Fig. 23.9a). The oocyte, surrounded by the corona radiata and cells of the cumulus oophorus, is released from the ruptured follicle. At the time of ovulation, the fimbriae of the uterine tube become closely apposed to the surface of the ovary, and the **cumulus mass** containing the oocyte is gently swept by the fimbriae into the abdominal ostium of the uterine tube. The cumulus mass firmly adheres to the fimbriae and is actively transported by the ciliated cells lining the uterine tube, preventing its passage into the peritoneal cavity. **Nonsurgical ultrasound technology can be used to monitor ovarian follicle development. Transvaginal ultrasound examination can provide detailed information about the number and size of developing follicles, which is useful during infertility assessment and treatment (Fig. 23.9b).** After ovulation, the secondary oocyte remains viable for approximately 24 hours. If fertilization does not occur during this period, the secondary oocyte degenerates as it passes through the uterine tube.

FIGURE 23.9. Endoscopic and ultrasound examination of the ovary. **a.** This photograph shows a view of the human ovary during endoscopic oocyte harvest surgery. The ovary is in the stage just before ovulation. Note the area of the bulging follicle with the follicular stigma clearly visible. The germinal epithelium covering the tunica albuginea is ruptured in the area of imminent ovulation. **b.** Development of nonsurgical techniques such as ultrasound imaging helps in monitoring of follicular growth and is useful as a method for determining the time for harvesting preovulatory oocytes. (Courtesy of Dr. Charles C. Coddington, III, Mayo Clinic.)

Oocytes that fail to enter the uterine tube usually degenerate in the peritoneal cavity. Occasionally, however, an oocyte may be fertilized and implant in the peritoneal cavity on the surface of the ovary or intestine or inside the rectouterine (Douglas) pouch. A pregnancy that develops at any site other than the endometrium of the uterine cavity is called an **ectopic pregnancy**. An ectopic pregnancy is not viable and must be removed surgically or with the use of certain medications (e.g., methotrexate). Ectopic pregnancy that develops at any site other than the endometrium of the uterine cavity continues to be the most common cause of maternal mortality in the first half of pregnancy.

Normally, only one follicle completes maturation in each cycle and ruptures to release its secondary oocyte. Rarely, oocytes are released from other follicles that have reached full maturity during the same cycle, leading to the possibility of multiple zygotes. Drugs such as clomiphene citrate or gonadotropins that stimulate ovarian activity greatly increase the possibility of multiple births by causing simultaneous maturation of several follicles.

The primary oocyte is arrested for 12-50 years in the diplotene stage of prophase of the first meiotic division.

The primary oocytes within the primordial follicles begin the first meiotic division in the embryo, but the process is arrested at the diplotene stage of meiotic prophase (see the section on meiosis in Chapter 3, The Cell Nucleus, page 102). The first meiotic prophase is not completed until just before ovulation. Therefore, the primary oocytes remain arrested in the first meiotic prophase for 12-50 years. This long period of meiotic arrest exposes the primary oocyte to adverse environmental influences and may contribute to errors in meiotic division, such as nondisjunction. Such errors result in an abnormal number of chromosomes (aneuploidy), such as trisomy of chromosome 21 (Down syndrome).

As the first meiotic division (reduction division) is completed in the mature follicle (Fig. 23.10), each daughter cell of the primary oocyte receives an equal share of chromatin, but one daughter cell receives most of the cytoplasm and becomes the secondary oocyte. It measures 150 μm in diameter. The other daughter cell receives a minimal amount of cytoplasm and becomes the first polar body.

FIGURE 23.10. Diagram illustrating changes that occur during growth, maturation, and fertilization of the oocyte. The primary oocyte remains arrested in prophase I of meiosis. The first meiotic or reductional division is completed only after the oocyte progresses to ovulation. The second meiotic or equatorial division is not completed unless the secondary oocyte is impregnated by a spermatozoon. Note the formation of the first and second polar bodies. In some mammals, the first polar body divides (as shown in this drawing) so that there are four total meiotic products. However, in humans, the first polar body does not divide but persists for about 20 hours; therefore, the fertilized egg can be recognized by the presence of two polar bodies.

The secondary oocyte is arrested at metaphase in the second meiotic division just before ovulation.

As soon as the first meiotic division is completed, the **secondary oocyte** begins the second meiotic division. As the secondary oocyte surrounded by the cells of the corona radiata leaves the follicle at ovulation, the second meiotic division (equatorial division) is in progress. This division is **arrested at metaphase** and completed only if the secondary oocyte is fertilized by a spermatozoon. If fertilization occurs, the secondary oocyte completes the second meiotic division and forms a mature **ovum** with the **female (maternal) pronucleus** containing a set of 23 chromosomes. The other cell produced at this division is a **second polar body**. In humans, the first polar body persists for more than 20 hours after ovulation and does not divide; therefore, the fertilized egg can be recognized by the presence of two polar bodies (diploid first polar body and haploid second polar body). In some mammals, the first polar body can divide, so the final outcome of meiosis consists of one oocyte and three haploid polar bodies (see Fig. 23.10). The polar bodies, which are not capable of further development, undergo apoptosis.

Corpus Luteum

The collapsed follicle undergoes reorganization into the corpus luteum after ovulation.

At ovulation, the **follicular wall**, composed of the remaining granulosa and thecal cells, is thrown into deep folds as the

follicle collapses and is transformed into the **corpus luteum** (yellow body) or **luteal gland** (Fig. 23.11a and Plate 23.3, page 960). At first, bleeding from the capillaries in the theca interna into the follicular lumen leads to the formation of the **corpus hemorrhagicum** with a central clot. Connective tissue from the stroma then invades the former follicular cavity. Cells of the granulosa and theca interna layers then differentiate into granulosa luteal and theca luteal cells in a process called **luteinization**. These luteal cells undergo dramatic morphologic changes, increasing in size and filling with lipid droplets (Fig. 23.11b). A lipid-soluble pigment, lipochrome, in the cytoplasm of the cells gives them a yellow appearance in fresh preparations (Fig. 23.12). At the ultrastructural level, the cells demonstrate features associated with steroid-secreting cells, namely, abundant sER and mitochondria with tubular cristae (Fig. 23.13).

FIGURE 23.11. Photomicrograph of human corpus luteum. a. The corpus luteum is formed from the collapsed follicle wall that contains the granulosa and theca cells. The granulosa lutein cells form a

thick, folded layer around the former follicular cavity (*Cav*). Within the folds are cells of the theca interna (*arrows*). $\times 12$. b. This photomicrograph shows the wall of the corpus luteum at higher magnification. The main cell mass is composed of granulosa lutein cells (*GLC*). These cells have a large spherical nucleus and a large amount of cytoplasm. The theca lutein cells (*TLC*) also have a spherical nucleus, but the cells are considerably smaller than the granulosa lutein cells. $\times 240$.

FIGURE 23.12. Human corpus luteum of menstruation. This photograph shows a section of a normal ovary that was surgically removed during an oophorectomy. The corpus luteum is fully developed in the cortex of the ovary, which indicates the midluteal phase of the ovarian cycle. The cortex of the ovary contains atretic follicles, a small ovarian cyst, and a few corpora albicantia that represent

remnants of corpora lutea from previous ovarian cycles. Note that the medulla of the ovary contains a larger corpus albicans, which is most likely a remnant of the corpus luteum of pregnancy. $\times 2$. (Courtesy of Dr. Edward Uthman.)

FIGURE 23.13. Electron micrograph of theca lutein cells from the corpus luteum of a monkey. At this early implantation stage (day 11 of gestation), membrane-bound dense bodies are clustered near

the Golgi apparatus (*G*); most of the cytoplasm is packed with tubules of smooth-surfaced endoplasmic reticulum (*sER*), lipid droplets (*L*), and mitochondria (*M*). Note the capillary (*Cap*) and the closely apposed cell membranes of the theca lutein cells (*arrows*). $\times 10,000$. (Courtesy of Dr. Carolyn B. Booher.)

Two types of luteal cells are identified:

- **Granulosa lutein cells** are large (about 30 μm in diameter), centrally located cells derived from granulosa cells. They constitute about 80% of the corpus luteum and synthesize **estrogens**, **progesterone**, and **inhibin**. The latter regulates the production and secretion of FSH from the anterior lobe of the pituitary gland.
- **Theca lutein cells** are smaller (about 15 μm), more deeply staining, and peripherally located cells derived from the cells of the theca interna layer (Plate 23.3, page 960). They represent the remaining 20% of cells in the corpus luteum and secrete **androgens** and **progesterone**.

As the **corpus luteum** begins to form, blood and lymphatic vessels from the theca interna rapidly grow into the granulosa layer. A rich vascular network is established within the corpus luteum. This highly vascularized structure located in the cortex of the ovary secretes progesterone and estrogens. These hormones stimulate the growth and secretory activity of the lining of the uterus, the endometrium, to prepare it for the implantation of the developing zygote in the event that fertilization occurs.

The corpus luteum of menstruation is formed in the absence of fertilization.

If fertilization and implantation do not occur, the corpus luteum remains active only for the next 10 days. In this case, it is called the **corpus luteum of menstruation**. In the absence of human chorionic gonadotropin (hCG) and other luteotropins, the rate of secretion of progestogens and estrogens declines, and the corpus luteum begins to degenerate about 10 days after ovulation.

The **corpus luteum degenerates** and undergoes a slow involution after pregnancy or menstruation. The cells become loaded with lipid, decrease in size, and undergo autolysis. A white scar, the **corpus albicans**, is formed as intercellular hyaline material accumulates among the degenerating cells of the former corpus luteum (Fig. 23.14). The corpus albicans sinks deeper into the ovarian cortex as it slowly disappears over a period of several months.

FIGURE 23.14. Photomicrograph of the corpus albicans of a human ovary. Large amounts of hyaline material can be seen among the degenerating cells of the former corpus luteum. The corpus albicans is surrounded by ovarian stroma. $\times 125$.

Capacitation and Fertilization

During capacitation, the mature spermatozoa acquire the ability to fertilize the oocyte.

Following their maturation in the epididymis, spermatozoa must be activated within the female reproductive tract for fertilization to occur. During this activation process, called **capacitation**, structural and functional changes take place in the spermatozoon that results in its increased affinity to bind to zona pellucida receptors. Processes leading to the acrosome reaction are associated with the sperm head, whereas those related to sperm motility occur in the tail. Successful capacitation is confirmed by **hyperactivation** of the spermatozoa, which manifests as a vigorous, whiplash-like beating pattern of their flagella.

Capacitation involves several biochemical changes and modifications to the spermatozoon and its plasma membrane, including:

- Increased activity of adenylyl cyclase leads to increasing levels of cAMP.
- The rate of tyrosine phosphorylation by the Src kinase family increases (measurement of tyrosine phosphorylation is used clinically as a biochemical marker of capacitation).
- Serine/threonine (Ser/Thr) phosphatase activity is inhibited.
- Increase in pH and plasma membrane hyperpolarization activates Ca^{2+} channels, resulting in increased intracellular Ca^{2+} levels essential for the acquisition of hyperactivated motility.
- Seminal fluid glycoconjugates are released from the surface of the head of the spermatozoon. These surface glycosides (also called *decapacitation factors*) added during sperm maturation in the epididymis inhibit binding to the zona pellucida receptors.

- The plasma membrane of the spermatozoon is extensively modified by removal of cholesterol, the predominant inhibitor of capacitation, and redistribution of phospholipids and carbohydrate moieties.

Fertilization normally occurs in the ampulla of the uterine tube.

Usually, only a few hundred of the millions of spermatozoa in an ejaculate reach the site of fertilization, typically the ampulla of the uterine tube. On arrival, spermatozoa encounter the secondary oocyte surrounded by the corona radiata. **Spermatozoa must penetrate the corona radiata** to gain access to the zona pellucida. Although several spermatozoa may penetrate the zona pellucida only one spermatozoon completes the fertilization process. Capacitation is complete when spermatozoa are able to **bind to the zona pellucida receptors**. Binding to the ZP-1, ZP-3, or ZP-4 receptors on the zona pellucida triggers the **acrosome reaction** in which enzymes (mainly hyaluronidases) released from the acrosome enable a single spermatozoon to penetrate the zona pellucida. Penetration is accomplished by limited **proteolysis of the zona pellucida** in front of the advancing hypermotile spermatozoon. During penetration, the spermatozoon must maintain its adherence to the oocyte coat via transient secondary binding supported by the ZP-1 and ZP-2 receptors.

After penetrating the zona pellucida the spermatozoon enters the **perivitelline space** between the zona pellucida and the oocyte plasma membrane (or oolemma). Here, the spermatozoon plasma membrane **binds to the oolemma** via fertilin (PH-30) and subsequently **fuses** with it. Fusion of both membranes occurs by lipid mixing that transforms the two gamete membrane bilayers into a single layer. After fusion, the nucleus of the sperm head is finally incorporated into the oocyte. It forms the **male (paternal) pronucleus** containing 23 paternal chromosomes. After the alignment and dissolution of nuclear membranes of the two pronuclei, the paternal and maternal chromosomes are united in the first mitotic spindle. The resulting **zygote**, with its diploid (2n) complement of 46 chromosomes, undergoes a mitotic

division or first cleavage. This two-cell stage marks the beginning of embryonic development.

Before spermatozoa can fertilize the secondary oocyte, they must acquire more thrust to penetrate the corona radiata and zona pellucida.

When approaching a secondary oocyte, a **spermatozoon** becomes hyperactivated: It swims faster, and its tail movements become more forceful and erratic. Recent studies indicate that this **hyperactivation reaction** is caused by a sudden influx of Ca^{2+} into the tails of spermatozoa. The plasma membrane of the sperm tail contains large numbers of transmembrane Ca^{2+} channel proteins called **CatSpers** (cation channels of sperm). CatSper proteins are expressed exclusively in membranes of the tail. Influx of Ca^{2+} causes the tail to be more active and bend more forcefully, resulting in faster sperm movement through the viscous environment of the uterine tube. Together with limited proteolysis of the zona pellucida, hyperactivation is responsible for the physical penetration of the oocyte. **Sperm hyperactivity is necessary for breaking physical barriers that protect the secondary oocyte from fertilization. Thus, activation of CatSpers is required for male fertility.**

Impregnation of the oocyte allows structures lying inside the spermatozoon to enter the cytoplasm of the oocyte.

After penetrating the zona pellucida, the **spermatozoon enters the perivitelline space** between the zona pellucida and the oolemma. Here, after binding to the oolemma, the spermatozoon plasma membrane fuses with it. This process, called the **impregnation of the oocyte**, allows the nucleus of the sperm (containing highly concentrated DNA), the centrosome, the midpiece with the mitochondria, and the kinocilium to be incorporated into the cytoplasm of the oocyte. The tail plasma membrane remains as an appendage to the oolemma.

An impregnating spermatozoon generates a molecular signal for resumption and termination of the **second meiotic division**. Currently, diffusion of sperm-derived phospholipase C zeta 1 (PLC ζ 1) into the oocyte cytoplasm is the most promising

candidate for this signaling mechanism. This second meiotic division transforms the secondary oocyte into a mature oocyte and triggers the expulsion of the second polar body into the perivitelline space. The **female pronucleus** resides in the cytoplasm adjacent to the second polar body.

The male genetic material carried within the nucleus of incorporated sperm head is unpacked and used for building the **male pronucleus**, which contains 23 paternal chromosomes. Both female and male pronuclei migrate toward the center to unite maternal and paternal DNA, as well as for the development of mitotic spindle. Nuclear membranes of both female and male pronuclei dissolve (without fusion), and the chromosomes align themselves within the first mitotic spindle. The resulting **zygote** contains a diploid (**2n**) complement of 46 chromosomes and later undergoes the first mitotic division or cleavage. The male centrosome is essential for the alignment of the mitotic spindle that divides chromosomes into the first two cells of the embryo. Only centrosomes from the father are used in building the first and subsequent mitotic spindles. The incorporated kinocilium is finally dissolved, and all **sperm mitochondria are eliminated** from the cytoplasm of the oocyte. Note that all mitochondria in human cells normally derive from the mother's oocyte, but all centrosomes originate from the father's sperm cell.

Several spermatozoa may penetrate the zona pellucida, but only one spermatozoon completes the fertilization process.

Preventing polyspermy, or the fertilization of an oocyte by more than one spermatozoon, is essential for normal embryonic development. Polyspermy causes severe chromosomal defects and embryonic mortality. As the fertilizing spermatozoon penetrates the ooplasm, at least three types of **postfusion reactions** occur to prevent other spermatozoa from entering the secondary oocyte. These events include the following:

- **Fast block to polyspermy.** A large and long-lasting (up to 1 minute) depolarization of the oolemma creates a transient electrical block to polyspermy. It is most likely achieved by

the fertilization-evoked activation of Ca^{2+} -activated Cl^- channel proteins.

- **Cortical reaction.** Changes in the polarity of the oolemma then trigger the release of Ca^{2+} from ooplasmic stores. The Ca^{2+} propagates a cortical reaction wave in which cortical granules move to the surface and fuse with the oolemma, leading to a transient increase in the surface area of the ovum and reorganization of the membrane. The contents of the cortical granules are released into the perivitelline space.
- **Zona reaction.** The released enzymes (proteases) of the cortical granules not only degrade the glycoprotein oocyte plasma membrane receptors for sperm binding but also form the **perivitelline barrier** by cross-linking proteins on the surface of the zona pellucida. This event creates the final and permanent block to polyspermy.

The corpus luteum of pregnancy is formed after fertilization and implantation.

If fertilization and implantation occur, the corpus luteum increases in size to form the **corpus luteum of pregnancy**. The existence and function of the corpus luteum depend on a combination of paracrine and endocrine secretions, collectively described as luteotropins.

Paracrine luteotropins are locally produced by the ovary. They include

- **estrogens**,
- **IGF-I** and **IGF-II**.

Endocrine luteotropins are produced at a distance from their target organ, the corpus luteum. They include

- **hCG**, a 37-kDa glycoprotein secreted by the trophoblast of the chorion, which stimulates LH receptors on the corpus luteum and prevents its degeneration (page 919);
- **LH** and **prolactin**, both secreted by the pituitary gland; and
- **insulin**, produced by the pancreas.

High levels of **progesterone**, produced from cholesterol by the corpus luteum, block the cyclic development of ovarian follicles. In early pregnancy, the corpus luteum measures 2-3 cm, thus filling most of the ovary. Its function begins to decline gradually after 8 weeks of pregnancy, although it persists throughout pregnancy. Although the corpus luteum remains active, the placenta produces sufficient amounts of estrogens and progestogens from maternal and fetal precursors to take over the function of the corpus luteum after 6 weeks of pregnancy. **Human chorionic gonadotropin (hCG)** can be detected in the serum as early as 6 days after fertilization and in the urine as early as 10-14 days after fertilization. Detection of hCG in the urine by specific antibodies forms the basis of **pregnancy tests**. In addition, the rapid increase in circulating level of hCG in early pregnancy is responsible for “**morning sickness**,” a condition characterized by nausea and vomiting. These symptoms usually occur in the early hours of the morning and are often among the first signs of pregnancy.

Atresia

Most ovarian follicles are lost by atresia mediated by apoptosis of granulosa cells.

As stated, very few of the ovarian follicles that begin their differentiation in the embryonic ovary are destined to complete their maturation. Most of the follicles degenerate and disappear through a process called **ovarian follicular atresia**. Atresia is mediated by apoptosis of granulosa cells. Large numbers of follicles undergo atresia during fetal development, early postnatal life, and puberty. After puberty, groups of follicles begin to mature during each menstrual cycle; normally, only one follicle completes its maturation. Atresia is now thought to be a mechanism whereby a few follicles are stimulated to maintain their development through the programmed death of the other follicles. Thus, at any stage of its maturation, a follicle may undergo atresia. The process becomes more complex as the follicle progresses toward maturation.

In atresia of primordial and small, growing follicles, the immature oocyte becomes smaller and degenerates; similar changes occur in the granulosa cells. **Atretic follicles** shrink and eventually disappear from the stroma of the ovary as a result of repeated apoptosis and phagocytosis by granulosa cells (Plate 23.2, page 958). As the cells are reabsorbed and disappear, the surrounding stromal cells migrate into the space previously occupied by the follicle, leaving no trace of its existence.

In atresia of large, growing follicles, the degeneration of the mature oocyte is delayed and appears to occur secondary to degenerative changes in the follicular wall (Plate 23.2, page 958). This delay indicates that once the oocyte has achieved its maturity and competence, it is no longer sensitive to the same stimuli that initiate atresia in granulosa cells. The follicular changes include the following sequential events:

- Initiation of apoptosis within the granulosa cells, indicated by cessation of mitosis and expression of endonucleases and other hydrolytic enzymes within the granulosa cells
- Invasion of the granulosa layer by neutrophils and macrophages
- Invasion of the granulosa layer by strands of vascularized connective tissue
- Sloughing of the granulosa cells into the antrum of the follicle
- Hypertrophy of the theca interna cells
- Collapse of the follicle as degeneration continues
- Invasion of connective tissue into the cavity of the follicle

Several gene products regulate the process of follicular atresia. One of these products is the gonadotropin-induced **neural apoptosis inhibitory protein (NAIP)**, which inhibits and delays apoptotic changes in the granulosa cell. NAIP gene expression is present in all stages of the growing follicle but absent in follicles undergoing atresia. A high level of gonadotropins inhibits apoptosis in ovarian follicles by increasing the expression of NAIP in the ovaries.

CLINICAL CORRELATION: IN VITRO FERTILIZATION

There are several indications for **in vitro fertilization (IVF)**, but the primary one is infertility as a result of surgically uncorrectable damage to, or absence of, the uterine tubes. Individuals choosing IVF must first undergo controlled hyperstimulation of the ovaries to induce multiple follicle development and maturation. Hyperstimulation for IVF is usually achieved by different hormonal therapies using human gonadotropins, with or without follicle-stimulating hormone (FSH).

Mature preovulatory oocytes are collected from the Graafian follicles by either laparoscopic or ultrasound-guided percutaneous aspiration or transvaginal aspiration. Before insemination, the oocytes are preincubated in a specialized medium with serum complements for a time determined by their stage of maturity.

The collected semen is placed in a special medium. The oocytes are then added to the medium containing the collected semen for fertilization. Twelve to 16 hours later, the oocytes are examined with the differential interference contrast microscope to determine the presence of female and male pronuclei, which indicates successful fertilization (Fig. F23.2.1a). At this stage, a fertilized oocyte may be frozen for future IVF transfers.

FIGURE F23.2.1. Early developmental stages of the human embryo. **a.** This image, obtained with an interference contrast microscope equipped with Nomarski optics, shows a human fertilized oocyte with two pronuclei. The zygote develops after alignment and dissolution of nuclear membranes of both female and male pronuclei. The resulting cell will contain a diploid complement of 46 chromosomes. $\times 400$. **b.** This image shows a 48-hour-old human embryo

growing in a special growth medium. At this stage, the embryo consists of four cells. In in vitro fertilization (IVF) procedures, it is at this stage that the embryo is usually transferred into the uterine cavity. $\times 400$. (Courtesy of Dr. Peter Fehr.)

Generally, 80% of mature oocytes cultured in vitro are fertilized. The embryo is transferred to a special growth medium for 24–48 hours, where it is allowed to grow to the stage of four to six cells (Fig. F23.2.1b). Embryos are then transferred under ultrasound guidance into the uterus via the vagina and cervical canal on the third or fourth day after the initial aspiration of the oocyte. Before embryo transfer, the uterus is prepared to receive the embryo by administration of appropriate hormones. Embryos are, therefore, placed into a hormonally prepared uterus under conditions equivalent to those in normal implantation (see pages 930–931). Intensive progesterone treatment is usually begun just after the transfer to mimic the function of the corpus luteum of pregnancy.

In recent years, existing treatment protocols have been optimized to such an extent that success rates of pregnancy and delivery with IVF programs have reached >30% per embryo transfer. Further improvements in pregnancy rates may be achieved by the introduction of new drugs, such as recombinant FSH or gonadotropin-releasing hormone (GnRH) antagonists that provide individualized hormonal treatment. In addition, the occurrence of multiple pregnancies, which is the main complication of IVF, may be limited by reducing the number of transferred embryos.

The oocyte undergoes typical changes associated with degeneration and autolysis, and the remnants are phagocytosed by invading macrophages. The zona pellucida which is resistant to the autolytic changes occurring in the cells associated with it, becomes folded and collapses as it is slowly broken down within the cavity of the follicle. Macrophages in the connective tissue are involved in the phagocytosis of the zona pellucida and the remnants of the degenerating cells. The basement membrane between the follicle cells from the theca interna may separate from the follicle cells and increase in thickness, forming a wavy hyaline layer called the **glassy membrane**. This structure is characteristic of follicles in the late stages of atresia.

Enlargement of the cells of the theca interna occurs in some atretic follicles. These cells are similar to theca lutein cells and become organized into radially arranged strands

separated by connective tissue. A rich capillary network develops in the connective tissue. These atretic follicles, which resemble an old corpus luteum, are called **corpora lutea atretica**.

The interstitial gland arises from the theca interna of the atretic follicle.

As **atretic follicles** continue to degenerate, a scar with hyaline streaks develops in the center of the cell mass, giving it the appearance of a small corpus albicans. This structure eventually disappears as the ovarian stroma invades the degenerating follicle. In the ovaries of a number of mammals, the strands of luteal cells do not degenerate immediately but become broken up and scattered in the stroma. These cords of cells contribute to the **interstitial gland** of the ovary and produce steroid hormones. The development of the interstitial gland is most extensive in animal species that have large litters.

In the human ovary, there are relatively few interstitial cells. They occur in the largest numbers in the first year of life and during the early phases of puberty, corresponding to times of increased follicular atresia. At menarche, involution of the interstitial cells occurs; therefore, few are present during the reproductive life span and menopause. It has been suggested that in humans, the interstitial cells are an important source of the estrogens that influence the growth and development of the secondary sex organs during the early phases of puberty. In other species, the interstitial cells have been shown to produce progesterone.

In humans, cells called **ovarian hilar cells** are found in the hilum of the ovary in association with vascular spaces and unmyelinated nerve fibers. These cells, which appear to be structurally related to the interstitial cells of the testis, contain **Reinke crystalloids**. The hilar cells appear to respond to hormonal changes during pregnancy and at the onset of menopause. Research suggests that the hilar cells secrete androgens; hyperplasia or tumors associated with these cells usually lead to masculinization.

Blood Supply and Lymphatics

Blood supply to the ovaries comes from two different sources: ovarian and uterine arteries.

The **ovarian arteries** are the branches of the abdominal aorta that pass to the ovaries through the suspensory ligaments and provide the principal arterial supply to the ovaries and uterine tubes. These arteries anastomose with the second blood source to the ovary, the **ovarian branches of the uterine arteries**, which arise from the internal iliac arteries. Relatively large vessels arising from this region of anastomosis pass through the mesovarium and enter the hilum of the ovary. These large arteries are called **spiral arteries** because they branch and become highly coiled as they pass into the ovarian medulla (see Fig. 23.2).

Veins accompany the arteries and form a plexus called the **pampiniform plexus** as they emerge from the hilum. The ovarian vein is formed from the plexus.

In the cortical region of the ovary, networks of lymphatic vessels in the thecal layers surround the large developing and atretic follicles and corpora lutea. The lymphatic vessels follow the course of the ovarian arteries as they ascend to para-aortic lymph nodes in the lumbar region.

Innervation

Ovaries are innervated by the autonomic ovarian plexus.

Autonomic nerve fibers that supply the ovary are conveyed mainly by the ovarian plexus. Although it is clear that the ovary receives both sympathetic and parasympathetic fibers, little is known about their actual distribution. Groups of parasympathetic ganglion cells are scattered in the medulla. Nerve fibers follow the arteries, supplying the smooth muscle in the walls of these vessels, as they pass into the medulla and cortex of the ovary. Nerve fibers associated with the follicles do not penetrate the basal lamina. Sensory nerve endings are scattered in the stroma. The sensory fibers convey impulses via the ovarian plexus and reach the dorsal root

ganglia of the first lumbar spinal nerves. Therefore, ovarian pain is referred over the cutaneous distribution of these spinal nerves.

At ovulation, about 45% of females experience **midcycle pain** (“mittelschmerz”). It is usually described as a sharp, lower abdominal pain that lasts from a few minutes to as long as 24 hours and may be accompanied by a small amount of bleeding from the uterus. It is believed that this pain is related to smooth muscle cell contraction in the ovary and its ligaments. These contractions are in response to an increased level of prostaglandin $F_{2\alpha}$ mediated by the surge of LH.

■ UTERINE TUBES

The **uterine tubes** are paired tubes that extend bilaterally from the uterus toward the ovaries (see Fig. 23.1). Also commonly referred to as the **fallopian tubes**, the uterine tubes transport the ovum from the ovary to the uterus and provide the necessary environment for fertilization and initial development of the zygote to the morula stage. One end of the tube is adjacent to the ovary and opens into the peritoneal cavity; the other end communicates with the uterine cavity.

Each **uterine tube** is approximately 10–12 cm long and can be divided into four segments by gross inspection:

- The **infundibulum** is the funnel-shaped segment of the tube adjacent to the ovary. At the distal end, it opens into the peritoneal cavity. The proximal end communicates with the ampulla. Fringed extensions, or **fimbriae**, extend from the mouth of the infundibulum toward the ovary.
- The **ampulla** is the longest segment of the tube, constituting about two-thirds of the total length, and is the site of fertilization.
- The **isthmus** is the narrow, medial segment of the uterine tube adjacent to the uterus.
- The **uterine** or **intramural** part, measuring about 1 cm in length, lies within the uterine wall and opens into the cavity of the uterus.

The wall of the uterine tube is composed of three layers.

The **uterine tube** wall resembles the wall of other hollow viscera, consisting of an external serosal layer, an intermediate muscular layer, and an internal mucosal layer. However, there is no submucosa.

- The **serosa** or peritoneum is the outermost layer of the uterine tube and is composed of mesothelium and a thin layer of connective tissue.
- The **muscularis**, throughout most of its length, is organized into an inner, relatively thick circular layer and an outer, thinner longitudinal layer. The boundary between these layers is often indistinct.
- The **mucosa**, the inner lining of the uterine tube, exhibits relatively thin longitudinal folds that project into the lumen of the uterine tube throughout its length. The folds are most numerous and complex in the ampulla (Fig. 23.15 and Plate 23.4, page 962) and become smaller in the isthmus.

FIGURE 23.15. Photomicrograph of a human uterine tube. **a.** This cross section is near the ampulla region of the uterine tube. The mucosa is thrown into extensive folds that project into the lumen of the tube. The muscularis is composed of a thick inner layer of circularly arranged fibers and an outer layer of longitudinal fibers. Note several branches of the uterine and ovarian arteries (*BV*) that travel along the uterine tube. $\times 16$. **b.** The lumen of the tube is lined by a simple columnar epithelium composed of ciliated cells (above the point of the *arrowhead*) and nonciliated cells (below the point of the *arrowhead*). $\times 640$.

The **mucosal lining** is simple columnar epithelium composed of two kinds of cells—ciliated and nonciliated (Fig. 23.15b). They represent different functional states of a single cell type.

- **Ciliated cells** are most numerous in the infundibulum and ampulla. The wave of the cilia is directed toward the uterus.
- **Nonciliated, peg cells** are secretory cells that produce the fluid that provides nutritive material for the ovum.

The epithelial cells undergo cyclic hypertrophy during the follicular phase and atrophy during the luteal phase in response to changes in hormonal levels, particularly estrogens. Also, the ratio of ciliated to nonciliated cells changes during the hormonal cycle. Estrogen stimulates ciliogenesis, and progesterone increases the number of secretory cells. At about the time of ovulation, the epithelium reaches a height of approximately 30 μm and is then reduced to about one-half that height just before the onset of menstruation.

Bidirectional transport occurs in the uterine tube.

The **uterine tube** demonstrates active movements just before ovulation as the fimbriae become closely apposed to the ovary and localize over the region of the ovarian surface where rupture will occur. As the oocyte is released, the ciliated cells in the infundibulum sweep it toward the opening of the uterine tube and thus prevent it from entering the peritoneal cavity. The oocyte is transported along the uterine tube by peristaltic contractions. The mechanisms by which spermatozoa and the oocyte are transported from opposite ends of the

uterine tube are not fully understood. Research suggests that both **ciliary movements** and **peristaltic muscular activity** are involved in the movements of the oocyte. The movement of the spermatozoa is much too rapid, however, to be accounted for by intrinsic motility. **Fertilization usually occurs in the ampulla**, near its junction with the isthmus. The ovum remains in the uterine tube for about 3 days before it enters the uterine cavity. **Several conditions that may alter the integrity of the tubal transport system (e.g., inflammation, use of intrauterine devices, surgical manipulation, tubal ligation) may cause a tubal ectopic pregnancy. Most ectopic pregnancies (98%) occur in the uterine tube (tubal pregnancies). An ectopic pregnancy that occurs in the uterine tube can cause life-threatening bleeding if the tube ruptures. Prompt treatment with surgery to remove the tube or medication to stop the growth of the fertilized ovum is needed.**

■ UTERUS

The uterus receives the rapidly developing morula from the uterine tube. All subsequent embryonic and fetal development occurs within the uterus, which undergoes dramatic increases in size and development. The human uterus is a hollow, pear-shaped organ located in the pelvis between the bladder and the rectum. In a nulliparous female, it weighs 30–40 g and measures 7.5 cm in length, 5 cm in width at its superior aspect, and 2.5 cm in thickness. Its lumen, which is also flattened, is continuous with the uterine tubes and the vagina.

Anatomically, the **uterus** is divided into two regions:

- The **body** is the large upper portion of the uterus. The anterior surface is almost flat; the posterior surface is convex. The upper, rounded part of the body that expands above the attachment of the uterine tubes is called the **fundus**.
- The **cervix** is the lower, barrel-shaped part of the uterus separated from the body by the **isthmus** (see Fig. 23.1). The lumen of the cervix, the **cervical canal**, has a constricted

opening at each end. The **internal os** communicates with the cavity of the uterus; the **external os** with the vagina.

Organization of the Uterine Wall

The uterine wall is composed of three layers (Fig. 23.16). From the lumen outward, they are as follows:

FIGURE 23.16. Photomicrograph of a sagittal section of a human uterus. This section shows the three layers of the uterine wall: the endometrium, the innermost layer that lines the uterine cavity; the myometrium, the middle layer of smooth muscle; and the perimetrium, the very thin layer of peritoneum that covers the exterior surface of the uterus. The deep portion of the myometrium contains the larger blood vessels (*BV*) that supply the uterus. $\times 8$.

- The **endometrium** is the mucosa of the uterus.
- The **myometrium** is the thick muscular layer. It is continuous with the muscle layer of the uterine tube and vagina. The smooth muscle fibers also extend into the ligaments connected to the uterus.
- The **perimetrium**, the outer serous layer or visceral peritoneal covering of the uterus, is continuous with the pelvic and abdominal peritoneum and consists of a mesothelium and a thin layer of loose connective tissue. Beneath the mesothelium, a layer of elastic tissue is usually prominent. The perimetrium covers the entire posterior surface of the uterus but only part of the anterior surface. The remaining part of the anterior surface consists of connective tissue or adventitia.

Both myometrium and endometrium undergo cyclic changes each month to prepare the uterus for implantation of an embryo. These changes constitute the menstrual cycle. If an embryo implants, the cycle stops, and both layers undergo considerable growth and differentiation during pregnancy (described in the next section).

The myometrium forms a structural and functional syncytium.

The **myometrium** is the thickest layer of the uterine wall. It is composed of three indistinctly defined layers of smooth muscle:

- The middle muscle layer contains numerous large blood vessels (venous plexuses) and lymphatics and is called the **stratum vasculare**. It is the thickest layer and has interlaced smooth muscle bundles oriented in a circular or spiral pattern.
- The smooth muscle bundles in the **inner and outer layers** are predominantly oriented parallel to the long axis of the

uterus.

As in most bulb-shaped hollow organs, such as the gallbladder and urinary bladder, muscular orientation is not distinctive. The muscle bundles seen in routine histologic sections appear to be randomly arrayed. During uterine contraction, all three layers of the myometrium work together as a functional syncytium expelling the contents of the lumen through a narrow orifice.

In the nonpregnant uterus, the smooth muscle cells are about 50 μm long. During pregnancy, the uterus undergoes enormous enlargement. The growth is primarily owing to the hypertrophy of existing smooth muscle cells, which may reach more than 500 μm in length, and secondarily attributable to the development of new fibers through the division of existing muscle cells and the differentiation of undifferentiated mesenchymal cells. The amount of connective tissue also increases. As pregnancy proceeds, the uterine wall becomes progressively thinner as it stretches because of the growth of the fetus. After parturition, although some muscle fibers degenerate, the uterus returns to almost its original size. The collagen produced during pregnancy to strengthen the myometrium is then enzymatically degraded by the cells that secreted it. The uterine cavity remains larger and the muscular wall remains thicker than before pregnancy.

Compared with the body of the uterus, the cervix has more connective tissue and less smooth muscle. Elastic fibers are abundant in the cervix but are found in appreciable quantities only in the outer layer of the myometrium of the body of the uterus.

The endometrium proliferates and then degenerates during a menstrual cycle.

Throughout the reproductive life span, the endometrium undergoes cyclic changes each month that prepare it for the implantation of the embryo and the subsequent events of embryonic and fetal development. Changes in the secretory activity of the endometrium during the cycle are correlated with the maturation of the ovarian follicles (see Folder 23.3).

The end of each cycle is characterized by the partial destruction and sloughing of the endometrium, accompanied by bleeding from the mucosal vessels. The discharge of tissue and blood from the vagina, which usually continues for 3–5 days, is referred to as **menstruation** or **menstrual flow**. The **menstrual cycle** is defined as beginning on the day when menstrual flow begins.

FOLDER 23.3

FUNCTIONAL CONSIDERATIONS: SUMMARY OF HORMONAL REGULATION OF THE OVARIAN CYCLE

During each **menstrual cycle**, the ovary undergoes cyclic changes that involve two phases:

- Follicular phase
- Luteal phase

Ovulation occurs between the two phases (Fig. F23.3.1).

FIGURE F23.3.1. Relationship of morphologic and physiologic events that occur in the menstrual cycle. This diagram illustrates the relationship of the morphologic changes in the endometrium and ovary to the pituitary and ovarian blood hormone levels that occur during the menstrual cycle. The pituitary and ovarian hormones and their plasma concentrations are indicated in arbitrary units. *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

The **follicular phase** begins with the development of a small number of primary follicles (10-20) under the influence of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Selection of dominant follicles occurs by days 5-7 of the menstrual cycle. During the first 8-10 days of the cycle, FSH is the principal hormone influencing the growth of the follicles. It stimulates the granulosa and thecal cells, which begin to secrete steroid hormones, principally estrogens, into the follicular lumen. As estrogen production from the dominant follicle increases, FSH production is inhibited by a negative feedback loop from the pituitary gland. Estrogens continue to accumulate in the follicular lumen, finally reaching a level that allows the follicle to be independent of FSH for its continued growth and development.

Late in the follicular phase, before ovulation, progesterone levels begin to increase under the influence of LH. The amount of estrogens in the circulating blood inhibits further production of FSH by the adenohypophysis. Ovulation is induced by a surge in the LH level, which occurs concomitantly with a smaller increase in the FSH level. It occurs ~34-36 hours after the start of the LH surge or about 10-12 hours after the peak of the LH surge.

The **luteal phase** begins immediately after ovulation as the granulosa and thecal cells of the ruptured follicle undergo rapid morphologic transformation to form the corpus luteum. Estrogens and large amounts of progesterone are secreted by the corpus luteum. Under the influence of both hormones, but primarily progesterone, the endometrium begins its secretory phase, which is essential for the preparation of the uterus for implantation in the event that the egg is fertilized. LH appears to be responsible for the development and maintenance of the corpus luteum during the menstrual cycle. If fertilization does not occur, the corpus luteum degenerates within a few days as hormone levels drop. If fertilization does occur, the corpus luteum is maintained and continues to secrete progesterone and estrogens. Human chorionic gonadotropin (hCG), which is initially produced by the embryo and later by the placenta, stimulates the corpus luteum and is responsible for its maintenance during pregnancy.

During reproductive life, the endometrium consists of two layers or zones that differ in structure and function (Fig. 23.17 and Plate 23.5, page 964):

FIGURE 23.17. Schematic diagram illustrating arterial blood supply to the endometrium of the uterus. The two layers of the endometrium, the stratum basale and stratum functionale, are supplied by branches of the uterine artery. The spiral arteries located at the interface between these two layers degenerate and regenerate during the menstrual cycle under the influence of estrogens and progesterone. (Based on Weiss L, ed. *Cell and Tissue Biology: A Textbook of Histology*. 6th ed. Urban & Schwarzenberg; 1988.)

- The **stratum functionale** or **functional layer** is the thick part of the endometrium, which is sloughed off at menstruation.
- The **stratum basale** or **basal layer** is retained during menstruation and serves as the source for the regeneration of the stratum functionale.

The stratum functionale is the layer that proliferates and degenerates during the menstrual cycle.

During the **phases of the menstrual cycle**, the endometrium varies from 1 to 6 mm in thickness. It is lined by a simple columnar epithelium with a mixture of secretory and ciliated cells. The surface epithelium invaginates into the underlying lamina propria, the **endometrial stroma**, forming the uterine glands. These simple tubular glands, containing fewer ciliated cells, occasionally branch into the deeper aspect of the endometrium. The endometrial stroma, which resembles mesenchyme, is highly cellular and contains abundant intercellular ground substance. As in the uterine tube, no submucosa separates the endometrium from the myometrium.

The vasculature of the endometrium also proliferates and degenerates during each menstrual cycle.

The endometrium contains a unique system of blood vessels (see Fig. 23.17). The uterine artery gives off 6-10 arcuate arteries that anastomose in the myometrium. Branches from these arteries, the **radial arteries**, enter the basal layer of the endometrium where they give off small straight arteries that supply this region of the endometrium. The main branch of the radial artery continues upward and becomes highly coiled; it is, therefore, called the **spiral artery**. Spiral arteries give

off numerous arterioles that often anastomose as they supply a rich capillary bed. The capillary bed includes thin-walled dilated segments called **lacunae**. Lacunae may also occur in the venous system that drains the endometrium. The straight arteries and the proximal part of the spiral arteries do not change during the menstrual cycle. The distal portion of the spiral arteries, under the influence of estrogens and progesterone, undergoes degeneration and regeneration with each menstrual cycle.

Cyclic Changes During the Menstrual Cycle

Cyclic changes of the endometrium during the menstrual cycle are represented by the proliferative, secretory, and menstrual phases.

The **menstrual cycle** is a continuum of developmental stages in the functional layer of the endometrium. It is ultimately controlled by gonadotropins secreted by the pars distalis of the pituitary gland that regulate the steroid secretions of the ovary. The cycle normally repeats every 28 days, during which the endometrium passes through a sequence of morphologic and functional changes. It is convenient to describe the cycle as having three successive phases:

- The **proliferative phase** occurs concurrently with follicular maturation and is influenced by ovarian estrogen secretion.
- The **secretory phase** coincides with the functional activity of the corpus luteum and is primarily influenced by progesterone secretion.
- The **menstrual phase** commences as hormone production by the ovary declines with the degeneration of the corpus luteum (see Folder 23.3).

The phases are part of a continuous process; there is no abrupt change from one to the next.

The proliferative phase of the menstrual cycle is regulated by estrogens.

At the end of the menstrual phase, the endometrium consists of a thin band of connective tissue, about 1 mm thick, containing the basal portions of the uterine glands and the lower portions of the spiral arteries (see Fig. 23.17). This layer is the stratum basale; the layer that was sloughed off was the stratum functionale. Under the influence of estrogens, the proliferative phase is initiated. Stromal, endothelial, and epithelial cells in the stratum basale proliferate rapidly, and the following changes can be seen:

- Epithelial cells in the basal portion of the glands reconstitute the glands and migrate to cover the denuded endometrial surface.
- Stromal cells proliferate and secrete collagen and ground substance.
- Spiral arteries lengthen as the endometrium is reestablished; these arteries are only slightly coiled and do not extend into the upper third of the endometrium.

The proliferative phase continues until 1 day after ovulation, which occurs on day 14 of a 28-day cycle. At the end of this phase, the endometrium has reached a thickness of about 3 mm. The glands have narrow lumina and are relatively straight but have a slightly wavy appearance (Fig. 23.18a). Accumulations of glycogen are present in the basal portions of the epithelial cells. In routine histologic preparations, extraction of the glycogen gives an empty appearance to the basal cytoplasm.

FIGURE 23.18. Photomicrographs of the uterine lining in proliferative, secretory, and menstrual phases of the menstrual cycle. *a.* The *upper panel* shows the endometrium at the proliferative phase of the cycle. During this phase, the stratum functionale (separated by the *dashed line* from the stratum basale) greatly thickens. $\times 15$. The *lower panel* shows at higher magnification the endometrial glands that extend from the stratum basale to the surface. $\times 55$. *b.* The *upper panel* shows the endometrium at the secretory phase of the cycle. The glands have acquired a corkscrew shape as the endometrium increases further in thickness. The stratum basale (below the *dashed line*) exhibits less dramatic changes in morphology. $\times 20$. The *lower panel* shows uterine glands that have been cut in a plane that is close to their long axes. Note the pronounced corkscrew shape of the glands and mucus secretion (*arrows*). $\times 60$. *c.* The *upper panel* shows the stratum functionale (above the *dashed line*). Much of the

stratum functionale has degenerated and sloughed away. $\times 15$. The *lower panel* shows the extravasated blood and necrosis of the stratum functionale. $\times 55$.

The secretory phase of the menstrual cycle is regulated by progesterone.

Under the **influence of progesterone**, dramatic changes occur in the stratum functionale, beginning a day or 2 after ovulation. The endometrium becomes edematous and may eventually reach a thickness of 5-6 mm. The glands enlarge and become corkscrew shaped, and their lumina become sacculated as they fill with secretory products (Fig. 23.18b). The mucoid fluid produced by the gland epithelium is rich in nutrients, particularly glycogen, required to support development if implantation occurs. Mitoses are now rare. The growth seen at this stage results from hypertrophy of the epithelial cells, an increase in vascularity, and edema of the endometrium. The spiral arteries, however, lengthen and become more coiled. They extend nearly to the surface of the endometrium (Plate 23.6, page 966).

The sequential influence of estrogens and progesterone on the **stromal cells** enables their transformation into **decidual cells**. The stimulus for transformation is the implantation of the blastocyst. Large, pale cells rich in glycogen result from this transformation. Although the precise function of these cells is not known, it is clear that they provide a favorable environment for the nourishment of the embryo and that they create a specialized layer that facilitates the separation of the placenta from the uterine wall following parturition.

The menstrual phase results from a decline in the ovarian secretion of progesterone and estrogen.

The **corpus luteum** actively produces hormones for about 10 days if fertilization does not occur. As hormone levels rapidly decline, changes occur in the blood supply to the stratum functionale. Initially, periodic contractions of the walls of the spiral arteries, lasting for several hours, cause the **stratum functionale** to become **ischemic**. The glands stop

secreting, and the endometrium shrinks in height as the stroma becomes less edematous. After about 2 days, extended periods of arterial contraction, with only brief periods of blood flow, cause disruption of the surface epithelium and rupture of the blood vessels. When the spiral arteries close off, blood flows into the stratum basale, but not into the stratum functionale. Blood, uterine fluid, and stromal and epithelial cells from the stratum functionale constitute the menstrual discharge. As patches of tissue separate from the endometrium, the torn ends of veins, arteries, and glands are exposed (Fig. 23.18c). The desquamation continues until only the stratum basale remains. Clotting of blood is inhibited during this period of menstrual flow. Arterial blood flow is restricted, except for the brief periods of relaxation of the walls of the spiral arteries. Blood continually seeps from the open ends of the veins. The period of **menstrual flow** normally lasts about 5 days. The average blood loss in the menstrual phase is 35–50 mL. Blood flow through the straight arteries maintains the stratum basale.

As noted, this process is cyclic. Figure F23.3.1 in Folder 23.3 shows a single cycle of the endometrium. In the absence of fertilization, cessation of bleeding accompanies the growth and maturation of new ovarian follicles. The epithelial cells rapidly proliferate and migrate to restore the surface epithelium as the proliferative phase of the next cycle begins.

In the absence of ovulation (a cycle referred to as an **anovulatory cycle**), a corpus luteum does not form, and progesterone is not produced. In the absence of progesterone, the endometrium does not enter the secretory phase and continues in the proliferative phase until menstruation. **In cases of infertility, biopsies of the endometrium can be used to diagnose anovulatory cycles as well as other disorders of the ovary and endometrium.**

Implantation

If fertilization and implantation occur, a gravid phase replaces the menstrual phase of the cycle.

If fertilization and subsequent **implantation** occur, decline of the endometrium is delayed until after parturition. As the blastocyst becomes embedded in the uterine mucosa in the early part of the second week, cells in the chorion of the developing placenta begin to secrete **hCG** and other luteotropins. These hormones maintain the corpus luteum and stimulate it to continue the production of progesterone and estrogens. Thus, the decline of the endometrium is prevented, and the endometrium undergoes further development during the first few weeks of pregnancy.

Implantation is the process by which the blastocyst settles into the endometrium.

The **fertilized human ovum (zygote)** undergoes a series of changes as it passes through the uterine tube into the uterine cavity in preparation for becoming embedded in the uterine mucosa. The developing embryo initiates an embryo-maternal dialogue, which is critical for further implantation and development. Shortly after fertilization, the viable embryo secretes **preimplantation factor (PIF)**, an embryo-specific 15-amino-acid peptide (MVR IKPGSANKPSDD) that promotes adhesion of the embryo to the endometrium. At the time of implantation, PIF stimulates proliferation and invasion of the trophoblast into the decidua basalis (see page 931).

The zygote undergoes cleavage, followed by a series of mitotic divisions without cell growth, resulting in a rapid increase in the number of cells in the embryo. Initially, the embryo is under the control of maternal informational macromolecules that have accumulated in the cytoplasm of the ovum during oogenesis. Later development depends on activation of the embryonic genome, which encodes various growth factors, cell junction components, and other macromolecules required for normal progression to the blastocyst stage. The cell mass resulting from the series of mitotic divisions is known as a **morula** [*L. morum, mulberry*], and the individual cells are known as **blastomeres**. During the third day after fertilization, the morula, which now contains 12-16 cells is still surrounded by the zona pellucida enters the uterine cavity. The morula

remains free in the uterus for about a day while continued cell division and development occur. The early embryo gives rise to a blastocyst, a hollow sphere of cells with a centrally located clump of cells. This **inner cell mass** will give rise to the tissues of the embryo proper; the surrounding layer of cells, the **outer cell mass**, will form the trophoblast and then the placenta (Fig. 23.19).

FIGURE 23.19. Schematic diagrams of sectioned blastocysts. a. A human blastocyst at about 4.5 days of development showing the formation of the inner cell mass. b. A monkey blastocyst at about 9 days of development. The trophoblastic cells of the monkey blastocyst have begun to invade the epithelial cells of the endometrium. In humans, the blastocyst begins to invade the endometrium at about the fifth or sixth day of development. c. A human blastocyst at 14 days after implantation. At this stage, the trophoblast cells have differentiated into syncytiotrophoblasts and cytotrophoblasts.

Fluid passes inward through the zona pellucida during this process, forming a fluid-filled cavity, the **blastocyst cavity**. This event defines the beginning of the **blastocyst**. As the blastocyst remains free in the uterine lumen for 1 or 2 days and undergoes further mitotic divisions, the zona pellucida disappears. The outer cell mass is now called the **trophoblast**, and the inner cell mass is referred to as the **embryoblast**.

Implantation occurs during a short period known as the **implantation window**.

The attachment of the blastocyst to the endometrial epithelium occurs during the **implantation window**, the period when the uterus is receptive for implantation of the blastocyst. This short period results from a series of programmed actions of progesterone and estrogens on the endometrium. **Antiprogesterone drugs** such as mifepristone (RU-486) and its derivatives compete for the receptors in the endometrial epithelium, thus blocking hormone binding. The failure of progesterone to gain access to its receptors prevents implantation, thus effectively closing the window. In human, the implantation window begins on day 6 after the LH surge and is completed by day 10.

As contact is made with the uterine wall by the **trophoblastic cells** over the embryoblast pole, the trophoblast rapidly proliferates and begins to invade the endometrium. The invading **trophoblast** differentiates into the syncytiotrophoblast and the cytotrophoblast.

- The **cytotrophoblast** is a mitotically active inner cell layer producing cells that fuse with the syncytiotrophoblast, the outer erosive layer. The fusion of the cytotrophoblast with the overlying multinucleated syncytiotrophoblast may be triggered by programmed cell death (apoptosis).
- The **syncytiotrophoblast** is not mitotically active and consists of a multinucleate cytoplasmic mass; it actively invades the epithelium and underlying stroma of the endometrium.

Through the activity of the trophoblast, the blastocyst is entirely embedded within the endometrium on about the 11th day of development. (Further development of the syncytiotrophoblast and cytotrophoblast is described in the section on the placenta.)

The syncytiotrophoblast has well-developed Golgi complexes, abundant sER and rER, numerous mitochondria, and relatively large numbers of lipid droplets. These features are consistent with the secretion of progesterone, estrogens, hCG, and lactogens by this layer. Recent evidence indicates that cytotrophoblast cells may also be a source of steroid hormones and hCG.

After implantation, the endometrium undergoes decidualization.

During pregnancy, the portion of the **endometrium** that undergoes morphologic changes is called the **decidua** or **decidua graviditatis**. As its name implies, this layer is shed with the placenta at parturition. The decidua includes all but the deepest layer of the endometrium. During the **decidualization process**, which typically takes at least 8–10 days, the stromal cells differentiate into large, rounded **decidual cells** in response to the elevated progesterone levels (see page 935). The uterine glands enlarge and become more coiled during the early part of pregnancy and then become thin and flattened as the growing fetus fills the uterine lumen.

Three different regions of the decidua are identified by their relationship to the site of implantation (Fig. 23.20):

FIGURE 23.20. Development of the placenta. This schematic drawing shows growth of the uterus during human pregnancy and development of the placenta and its membranes. Note that there is a gradual obliteration of the uterine lumen and disappearance of the decidua capsularis as the definitive placenta is established. (Modified from Williams J. Placenta circumvallata. *Am J Obstet Gynecol.* 1927;13:1–16.)

- The **decidua basalis** is the portion of the endometrium that underlies the implantation site.

- The **decidua capsularis** is a thin portion of endometrium that lies between the implantation site and the uterine lumen.
- The **decidua parietalis** includes the remaining endometrium of the uterus.

By the end of the third month of gestation, the fetus grows to the point that the overlying decidua capsularis fuses with the decidua parietalis of the opposite wall, thereby obliterating the uterine cavity.

By the 13th day of development, an extraembryonic space, the **chorionic cavity**, has been established (Fig. 23.19c). The cell layers that form the outer boundary of this cavity (i.e., the syncytiotrophoblast, cytotrophoblast, and extraembryonic somatic mesoderm) are collectively referred to as the **chorion**. The innermost membranes enveloping the embryo are called the **amnion** (see Fig. 23.20).

Cervix

The endometrium of the cervix differs from the rest of the uterus.

The **cervical mucosa** measures about 2–3 mm in thickness and differs dramatically from the rest of the uterine endometrium in that it contains large, branched glands (Fig. 23.21 and Plate 23.7, page 968). It also lacks spiral arteries. The cervical mucosa undergoes little change in thickness during the menstrual cycle and is not sloughed during the period of menstruation. During each menstrual cycle, however, the **cervical glands** undergo important functional changes that are related to the transport of spermatozoa within the cervical canal. The amount and properties of the mucus secreted by the gland cells vary during the menstrual cycle under the influence of ovarian hormones. At midcycle, the amount of mucus produced increases 10-fold. This mucus is less viscous and appears to provide a more favorable environment for sperm migration. The cervical mucus at other times in the cycle restricts the passage of sperm into the uterus. Thus, hormonal mechanisms ensure that ovulation and changes in the cervical mucus are

coordinated, thereby increasing the possibility that fertilization will occur if spermatozoa and the ovum arrive simultaneously at the site of fertilization in the uterine tube.

FIGURE 23.21. Photomicrograph of a human cervix. This hematoxylin and eosin (H&E)-stained specimen is from a postmenopausal female. Its lower portion projects into the upper vagina where an opening, the external os, leads to the uterus through the cervical canal. The surface of the cervix is covered by stratified squamous epithelium (*SSE*) that is continuous with the epithelial lining of the vagina. An abrupt transition from stratified squamous epithelium to simple columnar epithelium (*SCE*) occurs at the entry to the cervical canal. In this specimen, the stratified epithelium has extended into the canal, an event that occurs with aging. Mucus-secreting cervical glands are seen along the cervical canal. These are simple branched tubular glands that arise as invaginations of the epithelium lining the canal. Frequently, the glands develop into nabothian cysts as a result of retention of mucus secretion by blockage of the gland opening. The material marked by the *X* is mucus secreted from the cervical glands. $\times 10$.

Blockage of the openings of the mucosal glands results in the retention of their secretions, leading to the formation of dilated cysts within the cervix called nabothian cysts. Nabothian cysts develop frequently but are clinically important only if numerous cysts produce marked enlargement of the cervix.

The transformation zone is the site of transition between vaginal stratified squamous epithelium and cervical simple columnar epithelium.

The portion of the cervix that projects into the vagina, the vaginal part or ectocervix, is covered with a stratified squamous epithelium (Fig. 23.22). An abrupt transition between this squamous epithelium and the mucus-secreting columnar epithelium of the cervical canal, the endocervix, occurs in the transformation zone that during reproductive age is located just outside the external os (Plate 23.7, page 968). Before puberty and after menopause, the transformation zone resides in the cervical canal (Fig. 23.23). Metaplastic changes in this transformation zone constitute precancerous lesions of the cervix. Metaplasia [*Gr. change in form*] represents an adoptive and reversible response to persistent injury of the epithelium caused by chronic infection. It results from a reprogramming of epithelial stem cells that begin to differentiate into new cell lineage. Within the cervical canal (endocervix), it is

manifested as a replacement of the simple columnar epithelium with fully mature stratified squamous epithelium (Fig. 23.24). The cervical epithelial cells are constantly exfoliated into the vagina. Samples of the cervical cells may be stained and examined for morphologic changes (Papanicolaou [Pap] test) or tested for the presence of high-risk strains of human papillomavirus (HPV), the leading cause of cervical cancer. These tests are used routinely to screen for precancerous and cancerous lesions of the cervix.

FIGURE 23.22. Stratified squamous epithelium of the ectocervix. The stratified squamous epithelium and underlying fibrous connective tissue within the *lower rectangle* in Figure 23.21 are shown here at

higher magnification. The more mature epithelial cells have a clear cytoplasm (*arrowheads*), a reflection of their high glycogen content. Also, note the connective tissue papillae protruding into the epithelium (*arrows*). The bulk of the cervix is made up of dense, fibrous connective tissue with relatively little smooth muscle. $\times 120$.

FIGURE 23.23. Transformation zone of the cervix. The site of the squamocolumnar junction from the *upper rectangle* in Figure 23.21 is shown here at higher magnification. Note the abrupt change from stratified squamous epithelium to simple columnar epithelium (*arrow*). Neoplastic changes leading to the development of cervical cancer most frequently begin in this transformation zone. Within the connective tissue are the branched, mucus-secreting cervical glands (*CG*) composed

of a simple columnar epithelium that is continuous with the lining epithelium of the cervical canal. $\times 120$.

FIGURE 23.24. Metaplastic stratified squamous epithelium of the cervical canal. This photomicrograph shows an island of the fully mature stratified squamous epithelium surrounded by the simple columnar epithelium normally found in the cervical canal. $\times 450$. ■ PLACENTA

The developing fetus is maintained by the placenta, which develops from fetal and maternal tissues.

The placenta consists of a fetal portion, formed by the chorion, and a maternal portion, formed by the decidua basalis. The two parts are involved in physiologic exchange of substances between the maternal and fetal circulations.

The **uteroplacental circulatory system** begins to develop around day 9 after fertilization, with the development of

vascular spaces called **trophoblastic lacunae** within the syncytiotrophoblast. Maternal sinusoids, which develop from capillaries of the maternal side, anastomose with the trophoblastic lacunae (Fig. 23.25). The differential pressure between the arterial and venous channels that communicate with the lacunae establishes directional flow from the arteries into the veins, thereby establishing a primitive uteroplacental circulation. Numerous pinocytotic vesicles present in the syncytiotrophoblast indicate the transfer of nutrients from the maternal vessels to the embryo. Numerous pinocytotic vesicles present in the syncytiotrophoblast indicate the transfer of nutrients from the maternal vessels to the embryo.

FIGURE 23.25. Schematic diagrams of sections through a developing human embryo. **a.** This drawing shows the chorionic sac and placenta at 16 days of development. **b.** The same embryo at 21 days of development. The diagrams illustrate the separation of the fetal and maternal blood vessels by the placental membrane, which is composed of the endothelium of the capillaries, mesenchyme, cytotrophoblast, and syncytiotrophoblast.

Proliferation of the **cytotrophoblast**, growth of **chorionic mesoderm**, and blood vessel development successively give rise to the chorionic villi (Fig. 23.26). They undergo the following changes:

FIGURE 23.26. Schematic diagram of chorionic villi in various stages of development. This drawing shows the developmental stages of chorionic villi. Primary villi represent the first stage of development in which the syncytiotrophoblast and cytotrophoblast form finger-like extensions into the maternal decidua. In secondary chorionic villi, the extraembryonic connective tissue (mesenchyme) grows into the villi and is surrounded by a layer of cytotrophoblast. In tertiary chorionic villi, blood vessels and supportive cells differentiate within the mesenchymal core. In early pregnancy, villi are large and edematous with few blood vessels surrounded by many cells of connective tissue. They are covered by a thick layer of syncytiotrophoblast and a continuous layer of cytotrophoblast cells. In late pregnancy, the layer of cytotrophoblast appears to be discontinuous, and nuclei of the syncytiotrophoblast aggregate to form irregularly dispersed projections called *syncytial knots*. More fetal blood vessels are found in the connective tissue core, which becomes less cellular and contains fewer placental macrophages.

- **Primary chorionic villi** are formed by the rapidly proliferating cytotrophoblast. They send cords or masses of cells into the blood-filled trophoblastic lacunae within the syncytiotrophoblast (see Figs. 23.19b and 23.27). The primary villi appear between days 11 and 13 of development.

FIGURE 23.27. Photomicrographs of a human placenta. **a.** This hematoxylin and eosin (H&E)-stained specimen shows the amniotic surface (*A*), the chorionic plate (*CP*), and, below, the various-sized profiles of the chorionic villi (*CV*). These villi emerge from the chorionic plate as large stem villi and branch into increasingly smaller villi. Blood vessels (*BV*) are evident in the larger villi. The smallest villi contain capillaries where exchange takes place. $\times 60$. **Upper inset.** This higher magnification shows the simple cuboidal epithelium of the amnion and the underlying connective tissue. $\times 200$. **Lower inset.** This higher magnification shows a cross-sectioned villus containing several larger blood vessels and its thin surface syncytiotrophoblast layer. $\times 200$. **b.** This H&E-stained specimen shows the maternal side of the placenta. The basal plate (*BP*), the part of the uterus to which some of the chorionic villi (*CV*) anchor, is seen at the *bottom* of the micrograph. Also evident is a stromal connective tissue (*CT*) component, part of the basal plate, to which many of the chorionic villi are also attached. Within the basal plate and the connective tissue stroma are clusters of cells, the decidual cells (*arrows*), which arose from connective tissue cells. $\times 60$. **Inset.** Decidual cells seen at higher magnification. $\times 200$.

- **Secondary chorionic villi** are composed of a central core of mesenchyme surrounded by an inner layer of cytotrophoblast and an outer layer of syncytiotrophoblast (see Fig. 23.26).

They develop at about day 16 when the primary chorionic villi become invaded by loose connective tissue from chorionic mesenchyme. The secondary villi cover the entire surface of the chorionic sac.

- **Tertiary chorionic villi** are formed by the end of the third week as the secondary villi become vascularized by blood vessels that have developed in their connective tissue cores (see Fig. 23.25b and Plate 23.9, page 972).

As the tertiary villi are forming, cytotrophoblastic cells in the villi continue to grow out through the syncytiotrophoblast. When they meet the maternal endometrium, they grow laterally and meet similar processes growing from neighboring villi. Thus, a thin layer of cytotrophoblastic cells called the **trophoblastic shell** is formed around the syncytiotrophoblast. The trophoblastic shell is interrupted only at sites where maternal vessels communicate with the intervillous spaces.

Chorionic villi continuously form out of the trophoblastic sprouts throughout pregnancy. The chorionic villi can remain either free (**floating villi**) in the intervillous space or grow into the maternal side of the placenta (basal plate) to form **main stem villi** or **anchoring villi**. Future growth of the placenta is accomplished by interstitial growth of the trophoblastic shell. During pregnancy, the villi mature and become smaller in diameter. The layer of cytotrophoblast appears to be discontinuous, and in some areas, nuclei of the syncytiotrophoblast are gathered in clusters to form irregularly dispersed **syncytial knots** (see Fig. 23.26 and Plate 23.9, page 972). **The number of syncytial knots increases with gestational age of the placenta and can be used to evaluate villous maturity. An increased number of syncytial knots is also associated with some pathologic conditions, such as uteroplacental malperfusion.**

Several types of cells are recognized in the connective tissue stroma of the villi: mesenchymal cells, reticular cells, fibroblasts, myofibroblasts, smooth muscle cells, and **fetal placental antigen-presenting cells (placental macrophages)**, historically also known as **Hofbauer cells** (Plate 23.9, page

972). Fetal placental antigen-presenting cells are the specific villous macrophages of fetal origin that participate in placental innate immune reactions. In response to an antigen, they proliferate and upregulate specific surface receptors that recognize and bind to a variety of pathogens. Like other antigen-presenting cells, if stimulated, they increase the number of major histocompatibility complex II (MHC II) molecules on their surface. They are more common in the early placenta. The vacuoles in these cells contain lipids, glycosaminoglycans, and glycoproteins. [Studies of HIV-infected placentas indicate that HIV is primarily localized within the fetal placental antigen-presenting cells and in the syncytiotrophoblast.](#)

Early in development, the blood vessels of the villi become connected with vessels from the embryo.

Blood begins to circulate through the embryonic cardiovascular system and the villi at about 21 days. The intervillous spaces provide the site for exchange of nutrients, metabolic products and intermediates, and wastes between the maternal and fetal circulatory systems.

During the first 8 weeks, villi cover the entire chorionic surface, but as growth continues, villi on the decidua capsularis begin to degenerate, producing a smooth, relatively avascular surface called the **chorion laeve**. The villi adjacent to the decidua basalis rapidly increase in size and number and become highly branched. This region of the chorion, which is the fetal component of the placenta, is called the **chorion frondosum** or **villous chorion**. The layer of the placenta from which the villi project is called the **chorionic plate** (Plate 23.8, page 970).

During the period of rapid growth of the chorion frondosum, at about the fourth to fifth month of gestation, the fetal part of the placenta is divided by the **placental (decidual) septa** into 15–25 areas called **cotyledons**. Wedge-like placental septa form the boundaries of the cotyledons, and because they do not fuse with the chorionic plate, maternal blood can circulate

easily between them. Cotyledons are visible as the bulging areas on the maternal side of the basal plate.

The **decidua basalis** forms a compact layer that is the maternal component of the placenta (see Fig. 23.27). The **basal plate**, the outer part of the placenta that is in contact with the uterine wall, consists of embryonic tissues (trophoblastic shell containing a thin layer of syncytiotrophoblast and cytotrophoblast) and maternal tissues (decidua basalis). Vessels within this part of the endometrium supply blood to the intervillous spaces. With rare exceptions, fetal blood and maternal blood do not mix.

Fetal and maternal blood are separated by the placental barrier.

Separation of the fetal and maternal blood, referred to as the **placental barrier**, is maintained primarily by the layers of fetal tissue (Fig. 23.28). Starting at the fourth month, these layers become very thin to facilitate the exchange of products across the placental barrier. The thinning of the wall of the villus is caused in part by surface and volume expansion of the villi as well as by the degeneration of the inner cytotrophoblast layer (see Fig. 23.27). However, although the cytotrophoblast layer indeed becomes much thinner, it does not become discontinuous.

FIGURE 23.28. Human placental barrier in the third trimester of pregnancy. This high-magnification electron micrograph shows the thinnest layer of a fully developed placental barrier (section does not include cytotrophoblast cells that form a thin [or discontinuous] layer in the human placenta). The lumen of intervillous space containing maternal erythrocytes (*ME*) (*to the left*) is separated from the fetal capillary space containing fetal erythrocytes (*FE*) (*to the right*). The intervillous space is lined by the multinucleated syncytiotrophoblast (*Syn*). Its surface contains microvilli projecting into maternal blood space. The cytoplasm of the syncytiotrophoblast contains multiple nuclei (*N*) and has an abundance of transport vesicles, rER, sER, mitochondria, and occasional lipid droplets. The syncytiotrophoblast rests on the basal lamina (*TBL*), which is separated by a thin layer of the connective tissue (*CT*) from the basal lamina (*EBL*) of the fetal endothelial cells (*FEn*). $\times 11,000$. *rER*, rough-surfaced endoplasmic reticulum; *sER*, smooth-surfaced endoplasmic reticulum. (Courtesy of Dr. Holger Jastrow.)

At its thinnest, the **placental barrier consists** of

- syncytiotrophoblast,
- thin (or discontinuous) inner cytotrophoblast layer,
- basal lamina of the trophoblast,
- connective (mesenchymal) tissue of the villus,
- basal lamina of the endothelium, and
- endothelium of the fetal placental capillary in the tertiary villus.

This barrier bears a strong resemblance to the air-blood barrier of the lung, with which it has an important parallel function, namely, the exchange of oxygen and carbon dioxide—in this case, between the maternal blood and the fetal blood. It also resembles the air-blood barrier by having a particular type of macrophage in its connective tissue—in this instance, the fetal placental antigen-presenting cells (Hofbauer cell).

The placenta is the site of exchange of gases and metabolites between the maternal and fetal circulation.

Fetal blood enters the placenta through a pair of **umbilical arteries** (Fig. 23.29). As they pass into the placenta, these arteries branch into several radially disposed vessels that give numerous branches in the chorionic plate. Branches from

these vessels pass into the villi, forming extensive capillary networks in close association with the intervillous spaces. Gases and metabolic products are exchanged across the thin fetal layers that separate the two bloodstreams at this level. Antibodies can also cross this layer and enter the fetal circulation to provide passive immunity against a variety of infectious agents—for example, those of diphtheria, smallpox, and measles. Fetal blood returns through a system of veins that parallel the arteries, except that they converge on a single umbilical vein.

FIGURE 23.29. Schematic diagram of mature human placenta. The sagittal section of the uterus (*above*) with the developing embryo shows the most common location of the placenta. The mature placenta (*below*) is divided into cotyledons by placental septa that are formed by outgrowths of the decidua basalis. Maternal blood enters the placenta through numerous endometrial spiral arteries that penetrate the basal plate. As the blood enters the cotyledon, it is directed deep into the intervillous spaces (*red arrows*). It then passes over the surface of the villi, where exchange of gases and metabolic products occurs. The maternal blood finally leaves the intervillous space (*blue arrows*) through endometrial veins. The fetal blood enters the placenta through the umbilical arteries that divide into a series of radially disposed arteries within the chorionic plate. Branches from the vessels pass into the main stem villi and there form extensive capillary networks. The veins within the villi then carry the blood back through a system of veins that parallels that of the fetal arteries.

Maternal blood is supplied to the placenta through 80–100 spiral endometrial arteries that penetrate the basal plate. Blood from these spiral arteries flows into the base of the intervillous spaces, which contain about 150 mL of maternal blood that is exchanged 3–4 times per minute. The blood pressure in the spiral arteries is much higher than that in the intervillous spaces. As blood is injected into these spaces at each pulse, it is directed deep into the spaces. As the pressure decreases, the blood flows back over the surfaces of the villi and eventually enters endometrial veins also located in the base of the spaces.

Exchange of gases and metabolic products occurs as the blood passes over the villi. Normally, water, carbon dioxide, metabolic waste products, and hormones are transferred from the fetal blood to the maternal blood; water, oxygen, metabolites, electrolytes, vitamins, hormones, and some antibodies pass in the opposite direction. The placental barrier does not exclude many potentially dangerous agents, such as alcohol, nicotine, viruses, drugs, exogenous hormones, and heavy metals. Therefore, during pregnancy, exposure to or ingestion of such agents should be avoided to reduce the risk of injury to the embryo or fetus.

Before the establishment of blood flow through the placenta, the growth of the embryo is supported in part by metabolic

products that are synthesized by or transported through the trophoblast. The syncytiotrophoblast synthesizes glycogen, cholesterol, and fatty acids as well as other nutrients used by the embryo.

FOLDER 23.4

CLINICAL CORRELATION: THE PLACENTA

The placenta is a temporary organ made by the body only during pregnancy. The mature **placenta** measures about 15–20 cm in diameter and 2–3 cm in thickness, covers 25%–30% of the uterine surface, and weighs 500–600 g at term. The surface area of the villi of human placenta is estimated to be about 10 m². The microvilli on the syncytiotrophoblast increase the effective area for metabolic exchange to >90 m². After childbirth, the uterus continues to contract, reducing the luminal surface and inducing placental separation from the uterine wall. The entire fetal portion of the placenta, fetal membranes, and the intervening projections of decidual tissue are released. During uncomplicated labor, the placenta separates from the uterine wall and is delivered ~30 minutes after birth.

One of the most severe complications of labor results from **abnormal placentation** (abnormal attachment of the placenta on uterine wall). If decidual tissue during implantation is disrupted, the placenta invades deep into the uterine wall. This may cause one of the three clinical conditions: placenta accreta, placenta increta, or placenta percreta. Classification depends on the severity and deepness of the placental attachment. **Placenta accreta**, accounting for ~75% of all cases, occurs when the placenta attaches too deeply into the uterine wall but does not penetrate the myometrium. **Placenta increta** (about 15% of all cases) occurs when the placental villi penetrate deep into the muscular layer of the myometrium. In the remaining 10% of all cases, **placenta percreta** penetrates through the entire uterine wall and attaches to another organ, such as the bladder, rectum, intestines, or large blood vessels. It is the most serious complication of placentation and may cause rupture of the uterus and other complications related to its attachment. A retained abnormal placenta or placental fragments may cause massive postpartum bleeding and need to be manually removed. Placenta increta and percreta may need to be treated by emergency hysterectomy.

After physiologic delivery of the placenta, the endometrial glands and stroma of the decidua basalis regenerate. Endometrial regeneration is completed by the end of the third week postpartum, except at the placental site, where regeneration usually extends

for another 3 weeks. During the first week after delivery, remnants of the decidua are shed and constitute the red-brown uterine discharge known as **lochia rubra**.

The placenta is a major endocrine organ producing steroid and protein hormones.

The **placenta** also functions as an **endocrine organ**, producing steroid and peptide hormones as well as prostaglandins that play an important role in the onset of labor. Immunocytochemical studies indicate that the **syncytiotrophoblast** is the site of synthesis of these hormones. Hormones produced by syncytiotrophoblast are secreted directly into the maternal blood surrounding the placental villi.

The **steroid hormones** progesterone and estrogen have essential roles in the maintenance of pregnancy. As pregnancy proceeds, the placenta takes over the major role in the secretion of these steroids from the corpus luteum. The placenta produces enough progesterone by the end of the eighth week to maintain pregnancy if the corpus luteum is surgically removed or fails to function. In the production of placental estrogen, the fetal adrenal cortex plays an essential role, providing the precursors needed for estrogen synthesis. Because the placenta lacks the enzymes needed for the production of estrogen precursors, a cooperative **fetoplacental (endocrine) unit** is established. Clinically, monitoring of estrogen production during pregnancy can be used as an index of fetal development in certain situations.

The following **peptide hormones** are secreted by the placenta:

- **Human chorionic gonadotropin (hCG)** is required for implantation and maintenance of the pregnancy. Its synthesis begins around day 6 after fertilization, even before the syncytiotrophoblast is formed. hCG exhibits extensive (about 85%) sequence homology to LH, which is required for ovulation and maintenance of the corpus luteum during the menstrual cycle. Similar to the function of LH during the menstrual cycle, hCG maintains the corpus luteum during early pregnancy. hCG also possesses marked homology to thyroid-

stimulating hormone (TSH), which may account for hyperthyroidism in pregnancy by stimulating the maternal thyroid gland to increase the secretion of tetraiodothyronine (T_4). Measurement of hCG is used to detect early pregnancy and assess pregnancy viability. Two other clinical conditions that increase the blood levels of hCG include trophoblastic diseases and ectopic pregnancies.

- **Human chorionic somatomammotropin (hCS)**, also known as **human placental lactogen (hPL)**, is closely related to human growth hormone. Synthesized in the syncytiotrophoblast, it promotes general growth, regulates glucose metabolism, and stimulates mammary duct proliferation in the maternal breast. The effects of hCS on maternal metabolism are significant, but the role of this hormone in fetal development remains unknown.
- **IGF-I** and **IGF-II** are produced by and stimulate proliferation and differentiation of the cytotrophoblast.
- **Endothelial growth factor (EGF)** exhibits an age-dependent dual action on the early placenta. In the 4- to 5-week-old placenta, EGF is synthesized by the cytotrophoblast and stimulates proliferation of the trophoblast. In the 6- to 12-week-old placenta, synthesis of EGF is shifted to the syncytiotrophoblast; it then stimulates and maintains the function of the differentiated trophoblast.
- **Relaxin** is synthesized by decidual cells and is involved in the “softening” of the cervix and the pelvic ligaments in preparation for parturition.
- **Leptin** is synthesized by the syncytiotrophoblast, particularly during the last month of gestation. Leptin appears to regulate maternal nutrient storage to the nutrient requirements of the fetus. It is also involved in transporting nutrients across the placental barrier from the mother to the fetus.
- **Other growth factors** stimulate cytotrophoblastic growth (e.g., fibroblast growth factor [FGF], colony-stimulating factor [CSF-1], platelet-derived growth factor, and interleukins [IL-1 and IL-3]) or inhibit trophoblast growth and proliferation (e.g., tumor necrosis factor).

■ VAGINA

The vagina is a fibromuscular tube that joins internal reproductive organs to the external environment.

The **vagina** is a fibromuscular sheath extending from the cervix to the vestibule, which is the area between the labia minora. The opening into the vagina may be surrounded by the **hymen**, folds of mucous membrane extending into the vaginal lumen. The hymen or its remnants are derived from the endodermal membrane that separated the developing vagina from the cavity of the definitive urogenital sinus in the embryo.

The **vaginal wall** (Fig. 23.30) consists of the following:

FIGURE 23.30. Photomicrograph of a human vagina. This low-magnification hematoxylin and eosin (H&E)-stained specimen of the vaginal wall shows two of three layers of the vagina: the mucosal layer and the muscular layer (the outer layer, the adventitia, is not included). The mucosal layer consists of a stratified squamous epithelium and the underlying connective tissue. The epithelial-

connective tissue boundary is typically very irregular, with prominent papillae projecting into the undersurface of the epithelium. The muscular layer is seen only in part; it consists of irregularly arranged bundles of smooth muscle cells. Also, the deep region of the connective tissue contains a rich supply of blood vessels that supply the various layers of the vaginal wall. $\times 40$.

- An inner **mucosal layer** has numerous transverse folds or rugae (see Fig. 23.1) and is lined with stratified squamous epithelium (Fig. 23.31). Connective tissue papillae from the underlying lamina propria project into the epithelial layer. In humans and other primates, keratohyalin granules may be present in the epithelial cells, but under normal conditions, keratinization does not occur. Therefore, nuclei can be seen in epithelial cells throughout the thickness of the epithelium.

FIGURE 23.31. Photomicrograph of the vaginal mucosa. This micrograph, a higher magnification of Figure 23.30, shows the stratified squamous epithelium and mature cells with small pyknotic nuclei. Note a single layer of basal cells and two or three layers of cells undergoing differentiation (with eosinophilic cytoplasm). Projections of the connective tissue papillae into the epithelium

give the connective tissue-epithelial junction an uneven appearance. The tips of these projections often appear as isolated structures surrounded by epithelium (*arrows*). $\times 180$.

- An intermediate **muscular layer** is organized into two sometimes indistinct, intermingling smooth muscle layers, an outer longitudinal layer and an inner circular layer. The outer layer is continuous with the corresponding layer in the uterus and is much thicker than the inner layer. Striated muscle fibers of the bulbospongiosus muscle are present at the vaginal opening (Plate 23.10, page 974).
- An outer **adventitial layer** is organized into an inner dense connective tissue layer adjacent to the muscularis and an outer loose connective tissue layer that blends with the adventitia of the surrounding structures. The inner layer contains numerous elastic fibers that contribute to the elasticity and strength of the vaginal wall. The outer layer contains numerous blood and lymphatic vessels and nerves.

The vagina possesses a stratified, squamous nonkeratinized epithelium and lacks glands.

The lumen of the vagina is lined by **stratified squamous, nonkeratinized epithelium**. Its surface is lubricated mainly by mucus produced by the cervical glands. The greater and lesser vestibular glands located in the wall of the vaginal vestibule produce additional mucus that lubricates the vagina. Glands are not present in the wall of the vagina. The epithelium of the vagina undergoes **cyclic changes** during the menstrual cycle. Under the influence of estrogens, during the follicular phase, the epithelial cells synthesize and accumulate glycogen as they migrate toward the surface. Cells are continuously desquamated, but near or during the menstrual phase, the superficial layer of the vaginal epithelium may be shed.

The **lamina propria** exhibits two distinct regions. The outer region immediately below the epithelium is a highly cellular loose connective tissue. The deeper region, adjacent to the muscular layer, is denser and may be considered a submucosa. The deeper region contains many thin-walled veins that simulate erectile tissue during sexual arousal. Numerous elastic fibers

are present immediately below the epithelium, and some of the fibers extend into the muscular layer. Many lymphocytes and leukocytes (particularly neutrophils) are found in the lamina propria and migrate into the epithelium. Solitary lymphatic nodules may also be present. The number of lymphocytes and leukocytes in the mucosa and vaginal lumen dramatically increases around the time of menstrual flow. The vagina has few general sensory nerve endings. The sensory nerve endings that are more plentiful in the lower third of the vagina are probably associated primarily with pain and stretch sensations.

■ EXTERNAL GENITALIA

The **female external genitalia** consist of the structures located within the anterior (urogenital) triangle of the female perineum. These structures are collectively referred to as the **vulva** [*Lat., volva, womb, female sexual organ; Lat., volvere, to turn, twist, roll, revolve, wrap*]. As the etymology of the word “vulva” implies, this region appears to be wrapped by skin folds. Structures included in the vulva consist of the **mons pubis, labia majora, labia minora, clitoral complex, vestibule** and **opening of the vagina, hymen** (or hymenal caruncles after it is ruptured), and **external urethral orifice** (Fig. 23.32). The vulva and its components extend from the mons pubis anteriorly to the **perineal body** posteriorly, which is a fibromuscular structure located in the midline of the perineum (anterior to the anus).

FIGURE 23.32. Schematic diagram illustrating the components of the female external genitalia (vulva). The left side of the vulva shows intact structures that consist of the mons pubis, labium majus, labium minus, glans of the clitoris with associated prepuce and frenulum, vestibule and opening of the vagina, hymen, and external urethral orifice. The right side of the vulva is dissected and shows structures after the removal of skin and superficial fascia. Note the deep structures of the clitoral complex (body, crus of the clitoris, and the bulb of vestibule). The major vestibular (of Bartholin) gland is in close proximity to the distal ends of the bulbs of the vestibule.

Mons Pubis

Mons pubis is the rounded prominence over the pubic symphysis.

The **mons pubis** is the rounded prominence over the pubic symphysis formed by an accumulation of subcutaneous **adipose tissue**. The mons pubis becomes more prominent with the onset of puberty. Hair in the pubic area exhibits a characteristic growth pattern during puberty that can be used to evaluate the developmental stages of external genitalia. **Tanner staging**, also known as **sexual maturity rating (SMR)**, is an objective system to track the development of secondary sex characteristics during puberty. **Pubic hair** follicle depth in the mons pubis is the greatest compared with other parts of the vulva. The skin in this area is rich in **sebaceous** and **apocrine glands** that secrete pheromone-like chemicals. In addition, the skin of the mons pubis contains an abundance of **nerve endings**, including Meissner and Merkel corpuscles, free nerve endings, and Pacinian corpuscles.

Labia Majora and Labia Minora

The labia majora and labia minora represent two folds of skin that form the lateral boundaries of the vestibule of the vagina.

As mentioned earlier, during clinical examination, the vulva appears to be wrapped by two paired skin folds called the **labia majora** and **labia minora**. The labia majora and labia minora develop around cloacal membrane from the proliferating mesenchyme that forms the cloacal folds. These folds unite in the cranial portion to produce the **genital tubercle** (future clitoris). With the division of the cloaca into urogenital sinus and anorectal canal, the cloacal folds are likewise subdivided into **urogenital folds** and anal folds. At the same time, **labioscrotal swellings** develop on both sides of the urogenital folds. Labioscrotal swellings in the female embryo develop into labia majora, and the urogenital folds do not fuse (as they do in the male embryo) and instead develop into the

labia minora that border urogenital cleft (the vertical fissure of the vulva that develops into the vestibule of vagina). The development of external genitalia is a complex process driven by the sequential expression of regulatory **Wnt genes** encoding growth factors, especially **fibroblast growth factor (FGF)**.

- The **labia majora** [*sing. labium majus*] are two prominent longitudinal folds of skin that extend from the mons pubis anteriorly and to the perineal body posteriorly. The anterior parts of the labia majora unite beneath the mons pubis to form the **anterior labial commissure**. The posterior parts of the labia majora gradually merge with the surrounding skin of the perineum at their **posterior labial commissure** (see Fig. 23.32). The labia majora form the outer lateral boundaries of the urogenital cleft and are separated by the interlabial sulci from the labia minora. **The size and contour of the labia are related to the amount of underlying adipose tissue deposits. During puberty, the labia majora increase in size, and after menopause, the labia atrophy due to decreased estrogen and loss of adipose tissue.**

The skin of the labia majora is covered by **stratified squamous keratinized epithelium**. Sebaceous, eccrine, and apocrine sweat glands are present on both surfaces. The **outer surface** of the labium majus is darker than the inner surface and, like that of the mons pubis, has deeply imbedded **hair follicles** (Fig. 23.33a). Sebaceous glands associated with hair follicles are prominent, and they discharge their holocrine secretion into pilosebaceous canals. An abundance of apocrine sweat glands in the skin of labia majora discharge their secretion directly into the hair follicles (Fig. 23.33b). In addition to sebaceous and apocrine sweat glands, the labia majora have many eccrine sweat glands. The thin skin of the **inner surface** is smooth and devoid of hair. An abundance of **sebaceous glands** is found on the inner surface of labia majora. Their ducts open directly on the surface of the epithelium (Fig. 23.34). The skin of the labia majora is rich in **sensory receptors**, including Merkel and Meissner corpuscles for touch, Ruffini corpuscles for stretch

and torque, Pacinian corpuscles for pressure, and free nerve endings for pain. Below the skin surface, the labia majora contain a thin layer of smooth muscle (dartos tunic) resembling the dartos muscle of the scrotum (see Fig. 23.33a) and a large amount of subcutaneous adipose tissue. The **bulbs of the vestibule** lie deep into the adipose tissue beneath the labia majora (page 942). They are homologous to the bulb of the penis in males and represent erectile tissue. They are covered by the bulbospongiosus muscle, a striated muscle that belongs to superficial muscles of the perineum.

FIGURE 23.33. Photomicrograph of the labium majus. a. This low-magnification hematoxylin and eosin (H&E)-stained specimen shows tissue excised from the midportion of the outer surface of the labium majus. This surface shows the stratified squamous keratinized epithelium with two deeply embedded hair follicles. Sebaceous glands associated with the hair follicles are prominent, and they discharge their holocrine secretion into pilosebaceous canals. Below the skin surface, the labia majora contain a thin layer of smooth muscle resembling the dartos muscle of the scrotum. At this low magnification, dispersed smooth muscles bundle are difficult to identify in this layer. Note accumulations of subcutaneous adipose tissue in the hypodermis. $\times 25$. b. In addition to sebaceous glands, the labia majora have many eccrine sweat glands and an abundance of apocrine sweat glands that discharge their secretion directly into the hair follicles. $\times 260$. (Reprinted with permission from Hanley KZ. Vulva. In: Mills SM, ed. *Histology for Pathologists*. Wolters Kluwer; 2020:1031 - 1046.)

FIGURE 23.34. Photomicrograph of the inner surface of the labia majora. This low-power hematoxylin and eosin (H&E)-stained specimen of the labia majora's inner surface shows its stratified squamous epithelium (*Ep*) with no visible signs of keratinization and abundant sebaceous glands (*SG*). Two sebaceous ducts (*SD*) are also evident. Note the continuity of the duct epithelium with the

epithelium of the skin and the sebaceous gland epithelium. At this magnification, several smooth muscle bundles can just barely be discerned (*arrows*).

The oval **major vestibular (Bartholin) glands** are in close proximity to the distal ends of the bulbs of the vestibule. This paired tubuloalveolar gland corresponds to the male bulbourethral (Cowper glands). The secretory acini are lined by simple columnar cells that produce mucus secretions (Fig. 23.35) that lubricate the vestibulum and distal end of the vagina during sexual intercourse. The basal domain of secretory acini is ensheathed by myoepithelial cells. The secretion of the gland is discharged into the long (~2.5 cm) **Bartholin gland duct** that opens into the 4 o'clock and 8 o'clock positions (posterior lateral aspect) of the vestibule of the vagina. The epithelium of the duct transitions from simple cuboidal (near the acini) to stratified cuboidal and stratified squamous epithelium at the opening into the vestibule (see Fig. 23.35). **Bartholinitis** is a condition in which the major vestibular glands become infected and inflamed, and it may lead to the development of bacterial cysts or abscesses. If the duct of the Bartholin gland becomes obstructed, it usually dilates and fills with a secretion produced by the gland that may form a **Bartholin cyst**. Symptoms include severe pain, redness, swelling of the involved labium majus, and, sometimes, fever. On physical examination, the affected labium majus appears red and enlarged. A large abscess requires surgical incision with drainage or complete excision.

FIGURE 23.35. Photomicrograph of the major vestibular (Bartholin) gland. This low-magnification hematoxylin and eosin (H&E)-stained specimen shows mucus acini lined by simple columnar cells that produce mucus secretions. Note that nuclei of secretory mucus cells are positioned at their basal domain (*arrowheads*). The basal domain of secretory acini is ensheathed by myoepithelial cells (not visible at this magnification). The gland's secretion is discharged into the Bartholin gland duct, visible in the *center* of the image. The epithelium of the duct transitions from simple cuboidal (near the acini) to stratified cuboidal and stratified squamous epithelium at the opening into the vestibule. The gland is embedded in the dense irregular connective tissue (*CT*) of the labia majora. $\times 60$. (Reprinted with permission from Hanley KZ. Vulva. In: Mills SM, ed. *Histology for Pathologists*. Wolters Kluwer; 2020:1031 - 1046.)

- The **labia minora** [*sing. labium minus*] are paired, hairless folds of skin that border the vestibule. They lie immediately lateral to the vaginal vestibule and medial to the labia majora. Upon reaching the clitoris, the anterior end of the labia minora splits into two parts. The more anterior part travels above (anterior) to the body of the clitoris, forming the **prepuce (hood) of the clitoris**, whereas the posterior

part crossing below the clitoris forms the **frenulum of the clitoris**. The posterior ends of the labia minora terminate as they fuse into a skin fold called the **frenulum of the labia minora**, or fourchette. In most cases, the labia minora are not symmetrical and may protrude beyond the labia majora.

- The skin of the labia minora contains **stratified squamous epithelium** that exhibits a small degree of keratinization (Fig. 23.36). The epithelium lacks skin appendages; however, the lateral surface of the labia minora may contain sweat glands. In some individuals, large sebaceous glands are present in the stroma; their secretion is directly released on the surface of the labia minora. Abundant **melanin pigment** is present in the deep cells of the epithelium. The core of connective tissue within each fold is devoid of adipose tissue but does contain numerous blood vessels and fine **elastic fibers**. The labia minora are highly innervated structures that directly connect to the glans of the clitoris and the erectile tissues of the bulb of the vestibule located deep into the labia majora. The labia minora have the highest concentration of Meissner and Merkel corpuscles for sensitivity to light touch of the entire vulva (see Fig. 23.36). A high density of Pacinian corpuscles for pressure reception and free nerve endings are also found in the labia minora. **Enlarged labia minora can cause functional problems related to menstrual hygiene and irritation from clothing. In specific conditions, labial alteration procedures (e.g., labiaplasty) for medical indications (e.g., treatment of labial hypertrophy or asymmetrical labial growth or chronic irritation) can be performed. These procedures are sometimes performed for cosmetic purposes despite the lack of high-quality data about their safety and long-term outcomes. Potential complications of labiaplasty include pain, infection, and scarring. Patients who are dissatisfied with the appearance of their labia minora can be counseled about normal variations in the color, size, and shape of external genitalia.**

FIGURE 23.36. Photomicrograph of a labium minus. This low-magnification hematoxylin and eosin (H&E)-stained specimen shows a section through the labium minus that includes both the lateral and medial surfaces. Each labium minus represents a fold of thin skin with a stratified squamous epithelium demonstrating a small degree of keratinization on the surface. The epithelium lacks skin appendages. Abundant melanin pigment is present in the cells in the basal layer of the epithelium; however, it is difficult to discern them at this low magnification. The core of dense regular connective tissue within the labia minora is devoid of adipose tissue but does contain numerous blood vessels (BV), elastic fibers, and nerves. Note a Meissner corpuscle residing in the dermal papilla. $\times 60$. (Reprinted with permission from Hanley KZ. Vulva. In: Mills SM, ed. *Histology for Pathologists*. Wolters Kluwer; 2020:1031–1046.)

Clitoral Complex

The clitoral complex, composed of the glans, body, crura of the clitoris, and bulbs of the vestibule, is a female erectile organ that is sexually responsive.

The **clitoral complex** is composed of the **glans of the clitoris**, **body of the clitoris**, **left and right crus of the clitoris**, and **two bulbs of the vestibule**. In recent descriptions, the

clitoral complex is often compared to the “tip of the iceberg” because the glans of the clitoris, the only visible part of this complex, represents only 10% of the complex’s total size; the remainder is embedded deep into the vulva. The clitoral complex is well innervated, containing many nerve endings, especially Pacinian corpuscles. Other touch receptors (Meissner and Merkel corpuscles) are present in reduced numbers compared with the mons pubis or labia majora. Free nerve endings (pain receptors) are present in relatively high concentrations. The clitoral complex comprises two histologically distinct types of **specialized vascular tissue** that consist of:

- **Erectile tissue**, which is found in the body and crura of the clitoris and bulbs of the vestibule. The body of the clitoris (as seen in cross section in Fig. 23.37) contains numerous wide, irregularly shaped vascular spaces lined with vascular endothelium. These spaces are surrounded by connective tissue trabeculae with a thin layer of smooth muscle. Irregular smooth muscle bundles are frequently observed as “subendothelial cushions” surrounding irregular vascular spaces. During sexual arousal, the erectile tissue allows for distension with blood and volume expansion. The vascular spaces increase in size and rigidity by filling with blood, principally derived from the divisions of internal pudendal arteries. These include deep dorsal artery of the clitoris that is positioned at the dorsal aspect of the body of the clitoris, deep artery of the clitoris running within the erectile tissue of the body of the clitoris, and artery to the bulb of the vestibule that enters the deep surface of the bulb.

FIGURE 23.37. Schematic diagram and a photomicrograph of the body of the clitoris in cross section. **a.** The diagram shows a midsection through the body of the clitoris. The body of the clitoris is not completely surrounded by the skin; instead, it has contact with divisions originating from the proximal ends of the labia minora. On the dorsal and lateral surfaces, the body is covered by the prepuce of the clitoris (hood), which emerged from the anterior division of the labia minora. The ventral part of the body is in close proximity to the frenulum that originated from the posterior division of the labia minora. Corpora cavernosa, the erectile tissue of the clitoris, is surrounded by a thick fibrous layer of tunica albuginea. Note that the corpora cavernosa are separated by the incomplete septum, which is closely associated with deep arteries of the clitoris; they are visible on both sides of the septum. The fascia of the clitoris surrounds the corpora cavernosa and the neurovascular bundle located at the dorsal aspect of the clitoris. Note the arrangement of deep dorsal arteries, deep dorsal veins, and dorsal nerves of the clitoris, which lie between the tunica albuginea and the fascia of the clitoris. The superficial dorsal vein of the clitoris resides in the superficial fascia. **b.** This low-power photomicrograph hematoxylin and eosin (H&E)-stained specimen shows the body of the clitoris that corresponds to the drawing. The specimen has been removed through the incision of the prepuce and separated from the skin and fascial layers. Note the well-defined tunica albuginea and erectile vascular spaces incompletely separated by the septum. Vascular spaces contain numerous irregularly shaped channels lined by vascular endothelium. These spaces are defined by the connective tissue trabeculae with a thin layer of smooth muscle. The neurovascular bundle is visible on the dorsal aspect of the body of the clitoris. $\times 10$. (Courtesy of Dr. Karen Pinder from the University of British Columbia, Vancouver, Canada.)

- **Nonerectile vascular tissue**, which is found in the glans of the clitoris. This tissue is characterized by a high density of blood vessels dispersed within a dense irregular connective tissue stroma containing a minimal amount of smooth muscle. During sexual arousal, increased blood flow is observed; however, the tissue does not undergo physical expansion. This type of nonerectile, sexually responsive vascular tissue also surrounds the urethral orifice and is present within the labia minora and the adventitia of the vaginal wall.

The **body of the clitoris** is composed of paired conjoined **erectile bodies**, which originate from extensions of the crura of the clitoris. These bodies are surrounded by **tunica albuginea**, a thin fibroelastic connective tissue sheath (see Fig. 23.37). A connective tissue septum between the paired erectile bodies is incomplete, and vascular spaces communicate with each other at the dorsal aspect of the clitoris. The adventitia of the **deep arteries of the clitoris** blends on both sides with the connective tissue of the septum. The body of the clitoris with investing tunica albuginea is surrounded by the inner layer of the fascia, called the **fascia of the clitoris**, that is continuous with the deep perineal fascia investing the perineal muscles, vestibule of vagina, and crura of the clitoris. **Deep dorsal arteries, deep dorsal veins, and dorsal nerves of the clitoris** course between the tunica albuginea and the fascia of the clitoris (see Fig. 23.37). The outer layer is a part of the superficial (Colles) fascia of the perineum and may contain the superficial dorsal vein of the clitoris. The body of the clitoris is attached to the pubic symphysis by the connective tissue **suspensory ligaments**. They attach to the clitoral complex at the angle of the clitoris, a transition point (>90 degree) between the crura and the body of the clitoris. As mentioned in the section on the labia minora (see page 941), the body of the clitoris does not have circumferential skin coverage; instead, the skin of the prepuce and the frenulum of the clitoris flare laterally to the labia minora (see Fig. 23.37).

The **glans clitoris**, an oval tubercle at the tip of the corpora cavernosa (average length 8 mm and width 4 mm), is formed by nonerectile vascular tissue. The skin over the glans is very thin, forms the prepuce of the clitoris, and as discussed earlier, contains numerous sensory nerve endings (see page 941).

The two **crura of the clitoris** are extensions of erectile tissues of the body of the clitoris that firmly anchor the clitoris to the pubic rami. They are about 36 mm in length and 7 mm in width (as measured in magnetic resonance imaging [MRI] scans) and are composed of erectile tissue surrounded by tunica albuginea, consistent with that of the body of the clitoris. At the place of bony attachment, the tunica albuginea fuses with the fibrous layer of the periosteum of pubic rami. The unattached surface of the crura is invested by a thin layer of ischiocavernosus muscle (a superficial striated muscle of the perineum) that is covered by a deep layer of the perineal fascia.

The **bulbs of the vestibule** are paired structures formed from the erectile tissue similar to that described in the body of the clitoris with some modifications. The erectile tissue of a bulb has more pronounced fibromuscular trabeculae and more prominent bundles of smooth muscles located just under the epithelium of the vascular spaces. In addition, a distinct tunica albuginea is often missing in the bulbs. They have a single origin from the inferior aspect of the body of the clitoris. After splitting into right and left structures, they travel posteriorly on the lateral side of the urethra and vagina and medially to the crura of the clitoris. They are firmly attached to the perineal membrane just deep into the labia majora and are covered by the thin layer of the bulbospongiosus muscle (a superficial striated muscle of the perineum). During sexual excitation, the bulb of the vestibule becomes engorged with blood. This significant enlargement of the bulbs of vestibule during sexual arousal is a result of the tunica albuginea absence.

Vestibule of the Vagina

The vestibule of the vagina is the middle part of the vulva that contains the external urethral orifice, opening of the vagina, and multiple openings of a variety of secretory glands.

The vestibule of the vagina is a somewhat concave space positioned in the middle part of the vulva that extends from the frenulum of the clitoris anteriorly to the frenulum of the labia minora posteriorly. Its lateral borders are formed by the labia minora and majora. The vestibule is lined with endodermally derived stratified squamous nonkeratinized epithelium, which, on the lateral sides, blends with ectodermally derived stratified squamous keratinized epithelium of the labia minora and majora, prepuce of the clitoris, and frenulum of the labia minora. The epithelium of the vestibule is rich in glycogen and is similar to that found in the vagina. The vestibule of the vagina contains the vaginal opening, which may be partially covered by the hymen, and the external urethral meatus. Numerous small mucous glands, the lesser vestibular glands (often incorrectly called Skene glands), open directly into the mucosa of the vestibule. They are simple tubular glands lined by mucous-secreting columnar cells that merge with the stratified squamous nonkeratinized epithelium of the vestibule. In addition, as discussed earlier, the ducts of the major vestibular (Bartholin) glands (see page 940 and Fig. 23.35) and glands surrounding the urethra with prominent paraurethral (Skene) glands (see page 944) discharge their secretions into the vestibule. The mucosa of the vestibule has multiple sensory and pain receptors similar to those found in other regions of the vulva. The lesser vestibular glands may undergo squamous metaplasia similar to that described for the cervix (see page 126). Metaplastic epithelium may completely replace the glandular epithelium, forming vestibular clefts. Obstruction of the glands may also produce a vulvar mucous cyst due to the accumulation of the mucous secretion.

The hymen is a thin mucous membrane at the entrance to the vagina.

The **hymen** is the thin, fibrous tissue plate that surrounds and partially covers the entrance to the vagina, leaving an opening for vaginal and menstrual discharge. When it is ruptured, small tag-like elevations known as **hymenal caruncles** are present at the opening of the vagina. Embryologically, the hymen is derived from the **endodermal membrane** that separates the developing vagina from the cavity of the **definitive urogenital sinus** in the embryo. Thus, it marks the inferior boundary of the vagina and the superior boundary of the vestibule. Both vaginal and vestibular surfaces of the hymen are covered by a **mucosa** containing stratified squamous nonkeratinized epithelium, which is similar to that of the vaginal epithelium (Fig. 23.38). The lighter staining of epithelium on the vaginal surface reflects larger amounts of glycogen stored in the epithelial cells. The border between epithelium and underlying lamina propria is clearly defined by the closely packed small cells of the stratum basale (see Fig. 23.38). Deep connective tissue papillae are present on both vaginal and vestibular surfaces and are formed by invaginations of underlying lamina propria into the epithelium. The vaginal surface appears smooth; however, the vestibular surface may contain small projections, known as *vestibular papillae* (see Fig. 23.38). Dense irregular connective tissue containing a rich network of blood vessels with a few nerve fibers is present in the core of the hymen. The hymen has a limited number of nerve receptors. Only Merkel corpuscles and free nerve endings are present in the hymenal ring. The size, shape, and degree of the hymenal opening vary greatly among individuals. The hymen may be imperforate, round, annular, septate, or cribriform. In cases of **imperforate hymen**, the hymen lacks the opening between the vagina and the vestibulum. If this condition is diagnosed during puberty, it may lead to progressive accumulation of menstrual discharge that results in distension of the vagina (**hematocolpos**).

FIGURE 23.38. Photomicrograph of the hymen. This low-magnification hematoxylin and eosin (H&E)-stained specimen shows the section of the hymen that includes the free edge of the hymenal ring. Note a gradual transition of the stratified squamous nonkeratinized epithelium from the vaginal surface (vaginal mucosa) to the vestibular surface (vestibular mucosa). The lighter staining of epithelium on the vaginal surface reflects larger amounts of glycogen stored in the epithelial cells. The vaginal surface also appears smooth. The vestibular surface stains darker (less glycogen content) and may contain vestibular papillae, small surface projections caused by projections of underlying lamina propria into the epithelium. The border between epithelium and underlying lamina propria is clearly defined by closely packed small cells of the stratum basale (*arrows*). Dense irregular connective tissue containing blood vessels is present in the core of the hymen. $\times 45$. (Reprinted with permission from Hanley KZ. Vulva. In: Mills SM, ed. *Histology for Pathologists*. Wolters Kluwer; 2020:1031–1046.)

Glandular tissue surrounding the female urethra shares immunohistochemical characteristics with the prostate gland

in males.

The **external urethral orifice** is part of the vestibulum of the vagina and is located between the glans of the clitoris and the opening of the vagina. In most cases, the lumen of the urethra is lined by transitional epithelium (urothelium) that changes at the external urethra orifice into stratified squamous nonkeratinized epithelium of the vaginal vestibule. However, stratified columnar and pseudostratified epithelium have also been reported in the female urethra.

The glandular tissue around the urethra is represented by small **periurethral glands**. These glands are present in the wall of the urethra and open with the short ducts throughout the entire length of the urethral lumen being more numerous at the distal half of the urethra. Glandular tissue associated with the urethra has been given various names, such as glands of Littré, glands of Huffman, glands of Morgani, intermural glans of the urethra, and periurethral or paraurethral glans. These names are used interchangeably, reflecting the lack of consensus among researchers. However, two larger accumulations of glandular tissue often described in the literature, known as the **paraurethral glands (of Skene)**, are located near the distal end of the urethra. They have longer and more prominent ducts (1.5 cm in length) that empty in the distal part of the urethra. These ducts are lined by the stratified (two layers thick) cuboidal epithelium. In multiparas, where the urethral meatus can be considerably distended, the duct of Skene glands appears visible on the side and deep into the urethral orifice.

The entire glandular tissue complex surrounding the urethra exhibits a similar histologic appearance. All glands are of mixed branched tubuloalveolar type lined by the simple columnar epithelium with occasional nests of pseudocolumnar epithelium with basal cells. A prominent fibromuscular stroma separates glandular profiles. Immunohistochemical analysis reveals that all glandular tissue surrounding the lumen of the urethra stain positively for prostate-specific antigen (PSA), prostatic acid phosphatase (PAP), prostate-specific alkaline phosphatase (PSAkP), and androgen receptor (AR), leading some researchers to characterize the periurethral glandular tissue as the **female**

prostate. Also, physiologic studies determined that the urethra is the source of secretions that can occur during sexual excitement. Biochemical analysis suggests that this secretion is similar in composition to male ejaculate.

■ MAMMARY GLANDS

The **mammary glands**, or breasts, are a distinguishing feature of mammals. They are structurally dynamic organs, varying with age, menstrual cycle, and reproductive status of the female. During embryologic development, growth and development of breast tissue occur in both sexes. Multiple glands develop along paired epidermal thickenings called **mammary ridges (milk lines)** that extend from the developing axilla to the developing inguinal region. In humans, normally, only one group of cells develops into a breast on each side. **An extra breast (polymastia) or nipple (polythelia) may occur as an inheritable condition in about 1% of the female population. These relatively rare conditions may also occur in men.**

In females, mammary glands develop under the influence of sex hormones.

Until puberty, both females' and males' mammary glands develop in similar manner. At the onset of puberty in males, testosterone acts on the mesenchymal cells to inhibit further growth of the mammary gland. At the same time, the mammary glands undergo further development under hormonal influence of estrogen and progesterone. Estrogen stimulates further development of mesenchymal cells. The mammary gland increases in size, mainly due to the growth of interlobular adipose tissue. The ducts extend and branch into the expanding connective tissue stroma. Proliferation of epithelial cells is controlled by interactions between the epithelium and the specialized intralobular hormone-sensitive loose connective tissue stroma. By adulthood, the complete ductal architecture of the gland has been established.

CLINICAL CORRELATION: CERVICAL CYTOLOGY: THE PAP TEST

The examination of samples of cervical cells is a valuable diagnostic tool in evaluating the vaginal and cervical mucosae (Fig. F23.5.1). Superficial epithelial cells are removed from the mucosa, added to a liquid medium, and sent to a laboratory for microscopic examination. Before the advent of liquid-based cervical cytology, cervical cell samples were spread on glass slides and stained with the Papanicolaou (Pap) stain (a combination of hematoxylin, orange G, and eosin azure). Cervical cytology provides valuable diagnostic information about the epithelium regarding pathologic changes, response to hormonal changes during the menstrual cycle, and the microbial environment of the vagina.

FIGURE F23.5.1. Photomicrographs of cervical cytology. **a.** Negative cervical cytology. The surface squamous cells reveal small pyknotic nuclei and abundant cytoplasm. Other cells in the micrograph include red blood cells and neutrophils. $\times 600$. **b.** Abnormal cytology. Many of the cells in this specimen contain large nuclei with no evidence of pyknosis (*arrows*). The cytoplasm is relatively scant. Other cells exhibit a more normal appearance with pyknotic nuclei and more surrounding cytoplasm (*arrowheads*). Neutrophils are also present. $\times 600$.

Cervical cytology results are reported using the Bethesda system. This system stratifies results into three major categories:

- **Negative for intraepithelial lesions or malignancy:** This category includes both normal results and results that indicate infectious organisms or other nonneoplastic changes.
- **Other:** This category is used to report the presence of benign-appearing endometrial cells in a female aged 45 years or older. This finding may indicate an endometrial abnormality.
- **Epithelial cell abnormalities:** This category is used to report both squamous and glandular cell abnormalities.

Nonneoplastic Changes

The synthesis and release of glycogen by the epithelial cells of the uterus and vagina are directly related to changes in the pH of vaginal fluid. The pH of the fluid, which is normally low, around pH 4, becomes more acid near midcycle as *Lactobacillus acidophilus*, a lactic acid-forming bacterium in the vagina, metabolizes the secreted glycogen. An alkaline environment can favor the growth of infectious agents such as *Staphylococci*, *Corynebacterium vaginale*, *Trichomonas vaginalis*, and *Candida albicans*, causing an abnormal increase in vaginal transexudates and inflammation of the vaginal mucosa and vulvar skin known as **vulvovaginitis**. These pathologic conditions are readily diagnosed with cervical cytology. Specific antimicrobial agents (antibiotics, sulfonamides, and antifungals) may be used together with nonspecific therapy (acidified 0.1% hexetidine gel) to restore the normal low pH in the vagina and thus prevent the growth of these agents.

Epithelial Cell Abnormalities

Cervical cytology is widely used to screen for precancer stages of the cervix. Because precancerous cervical lesions may exist for as long as 20 years, the abnormal cells shed from the epithelium are easily detected with cervical cytology. Microscopic examination of these cells permits differentiation between normal and abnormal cells, determines their site of origin, and allows classifying cellular changes related to the spread of the disease.

In the Bethesda system, epithelial lesions are differentiated as either squamous or glandular into the following categories:

- Squamous cells
 - Atypical squamous cells
 - Low-grade squamous intraepithelial lesion
 - High-grade squamous intraepithelial lesion
 - Squamous cell carcinoma
- Glandular cells
 - Atypical (endocervical, endometrial, or glandular cells)
 - Endocervical adenocarcinoma in situ
 - Adenocarcinoma

The Pap test is an extremely effective and inexpensive screening method for preventing cervical cancer. Because most of the cell abnormalities detected by Pap tests are in the precancerous stage, it allows prompt treatment and follow-up that is able to prevent the onset of invasive cervical cancer. Since the 1950s, when cervical cytology was first introduced, deaths from cervical cancer in the United States have declined ~70%. However, in areas where cervical cancer screening is not as widely used, cervical cancer deaths remain high.

The mammary glands remain in an **inactive state** until pregnancy, during which the mammary glands assume their complete morphologic and functional maturation. This occurs in response to estrogens and progesterone initially secreted from the corpus luteum and later from placenta, prolactin (PRL) from pituitary gland, and gonadocorticoids produced by the adrenal cortex. By the end of pregnancy, secretory vesicles are found in the epithelial cells, but milk production is inhibited by high levels of progesterone. The actual initiation of **milk secretion** occurs immediately after birth and is induced by **prolactin (PRL)** secreted by the adenohypophysis. The ejection of milk from the breast is stimulated by **oxytocin** released from the neurohypophysis. With the change in the hormonal environment at menopause, the glandular component of the breast regresses or involutes and is replaced by fat and connective tissue. In men, some additional development of the mammary glands normally occurs after puberty, and the glands remain rudimentary.

Hormonal exposure and genetic predisposition are the major risk factors for the development of **breast cancer**. It is the most common malignancy in women in the United States. Each year, an estimated nearly 270,000 women (and also 2,500 men) are diagnosed with breast cancer. Most breast cancers are linked to hormonal exposure (which increases with age, early menarche, late menopause, and with older age of a first full-term pregnancy). About 5%-10% of all breast cancers are attributable to mutation in autosomal dominant **breast cancer genes (BRCA1 and BRCA2)**.

Mammary glands are modified tubuloalveolar apocrine sweat glands.

The tubuloalveolar **mammary glands**, derived from modified sweat glands in the epidermis, lie in the subcutaneous tissue. The inactive adult mammary gland is composed of 15-20 irregular lobes separated by fibrous bands of connective tissue. They radiate from the **mammary papilla**, or **nipple**, and are further subdivided into numerous lobules known as **terminal duct lobular units (TDLUs)** (Fig. 23.39). Some of the fibrous bands, called

suspensory or **Cooper ligaments**, connect with the dermis. Abundant adipose tissue is present in the dense connective tissue of the interlobular spaces.

FIGURE 23.39. Schematic drawing of the human breast as seen during lactation. The breast is composed largely of terminal duct lobular units (TDLUs) containing branched tubuloalveolar glands. TDLUs are contained within an extensive connective tissue stroma and variable amounts of adipose tissue.

Each gland ends in a **lactiferous duct** that opens through a constricted orifice into the nipple. Beneath the **areola**, the pigmented area surrounding the **nipple**, each duct has a dilated portion, the **lactiferous sinus**. Near their openings, the lactiferous ducts are lined with stratified squamous keratinized epithelium. The epithelial lining of the duct shows a gradual transition from stratified squamous to two layers of cuboidal cells in the lactiferous sinus and finally to a single layer of columnar or cuboidal cells through the remainder of the duct system.

The epidermis of the adult nipple and areola is highly pigmented and somewhat wrinkled and has long dermal papillae invading its deep surface (Fig. 23.40). It is covered by keratinized stratified squamous epithelium. The pigmentation of the nipple increases at puberty, and the nipple becomes more prominent. During pregnancy, the areola becomes larger, and the degree of pigmentation increases further. Deep to the areola and nipple, bundles of smooth muscle fibers are arranged radially and circumferentially in the dense connective tissue and longitudinally along the lactiferous ducts. These muscle fibers allow the nipple to become erect in response to various stimuli.

FIGURE 23.40. Photomicrographs of a section through the female nipple. a. This low-magnification micrograph of a hematoxylin and eosin (H&E)-stained sagittal section through the nipple shows the wrinkled surface contour, a thin stratified squamous epithelium, and associated sebaceous glands (*arrows*). The core of the nipple consists of dense connective tissue, smooth muscle bundles, and the lactiferous ducts that open at the nipple surface. $\times 6$. b. The wall of one of the lactiferous ducts is shown here at higher magnification. Its epithelium is stratified cuboidal, consisting of two-cell layers. As it approaches the tip of the nipple, it changes to a stratified squamous epithelium and becomes continuous with the epidermis. $\times 175$. c. A higher magnification of the sebaceous gland from the *rectangle* in a. Note how the glandular epithelium is continuous with the epidermis (*arrows*), and the sebum is being secreted onto the epidermal surface. $\times 90$. d. A higher magnification showing bundles of smooth muscle in longitudinal and cross-sectional profiles. $\times 350$.

The **areola** contains sebaceous glands, sweat glands, and modified mammary glands (**Montgomery glands**). These glands have a structure intermediate between that of sweat glands and true mammary glands, and they produce small elevations on the surface of the areola. It is believed that Montgomery glands produce a lubricating and protective secretion that changes the skin's pH and discourages microbial growth. Numerous sensory nerve endings are present in the nipple; the areola contains fewer sensory nerve endings.

The terminal duct lobular unit (TDLU) of the mammary gland represents a cluster of small secretory alveoli (in a lactating gland) or terminal ductules (in an inactive gland) surrounded by intralobular stroma.

Successive branching of lactiferous ducts leads to the **terminal duct lobular unit (TDLU)**. Each TDLU represents a grape-like cluster of small alveoli that forms a lobule (Fig. 23.41) and consists of the following:

FIGURE 23.41. Terminal duct lobular unit. **a.** This schematic diagram shows components of the terminal duct lobular unit (*TDLU*). Terminal ductules and the intralobular collecting duct are surrounded by a specialized hormonally sensitive loose connective tissue called *intralobular stroma*. *TDLUs* are separated from each other by interlobular stroma containing a variable amount of dense irregular connective tissue and adipose tissue. In active mammary glands, terminal ductules differentiate into milk-producing alveoli. **b.** This photomicrograph shows the *TDLU* from an inactive mammary gland. The clear area in the *upper part* of the image represents adipose cells. $\times 120$.

- **Terminal ductules** are present in the inactive gland. During pregnancy and after childbirth, the epithelium of the terminal ductules, which is lined by secretory cells, differentiates into fully functional secretory alveoli that produce milk.
- The **intralobular collecting duct** carries alveolar secretions into the lactiferous duct.
- The **intralobular stroma** is a specialized, hormonally sensitive loose connective tissue that surrounds the terminal ductules and alveoli. The intralobular connective tissue contains few adipose cells.

Glandular epithelial and myoepithelial cells are the most important cells associated with mammary ducts and lobules.

Glandular epithelial cells line the duct system, whereas myoepithelial cells lie deep within the epithelium between the epithelial cells and the basal lamina. These cells, arranged in a basket-like network, are present in the secretory portions of the gland. In a routine hematoxylin and eosin (H&E) preparation, the myoepithelial cells are more apparent in the larger ducts. However, in an immunocytochemical preparation, their discontinuous, basket-like arrangement is better visualized within the alveoli (Fig. 23.42). Contraction of myoepithelial cells assists in milk ejection during lactation. Recent immunofluorescence studies have proven that breast progenitor cells found in the ductular epithelium give rise to both glandular cells of the alveoli and myoepithelial cells.

FIGURE 23.42. Myoepithelial cells in the mammary gland. This immunofluorescence image is obtained from the mammary gland of a lactating mouse 2 days postparturition. The mouse carries a transgene composed of the smooth muscle α -actin promoter conjugated to enhance the green fluorescent protein (GFP) reaction. Three-dimensional organization of myoepithelial cells is visualized in *green color* due to the expression of the promoter transgene in myoepithelial cells. The tissue was also stained *red* with antibody against smooth muscle α -actin conjugated directly with CY3 fluorescent dye. The *orange color* staining results from overlapping of the *green* and *red* staining. The cells on the surface of the terminal duct lobular unit are stained *orange*, whereas those deeper in the tissue stained only *green* because the antibody did not penetrate deep into the tissue. Note a small intralobular duct that merges into the larger lactiferous duct. $\times 600$. (Courtesy Dr. James J. Tomasek, University of Oklahoma Health Science Center.)

The morphology of the secretory portion of the mammary gland varies with the menstrual cycle.

In the **inactive gland**, the glandular component is sparse and consists chiefly of duct elements (Fig. 23.43 and Plate 23.11, page 976). During the menstrual cycle, the inactive breast undergoes slight cyclic changes. Early in the follicular phase, the intralobular stroma is less dense, and terminal ductules appear as cords formed by the cuboidal-shaped epithelial cells with little or no lumen. During the luteal phase, the epithelial cells increase in height, and lumina appear in the ducts as small amounts of secretions accumulate. Also, fluid accumulates in the connective tissue. This is followed by abrupt involution and apoptosis during the last few days of the menstrual cycle before the onset of menstruation.

FIGURE 23.43. Photomicrograph of an inactive mammary gland. a. This low-magnification hematoxylin and eosin (H&E)-stained specimen shows several lobules within the dense connective tissue of the breast. The epithelial component consists of a branching duct system that makes up the lobule. The clear areas (*arrows*) are adipose cells. $\times 60$. b. A higher magnification of the area in the *rectangle* of a. The epithelial cells of the ducts are columnar and exhibit interspersed lymphocytes (*arrows*) that have entered the epithelium. The surrounding

stained material (*arrowheads*) represents the myoepithelial cells (*MEp*) and collagen bundles in the adjacent connective tissue. $\times 700$.

Mammary glands undergo dramatic proliferation and development during pregnancy.

The **mammary glands** exhibit a number of changes in preparation for lactation. These can be examined during the trimester of pregnancy.

- **First trimester** is characterized by elongation and branching of the terminal ductules. The lining epithelial and myoepithelial cells proliferate and differentiate from breast progenitor cells found in the epithelium of terminal ductules. Myoepithelial cells proliferate between the base of the epithelial cells and the basal lamina in both the alveolar and ductal portions of the gland.
- **Second trimester** is characterized by differentiation of alveoli from the growing ends of the terminal ductules. The development of the glandular tissue is not uniform, and variation in the degree of development is seen even within a single lobule. The cells vary in shape from flattened to low columnar. Plasma cells, lymphocytes, and eosinophils infiltrate the intralobular connective tissue stroma as the breast develops (Plate 23.12, page 978). At this stage, the amount of glandular tissue and mass of the breast increase, mainly due to the growth of the alveoli (Fig. 23.44).

FIGURE 23.44. Photomicrograph of an active mammary gland during late pregnancy. **a.** This low-magnification hematoxylin and eosin (H&E)-stained specimen shows the marked proliferation of the duct system giving rise to the secretory alveoli that constitute the major portion of the lobules. The intralobular ducts are difficult to identify because their epithelium also secretes. Outside the lobules is a large excretory duct. $\times 60$. **b.** A higher magnification of an area in **a.** The secretory alveolar cells are mostly cuboidal here. A myoepithelial cell (*mEp*) as well as a number of plasma cells (*arrows*) can be identified in the adjacent loose connective tissue. $\times 700$.

- **Third trimester** commences maturation of the alveoli. The epithelial glandular cells become cuboidal, with nuclei positioned at the basal cell surface. They develop an extensive rER; secretory vesicles and lipid droplets appear in the cytoplasm. The actual proliferation of the interlobular stromal cells declines, and subsequent enlargement of the breast occurs through hypertrophy of the secretory cells and accumulation of secretory product in the alveoli.

The changes in glandular tissue during pregnancy are accompanied by a decrease in the amount of connective tissue

and adipose tissue.

Both merocrine and apocrine secretion are involved in the production of milk.

The secreting cells contain abundant granular endoplasmic reticulum, a moderate number of large mitochondria, a supranuclear Golgi apparatus, and a number of dense lysosomes (Fig. 23.45). Depending on the secretory state, large lipid droplets and secretory vesicles may be present in the apical cytoplasm. The secretory cells produce two distinct products that are released by different mechanisms.

FIGURE 23.45. Photomicrographs and diagram of a lactating mammary gland. **a.** Low-magnification micrograph of a fast-green osmium-stained section of a lactating mammary gland. Portions of several large lobules and an excretory duct are seen. Many of the alveoli exhibit a prominent lumen, even at this magnification. $\times 60$. **b.** A higher magnification of an area in **a** shows lipid droplets (black circular profiles) within the secretory cells of the alveoli as well as in the alveolar lumina. The arrows indicate plasma cells within the interstitial spaces. $\times 480$. **c.** Diagram of a lactating mammary gland epithelial cell. *rER*, rough-surfaced endoplasmic reticulum. (Redrawn after Bloom W, Fawcett DW. *A Textbook of Histology*. 10th ed. WB Saunders; 1975.)

- **Merocrine secretion.** The protein component of the milk is synthesized in the rER, packaged into membrane-limited secretory vesicles for transport in the Golgi apparatus, and released from the cell by fusion of the vesicle's limiting membrane with the plasma membrane.
- **Apocrine secretion.** The fatty or lipid component of the milk arises as lipid droplets that are free in the cytoplasm. The lipid coalesces to form large droplets that pass to the apical region of the cell and project into the lumen of the acinus. The droplets are invested with an envelope of plasma membrane as they are released. A thin layer of cytoplasm is trapped between the plasma membrane and lipid droplet and is released with the lipid, but the cytoplasmic loss in this process is minimal.

The secretion released in the first few days after childbirth is known as **colostrum**. This premilk is an alkaline, yellowish secretion with a higher protein, vitamin A, sodium, and chloride content and a lower lipid, carbohydrate, and potassium content than milk. It contains considerable amounts of antibodies (mainly **secretory IgA**) that provide the newborn with some degree of passive immunity. The antibodies in the colostrum are believed to be produced by the lymphocytes and plasma cells that infiltrate the loose connective tissue of the breast during its proliferation and development and are secreted across the glandular cells as in salivary glands and intestine. As these wandering cells decrease in number after parturition, the production of colostrum stops, and lipid-rich milk is produced.

Hormonal Regulation of the Mammary Gland

The initial growth and development of the mammary gland at puberty occur under the influence of estrogens and progesterone produced by the maturing ovary. Under hormonal influence, the TDLUs develop and differentiate into dynamic functional units. Subsequent to this initial development, slight changes in the morphology of the glandular tissue occur during each ovarian cycle. During the follicular phase of the menstrual cycle,

estrogen in the circulation stimulates proliferation of the lactiferous duct components. After ovulation in the luteal phase, progesterone stimulates the growth of alveoli; intralobular stroma becomes edematous. Clinically, during the luteal phase, tenderness and a progressive increase in breast tissue mass may be felt. During pregnancy, the corpus luteum and placenta continuously produce estrogens and progesterone, causing a massive increase in TDLUs. It is now believed that the growth of the mammary glands also depends on the presence of PRL, which is produced by the anterior lobe of the pituitary gland (adenohypophysis); hCS, which is produced by the placenta; and adrenal glucocorticoids.

FOLDER 23.6

CLINICAL CORRELATION: CERVICAL CANCER AND HUMAN PAPILLOMAVIRUS INFECTION

Human papillomavirus (HPV) is the most common sexually transmitted virus in the United States. Most individuals will become infected with HPV during their lifetime. More than 30 HPV types are known to infect the urogenital and anal regions of both sexes, targeting the stratified squamous epithelium of the perineal skin or mucous membranes. About 12 types of HPV, called *low-risk* HPV types, cause **genital warts**. Most cases of genital warts are caused by HPV types 6 and 11. Approximately 13 types of HPV, called *high-risk* HPV types, can cause cancer of the cervix, anus, vagina, vulva, penis, and head and neck. Most cases of HPV-associated cancer are caused by HPV types 16 and 18.

HPV infection usually resolves on its own. Persistent infection develops in only a small percentage (5%–10%) of cases. Risk factors for persistent infection include older age and smoking. Persistent infection with high-risk HPV types is associated with an increased risk of cervical cancer.

Most HPV-associated lesions can be diagnosed by cervical cytology. In difficult cases, ancillary techniques such as in situ hybridization can help confirm the diagnosis (Fig. F23.6.1). An HPV vaccine, called *Gardasil 9*, is available for the prevention of HPV. Gardasil 9 protects against types 6, 11, 16, and 18 and five other high-risk HPV types. Vaccinations against HPV virus are recommended for both sexes between the ages of 9 and 26 years.

FIGURE F23.6.1. Photomicrograph of in situ hybridization of a human cervical biopsy showing human papillomavirus (HPV) infection. **a.** This low-magnification photomicrograph shows stratified squamous epithelium of the cervix hybridized with DNA probes to HPV types 6 and 11 and counterstained with nuclear fast red. Note that the majority of infected cells are mature cells located in the upper layers of the stratified squamous epithelium of the ectocervix. $\times 120$. **b.** This higher magnification photomicrograph shows viral particles stained *purple* within the nuclei of infected cells. $\times 225$. (Courtesy of Dr. Fabiola Medeiros.)

None of the vaccines are therapeutic (i.e., they do not clear prior infection), but both lead to the development of specific immunity against HPV infections. The vaccines are most effective in those who have had no prior HPV exposure and who are immunized before initiation of sexual activity.

Cervical cancer screening now includes HPV testing in addition to cervical cytology for certain age groups. The following are the most current **cervical cancer screening recommendations** for people who have no other risks factors for cervical cancer from the American College of Obstetricians and Gynecologists:

- Age 21 years and younger: no screening
- Ages 21–29 years: cervical cytology (Pap test) every 3 years
- Ages 30–65 years: primary HPV testing alone every 5 years or HPV testing plus cervical cytology every 5 years OR cervical cytology every 3 years

The increased interval between screening tests (as opposed to annual testing) and the avoidance of HPV testing in younger

individuals are recommended to decrease the number of false-positive results and unnecessary diagnostic procedures. HPV infection usually resolves spontaneously in younger patients. When infections do persist, they usually do so for many years before precancerous changes can be detected.

Diagnosis of precancer of the cervix includes **colposcopy**, in which a colposcope (a specifically designed microscope to magnify the view of the cervix) is used to examine the cervix for lesions and to perform cervical biopsy. Treatment for precancerous lesions is accomplished by removal of the precancerous cells by **cone biopsy (conization)**, a procedure in which a cone-shaped tissue of the cervix containing part of ectocervix, transformation zone, and cervical canal is excised or destroyed. Conization can be performed with a scalpel (cold-knife conization), laser, electrosurgical loop, or freezing (cryoconization).

Lactation is under the neurohormonal control of the adenohypophysis and hypothalamus.

Although estrogen and progesterone are essential for the physical development of the breast during pregnancy, both of these hormones also suppress the effects of PRL and hCS, the levels of which increase as pregnancy progresses. Immediately after childbirth, however, the sudden loss of estrogen and progesterone secretion from the placenta and corpus luteum allows PRL to assume its lactogenic role. Production of milk also requires adequate secretion of growth hormones, adrenal glucocorticoids, and parathyroid hormones.

The act of **suckling** during breastfeeding initiates sensory impulses from receptors in the nipple to the hypothalamus. The impulses inhibit the release of prolactin-inhibiting factor, and **prolactin** is then released from the adenohypophysis. The sensory impulses also cause the release of **oxytocin** in the neurohypophysis. Oxytocin stimulates the myoepithelial cells that surround the base of the alveolar secretory cells and the base of the cells in the larger ducts, causing them to contract and eject the milk from the alveoli and the ducts. **In the absence of suckling, secretion of milk ceases, and the mammary glands begin to regress and atrophy. The glandular tissue then returns to an inactive condition.**

Involution of the Mammary Gland

After menopause, the specialized stroma of the mammary gland involutes, causing the gland to atrophy. In the absence of ovarian hormone stimulation, the secretory cells of the TDLUs degenerate and disappear, leaving only ducts to create a histologic pattern that resembles that of the male breast. The connective tissue also demonstrates degenerative changes, marked by a decrease in the number of fibroblasts and collagen fibers and loss of elastic fibers.

FOLDER 23.7

FUNCTIONAL CONSIDERATIONS: LACTATION AND INFERTILITY

Almost 50% of females who fully breastfeed exhibit **lactational amenorrhea** (lack of menstruation during lactation) and infertility. This effect is caused by high levels of serum prolactin, which inhibit secretion of pulsatile gonadotropin-releasing hormone (GnRH), thus suppressing secretion of the luteinizing hormone (LH). Ovulation usually resumes after 6 months or earlier with a decrease in suckling frequency.

Blood Supply and Lymphatics

The arteries that supply the breast are derived from the thoracic branches of the **axillary artery**, the **internal thoracic artery**, and anterior intercostal arteries. Branches of the vessels pass primarily along the path of the alveolar ducts as they reach capillary beds surrounding the alveoli. In general, veins basically follow the path of the arteries as they return to the axillary and internal thoracic veins.

Lymphatic capillaries are located in the connective tissue surrounding the alveoli. The larger lymphatic vessels drain into **axillary**, **supraclavicular**, or **parasternal lymph nodes**.

Innervation

The nerves that supply the breast are anterior and lateral cutaneous branches from the second to sixth **intercostal nerves**. The nerves convey afferent and sympathetic fibers to and from

the breast. The secretory function is primarily under hormonal control, but afferent impulses associated with suckling are involved in the reflex secretion of PRL and oxytocin.

FEMALE REPRODUCTIVE SYSTEM

OVERVIEW OF THE FEMALE REPRODUCTIVE SYSTEM

- The female reproductive system consists of **internal female reproductive organs** (ovaries, uterine tubes, uterus, and vagina) and **external genitalia** (vulva).
- Internal female reproductive organs undergo regular cyclic changes during each **menstrual cycle**, from **puberty** to **menopause**, that reflect changes in hormone levels.

OVARY

- The major functions of the ovaries are the production of gametes (**oogenesis**) and the production of steroid hormones (estrogen and progesterone; **steroidogenesis**).
- Ovaries have a **medulla** in their center that contains loose connective tissue, nerves, blood and lymphatic vessels, and a **cortex** on their periphery that contains a large number of **ovarian follicles** that provide a microenvironment for developing oocytes.
- The surface of the ovary is covered by **germinal epithelium**, which is a single cuboidal epithelium that overlies a dense layer of connective tissue called **tunica albuginea**.

OVARIAN FOLLICLE DEVELOPMENT

- There are three basic developmental stages of an ovarian follicle: primordial, growing (both primary and secondary), and mature (Graafian) follicle.
- Before puberty, the cortex of an ovary is occupied only by primordial follicles. They contain a single primary oocyte that is arrested in the first meiotic prophase and is surrounded by a single layer of squamous follicle cells.
- After puberty following cyclic hormonal changes, a selected cohort of primary follicles develops into growing follicles. Follicle cells surrounding the oocyte become cuboidal and undergo further stratification to form the primary follicle.
- Cells of the growing follicle develop into granulosa cells; connective tissue surrounding the follicle differentiates into the theca interna and theca externa; and the oocyte grows and produces the zona pellucida (ZP) that contains specific ZP glycoproteins involved in the fertilization process.
- As granulosa cells proliferate, they become involved in steroid hormone metabolism (conversion of androgens produced by the theca interna into estrogens) and actively secrete follicular fluid that accumulates in cavities between the granulosa cells.
- A growing follicle that contains a single fluid cavity (antrum) is called the secondary (antral) follicle. It still contains the primary oocyte arrested in the first prophase of meiotic division.
- As the secondary follicle enlarges and undergoes further maturation, the thin layer of granulosa cells that is associated with the oocyte forms the cumulus oophorus and corona radiata.
- The mature (Graafian) follicle has a large antrum and a prominent, steroid-producing theca interna layer. Triggered by an LH surge just before ovulation, the

oocyte resumes its first meiotic division and becomes the secondary oocyte.

OVULATION

- During the ovarian cycle, usually, only one Graafian follicle undergoes **ovulation**. All other follicles in the developing cohort undergo **follicular atresia**, a process of degeneration involving apoptosis.
- During ovulation, a **secondary oocyte** is released from the ruptured Graafian follicle. The released oocyte is arrested in the metaphase of the second meiotic division.
- At ovulation, the **follicular wall**, composed of the remaining granulosa and thecal cells, is transformed into the **corpus luteum**. Under the influence of LH in the process of **luteinization**, the **granulosa lutein cells** (produce estrogen) and the **theca lutein cells** (produce progesterone) are formed.
- The **corpus luteum of menstruation** is formed in the absence of fertilization; it degenerates 10–12 days after ovulation to become the **corpus albicans**.
- The **corpus luteum of pregnancy** is formed after fertilization and implantation; it is a major source of **progesterone** and **luteotropins** (estrogen, insulin-like growth factor) during the first 8 weeks of pregnancy, after which it degenerates and leaves a permanent scar in the ovary.

CAPACITATION AND FERTILIZATION

- During **capacitation**, the mature spermatozoa acquire the ability to fertilize the oocyte within the female reproductive tract.
- **Fertilization** normally occurs in the ampulla of the uterine tube; it involves the capacitation of

spermatozoa and their penetration of the corona radiata to reach the oocyte.

- After capacitation, the spermatozoa bind to the **zona pellucida receptors**, which trigger the **acrosome reaction**. Enzymes released from the acrosome allow a single spermatozoon to penetrate the zona pellucida and **impregnate the oocyte**.
- During impregnation, the entire spermatozoon, except for the tail plasma membrane, becomes incorporated into the ooplasm, which triggers resumption of the **second meiotic division** (transforms the secondary oocyte into a mature oocyte).
- At least three types of **postfusion reactions** prevent other spermatozoa from entering the oocyte: fast depolarization of the oolemma, the cortical reaction (changes of polarity of the oolemma), and the zona reaction (which forms a **perivitelline barrier** by cross-linking proteins on the oocyte surface and degrading ZP receptors).
- The sperm head within the oocyte cytoplasm undergoes changes to form the **male pronucleus**. Nuclear membranes of both **male and female pronuclei** break down without fusion to form a diploid **zygote**. The zygote immediately enters its first mitotic division.

UTERINE TUBES

- The **uterine tubes** are paired bilateral structures that connect the uterus with the ovaries.
- Each uterine tube has four segments: **infundibulum** (a funnel-shaped end surrounded by **fimbriae** adjacent to the ovary), **ampulla** (common site of fertilization), **isthmus** (narrow segment adjacent to the uterus), and **intramural part** (traversing the uterine wall).
- The uterine tube wall consists of three layers: external **serosa**, thick **muscularis**, and highly folded **mucosa**.

- The mucosal lining is simple columnar epithelium composed of two cell types: ciliated and nonciliated (peg) cells.
- The oocyte (and zygote after fertilization) is propelled into the uterine cavity by a coordinated movement of cilia on the surface of mucosa and peristaltic muscular contractions of the uterine tube.

UTERUS

- The uterus is divided into the body (upper portion containing fundus) and the cervix (lower portion that projects into the vagina).
- The uterine wall is composed of endometrium (lining mucosa of the uterus), myometrium (smooth muscular layer), and perimetrium (a serous layer of visceral peritoneum).
- The endometrium is lined by simple columnar epithelium that invaginates into the underlying lamina propria (endometrial stroma), forming uterine glands.
- The endometrium consists of stratum basale and stratum functionale, which undergoes cyclic changes due to fluctuating levels of estrogens and progesterone during the menstrual cycle.
- The thickness of the endometrium, its glandular activity, and its vascular pattern are unique for each of the three phases (proliferative, secretory, and menstrual) of the menstrual cycle, which lasts an average of 28 days.
- The proliferative phase is influenced by estrogens produced by the growing follicles; the secretory phase is influenced by progesterone secreted from the corpus luteum; and if no implantation occurs, the menstrual phase represents ischemia of the stratum functionale that is being sloughed off during menses.
- If the embryo implants successfully, the endometrium undergoes decidualization (the process of conversion to

decidua) and, together with the trophoblastic cells from the embryo, initiates the development of the **placenta**.

- The endometrium of the **cervix** differs from the rest of the uterus in that it is not sloughed off during menstruation. **Cervical glands** modify the viscosity of the secreted mucus during each menstrual cycle.
- The part of the cervix projecting into the vagina has a **transformation zone** where simple columnar epithelium of the cervix changes abruptly into stratified squamous epithelium of the vagina.

PLACENTA

- The **placenta** allows for exchange of gases and metabolites between the maternal and fetal circulations; it consists of a **fetal portion (chorion)** and a **maternal portion (decidua basalis)**.
- After implantation, the invading **trophoblast** differentiates into the **syncytiotrophoblast** (multinucleate cytoplasmic mass that actively invades the decidua) and the **cytotrophoblast** (a mitotically active layer producing cells that fuse with the syncytiotrophoblast).
- Fetal and maternal blood remain separated by the **placental barrier**, which develops in the **tertiary chorionic villi** (projections of chorion containing syncytiotrophoblast, occasional cytotrophoblast cells, mesenchymal connective tissue, and fetal blood vessels).
- Villi are immersed in the maternal blood that fills vascular spaces in the placenta (**cotyledons**).
- The placenta is a major **endocrine organ** that supports the development of the fetus; it produces both **steroid hormones** (mainly progesterone) and **protein hormones** (e.g., hCG, hCS, relaxin, and leptin).

VAGINA AND EXTERNAL GENITALIA

- The **vagina** extends from the cervix to the vestibule; it is lined with **stratified squamous nonkeratinized epithelium** and lacks glands.
- **Female external genitalia (vulva)** consist of the **mons pubis** (formed by underlying adipose tissue), **labia majora** (longitudinal folds of skin containing adipose tissue, a thin layer of smooth muscle, and sebaceous and sweat glands), **labia minora** (core of connective tissue devoid of adipose tissue but contains large sebaceous glands), **clitoral complex**, **vestibule** (lined with stratified squamous epithelium with numerous small mucous glands), **opening of the vagina**, **hymen**, and **external urethral orifice**.
- The **clitoral complex** is composed of the **glans of the clitoris**, **body of the clitoris**, **left and right crus of the clitoris**, and **two bulbs of the vestibule**. They possess **erectile and nonerectile vascular tissue** homologous to the penis.

MAMMARY GLANDS

- The **mammary glands** develop in both sexes from **mammary ridges** in the embryo, but they undergo further development after puberty due to the hormonal influence of estrogen and progesterone.
- **Mammary glands** are modified **tubuloalveolar apocrine sweat glands** consisting of **terminal duct lobular units (TDLUs)**. Each TDLU is connected to collecting duct systems, which form the **lactiferous ducts** that open at the **nipple**.
- The TDLU of the mammary gland represents a cluster of small **secretory alveoli** (in active lactating gland) or **terminal ductules** (in inactive gland) surrounded by a hormonally sensitive **intralobular stroma**.

- The morphology of the secretory portion of the **inactive mammary gland** varies with the menstrual cycle.
- Mammary glands undergo dramatic proliferation and development during pregnancy in preparation for **lactation** under the influence of estrogen (proliferation of duct components) and progesterone (growth of alveoli).
- The protein component of milk is released by alveolar cells using **merocrine secretion**, whereas the lipid component of milk is released by **apocrine secretion**.

PLATE 23.1 ■ OVARY I

The **ovaries** are small, paired, ovoid structures that exhibit a **cortex** and **medulla** when sectioned. On one side is a hilum for the transit of neurovascular structures; on this same side is a **mesovarium** that joins the ovary to the broad ligament. The functions of the ovary are the production of *ova* and the synthesis and secretion of **estrogen** and **progesterone**.

In the cortex are numerous **primordial follicles** that are present at the time of birth and that remain unchanged until sexual maturation. The oogonia in these follicles are arrested in prophase of the first meiotic division. At puberty, under the influence of pituitary gonadotropins, the ovaries begin to undergo the cyclical changes designated the **ovarian cycle**. During each cycle, the ovaries normally produce a single oocyte that is ready for fertilization.

At the beginning of the ovarian cycle, under the influence of pituitary follicle-stimulating hormone (FSH), some of the primordial follicles begin to undergo changes that lead to the development of a **mature (Graafian) follicle**. These changes include proliferation of follicle cells and enlargement of the follicle. Although several primordial follicles begin these developmental changes, usually, only one reaches maturity and yields an oocyte. Occasionally, two follicles will mature and ovulate, leading to the possibility of dizygotic twin development. The discharge of the oocyte and its adherent cells is called **ovulation**. At ovulation, the oocyte completes the first meiotic division. Only if fertilization occurs does the oocyte complete the second meiotic division. Whether or not fertilization occurs, the other follicles that began to

proliferate in the same cycle degenerate, a process referred to as atresia.

Cortex, ovary, monkey, hematoxylin and eosin (H&E) $\times 120$.

The **cortex** of an ovary from a sexually mature individual is shown here. On the surface, there is a single layer of epithelial cells designated the **germinal epithelium** (*GEp*). This epithelium is continuous with the serosa (peritoneum) of the mesovarium. Contrary to its name, the epithelium does not give rise to the germ cells. The germinal epithelium covers a dense fibrous connective tissue layer, the **tunica albuginea** (*TA*); under the tunica albuginea are the **primordial follicles** (*PF*). It is not unusual to see follicles at various stages of development or atresia in the ovary. In this figure, along with the large number of primordial follicles, there are four **growing follicles** (*GF*), with a clearly visible eosinophilic layer of the zona pellucida (*ZP*), an atretic follicle (*AF*), and part of a large follicle on the *right*. The region of the large follicle shown in the figure includes the theca interna (*TI*), granulosa cells (*GC*), and part of the antrum (*A*).

Early primary follicles, ovary, monkey, H&E $\times 450$.

When a **primordial follicle** begins the changes leading to the formation of a mature follicle, the layer of squamous follicle cells becomes cuboidal (*FC*), as in this figure. In addition, the follicle cells proliferate and become multilayered. A follicle undergoing these early changes is called a **primary follicle**. Thus, an early primary follicle may still be unilaminar, but it is surrounded by cuboidal cells, and this distinguishes it from the more numerous unilaminar primordial follicles that are surrounded by squamous cells. Note the large nucleus (*N*) of the oocyte in the primary follicle. Some oocytes may not have visible nuclei (see cell label *X*) due to the plane of section.

Primordial follicles, ovary, monkey, H&E $\times 450$.

This figure shows several **primordial follicles** at higher magnification. Each follicle consists of an oocyte surrounded by a single layer of squamous follicle cells (*F*). The nucleus (*N*) of the oocyte is typically large, but the oocyte itself is so large that the nucleus is often not included in the plane of section, as in the oocyte marked *X*. The group of epithelioid-appearing cells (*arrowhead*) are follicle cells of a primordial follicle that has been sectioned in a plane that just grazes the follicular surface. In this case, the follicle cells are seen en face.

Late primary follicle, ovary, monkey, H&E ×450.

The **primary follicle** in this figure shows a multilayered mass of **follicle cells** (*FC*) surrounding the oocyte with a clearly visible large nucleus (*N*). The innermost layer of follicle cells is adjacent to a thick eosinophilic layer of extracellular homogeneous material called the **zona pellucida** (*ZP*). At this stage of development, the oocyte has also enlarged slightly. The entire structure surrounded by the zona pellucida is actually the oocyte.

Surrounding the follicles are elongate cells of the highly cellular connective tissue, referred to as *stromal cells*. The stromal cells surrounding a secondary follicle become disposed into two layers designated the theca interna and the theca externa. As seen in the previous figure, stromal cells become epithelioid in the cell-rich theca interna (*TI*).

 ZP, zona pellucida
 arrowhead, follicle cells seen en face

PLATE 23.2 ■ OVARY II

Atresia of follicles is a regular event in the ovary, beginning in embryonic life. In any section through the postpubertal ovary, follicles of various stages can be seen undergoing atresia. In atresia, the initial changes involve pyknosis of the nuclei of the follicle cells and dissolution of their cytoplasm. The follicle is then invaded by macrophages and other connective tissue cells. The oocyte degenerates, leaving behind the prominent zona pellucida. This may fold inward or collapse, but it usually retains its thickness and staining characteristics. When included in the plane of section, a distorted zona pellucida serves as a reliable diagnostic feature of an **atretic follicle**.

In atresia of large, nearly mature follicles, cells of the theca interna remain to form clusters of epithelioid cells in the ovarian cortex. These are referred to collectively as *interstitial glands* and continue to secrete steroid hormones.

Secondary follicles, ovary, monkey,
hematoxylin and eosin (H&E) $\times 120$.

Two follicles growing under the influence of follicle-stimulating hormone (FSH) are shown in the figure on the *left*. The more advanced follicle is a **secondary follicle**. The oocyte in this follicle is surrounded by several layers of **follicle cells** (*FC*) that, at this stage, are identified as granulosa cells. At a slightly earlier time, small lakes of fluid formed between the follicle cells, and these lakes have now fused into a well-defined larger cavity called the **follicular antrum** (*FA*), which is evident in the figure. The antrum is also filled with fluid and stains with the periodic acid-Schiff (PAS) reaction, although only lightly. The substance that stains with the PAS reaction has been retained as an eosinophilic precipitate in the antra of the secondary follicles shown here and in the figure on the *right*. Immediately above the obvious secondary follicle is a slightly smaller follicle. Because no antral spaces are evident between the follicle cells, it is appropriate to classify it as a **primary follicle**. In both follicles, but particularly in the larger follicle with the antrum, the surrounding stromal cells have become altered to form two distinctive layers designated **theca interna** (*TI*) and **theca externa** (*TE*). The theca interna is a more cellular layer, and the cells are epithelioid. When

seen with the electron microscope, they display the characteristics of endocrine cells, particularly steroid-secreting cells. In contrast, the theca externa is a connective tissue layer. Its cells are more or less spindle shaped.

In the figure on the *right*, a later stage in the growth of the secondary follicle is shown. The antrum (*FA*) is larger, and the oocyte is off to one side, surrounded by a mound of follicle cells called the *cumulus oophorus*. The remaining follicle cells that surround the antral cavity are referred to as the *membrana granulosa* (*MG*), or simply granulosa cells.

Atretic follicle, ovary, monkey, H&E $\times 65$.

Atretic follicles (*AF*) are shown here and at higher magnification in the adjacent figure on the *right*. The two smaller atretic follicles can be identified by virtue of the retained zona pellucida (*ZP*) labeled on the adjacent figure to the *right*. The two larger, more advanced follicles do not display the remains of a zona pellucida, but they do display other features of follicular atresia.

Atretic follicles, ovary, monkey, H&E $\times 120$.

During atresia of a more advanced follicle, the follicle cells tend to degenerate more rapidly than the cells of the theca interna, and the basement membrane separating the two becomes thickened to form a hyalinized membrane, the glassy membrane. Thus, the **glassy membrane** (*arrows*) separates an outer layer of remaining theca interna cells from the degenerating inner follicle cells. The remaining theca interna cells may show cytologic integrity (*RTI*); these intact theca cells remain temporarily functional in steroid secretion.

Atretic follicles, ovary, monkey, H&E $\times 120$.

Additional **atretic follicles** (*AF*) are shown here. Again, some show remnants of a zona pellucida (*ZP*), and two show a glassy membrane (*arrows*). Note that although the atresia in these follicles is well advanced, some of the cells external to one of the glassy membranes still retain their epithelioid character (*arrowhead*). These are persisting theca interna cells.

AF, atretic follicle

PLATE 23.3 ■ CORPUS LUTEUM

After the oocyte and its immediately surrounding cells (i.e., the cells of the cumulus oophorus) are discharged from the mature ovarian follicle (ovulation), the remaining follicle cells (membrana granulosa) and the adjacent theca interna cells differentiate into a new functional unit, the **corpus luteum**.

The cells of the corpus luteum, luteal cells, rapidly increase in size and become filled with lipid droplets. A lipid-soluble pigment in the cytoplasm of the cells, lipochrome, gives them their yellow appearance in fresh tissue. Electron micrographs of the luteal cells demonstrate that they have features typical of steroid-secreting cells, namely, abundant smooth-surfaced endoplasmic reticulum and mitochondria with tubular cristae. Two types of luteal cells are identified: Large, centrally located **granulosa lutein cells** are derived from the granulosa cells; smaller, peripherally located **theca lutein cells** are derived from the theca interna. A rich vascular network is established in the corpus luteum into which progesterone and estrogen are secreted by the lutein cells. These hormones stimulate the growth and differentiation of the uterine endometrium to prepare it for implantation of a fertilized ovum.

Corpus luteum, ovary, human, hematoxylin and eosin (H&E) $\times 20$.

This figure shows ovarian **cortex** shortly after ovulation. The *arrowhead* points toward the surface of the ovary at the site of ovulation. The cavity (*FC*) of the former follicle has been invaded by connective tissue (*CT*). The membrana granulosa has become plicated, and the granulosa cells, now transforming into cells of the corpus luteum, are called **granulosa lutein cells** (*TC*). The plication of the membrana granulosa begins just before ovulation and continues as the corpus luteum develops. As the corpus luteum becomes more plicated, the former follicular cavity becomes reduced in size. At the same time, blood vessels (*BV*) from the theca of the follicle invade the former cavity and the transforming membrana granulosa cells. Cells of the theca interna follow the blood vessels into the outermost depressions of the plicated structure. These theca interna cells become transformed into cells of the corpus luteum called *theca lutein cells*.

Corpus luteum, ovary, human, H&E $\times 20$.

A portion of a fully formed **corpus luteum** is shown here. Most endocrine cells are the **granulosa lutein cells** (*GLC*). These form a folded cell mass that surrounds the remains of the former follicular cavity (*FC*). External to the corpus luteum is the connective tissue of the ovary (*CT*) with a large quantity of blood vessels (*BV*). Keep in mind that the theca interna is derived from the connective tissue stroma of the ovary. The location of **theca lutein cells** (*TLC*) reflects this origin, and these cells can be found in the deep outer recesses of the glandular mass, adjacent to the surrounding connective tissue.

Corpus luteum, ovary, human, H&E $\times 65$ (on left) and $\times 240$ (on right).

A segment of the plicated **corpus luteum** is shown in the figure on the *left* at slightly higher magnification. As noted earlier, the main cell mass is composed of **granulosa lutein cells** (*GLC*). On one side of this cell mass is the connective tissue (*CT*) within the former follicular cavity; on the other side are the theca lutein cells. The same arrangement of cells is shown in the figure on the *right* at much higher magnification. The granulosa lutein cells contain a large, spherical nucleus (see also *GLC*, in the figure on that *right*) and a large amount of cytoplasm. The cytoplasm contains a yellow pigment (usually not evident in routine H&E sections), hence the name, corpus luteum. **Theca lutein cells** (*TLC*) also contain a spherical nucleus, but the cells are smaller than the granulosa lutein cells. Thus, when identifying the two cell types, aside from location, note that the nuclei of adjacent theca lutein cells generally appear to be closer to each other than nuclei of adjacent granulosa lutein cells. The connective tissue (*CT*) and small blood vessels that invaded the mass of granulosa lutein cells can be identified as the flattened and elongated components between the granulosa lutein cells.

The changes whereby the ruptured ovarian follicle is transformed into a corpus luteum occur under the influence of pituitary luteinizing hormone. In turn, the corpus luteum itself secretes progesterone, which has a profound effect on the estrogen-primed uterus. If pregnancy occurs, the corpus luteum remains functional; if pregnancy does not occur, the corpus luteum regresses after having reached a point of peak development, roughly 2 weeks after ovulation. The regressing cellular components of the corpus luteum are replaced

by fibrous connective tissue, and the structure is then called a *corpus albicans*.

TC, granulosa cells transforming into corpus luteum cells

TLC, theca lutein cells

PLATE 23.4 ■ UTERINE TUBE

The **uterine tubes** (oviducts, fallopian tubes) are joined to the uterus and extend to the ovaries, where they present an open flared end (abdominal ostium) for entry of the ovum at ovulation. The oviduct undergoes cyclical changes along with those of the uterus, but these are not nearly as pronounced. The epithelial cells increase in height during the middle of the cycle, just about the time the ovum will be passing through the tube and become reduced during the premenstrual period. Some of the epithelial cells are ciliated. The epithelial cells depend on the ovaries for their viability. Not only does the number of ciliated cells increase during the follicular phase of the ovarian cycle, but removal of the ovaries leads to atrophy of the epithelium and loss of ciliated cells.

The uterine tube varies in size and degree of mucosal folding along its length. The mucosal folds are evident in its distal portion, the **infundibulum**, as it nears the open end. Near the opening, the tube flares outward and is called the **infundibulum**. It has fringed folded edges called **fimbria**. The infundibulum leads proximally to the **ampulla**, which constitutes about two-thirds of the length of the oviduct, has the most numerous and complex mucosal folds, and is the site of fertilization. Mucosal folds are least numerous at the proximal end of the oviduct, near the uterus, where the tube is narrow and referred to as the **isthmus**. A **uterine** or **intramural** portion measures about 1 cm in length and passes through the uterine wall to empty into the uterine cavity.

Fertilization of the ovum usually occurs in the distal portion of the ampulla. For the first several days of development, as it navigates the complex pathway created by the mucosal folds, the embryo is transported proximally by the beating of the cilia of the ciliated epithelial cells and by peristaltic contractions of the well-developed muscularis layer that underlies the mucosa.

Uterine tube, human, hematoxylin and eosin (H&E) $\times 40$.

A cross section through the **ampulla** of the uterine tube is shown here. Many mucosal folds project into the lumen (*L*), and the complicated nature of the folds is evident by the variety of profiles that are seen. In addition to the **mucosa** (*Muc*), the remainder of the wall consists of a **muscularis** (*Mus*) and connective tissue.

The muscularis consists of smooth muscle that forms a relatively thick layer of circular fibers and a thinner outer layer of longitudinal fibers. The layers are not clearly delineated, and no sharp boundary separates them.

**Mucosal fold, uterine tube, human, H&E $\times 160$;
inset $\times 320$.**

The area enclosed by the *rectangle* in the previous figure is shown here at higher magnification. The specimen shows a longitudinal section through a lymphatic vessel (*Lym*). In other planes of section, the lymphatic vessels are difficult to identify. The fortuitously sectioned lymphatic vessel is seen in the core of the **mucosal fold**, along with a highly cellular connective tissue (*CT*) and the blood vessels (*BV*) within the connective tissue. The epithelium (*Ep*) lining the mucosa is shown in the *inset*. The ciliated cells are readily identified by the presence of well-formed cilia (*C*). Nonciliated cells, also called *peg cells* (*PC*), are readily identified by the absence of cilia; moreover, they have elongate nuclei and sometimes appear to be squeezed between the ciliated cells. The connective tissue (*CT*) contains cells whose nuclei are arranged typically in a random manner. They vary in shape, being elongated, oval, or round. Their cytoplasm cannot be distinguished from the intercellular material (*inset*). The character of the connective tissue is essentially the same from the epithelium to the muscularis, and for this reason, no submucosa is described.

BV, blood vessels
C, cilia
CT, connective tissue
Ep, epithelium
L, lumen
Lym, lymphatic vessel
Muc, mucosa
Mus, muscularis
PC, peg cells

PLATE 23.5 ■ UTERUS I

The **uterus** is a hollow, pear-shaped organ with a thick wall and, in the nonpregnant state, a narrow cavity. The uterine wall is composed of a mucosa, referred to as the **endometrium**; a muscularis, referred to as the **myometrium**; and, externally, a serosal cover, the **perimetrium**. The myometrium consists of smooth muscle and connective tissue and contains the large blood vessels that give rise to the vessels that supply the endometrium.

The uterus undergoes cyclical changes that are largely manifested by changes that occur in the endometrium. If implantation of a fertilized ovum does not occur after preparation for this event, the state of readiness is not maintained, and much of the endometrium degenerates and is sloughed off, constituting the menstrual flow. The part of the endometrium that is lost is referred to as the **stratum functionale**; the part that is retained is called the **stratum basale**. The stratum basale is the deeper part of the endometrium and adjoins the myometrium.

The myometrium also undergoes changes associated with implantation of a zygote. In the nonpregnant uterus, the smooth muscle cells are about 50 μm in length; during pregnancy, they undergo enormous hypertrophy, often reaching $>500\ \mu\text{m}$ in length. In addition, new muscle fibers develop after division of existing muscle cells and division and differentiation of undifferentiated mesenchymal cells. The connective tissue also increases to strengthen the uterine wall. Fibroblasts increase by division and secrete additional collagen and elastic fibers. After parturition, the uterus nearly returns to its normal size. Most muscle fibers return to their normal size, and some degenerate. Collagen secreted during pregnancy is digested by the very cells that secreted it, the fibroblasts. Similar, but less pronounced, proliferation and degeneration of fibroblasts and collagen occur in each menstrual cycle.

Uterus, human, hematoxylin and eosin (H&E) $\times 25$; inset $\times 120$.

After the **stratum functionale** (*SF*) is sloughed off, resurfacing of endometrium occurs. The epithelial resurfacing comes from the glands that remain in the **stratum basale** (*SB*). The gland epithelium simply proliferates and grows over the surface. This figure shows the endometrium as it appears when resurfacing is complete. The area

inscribed in the *upper small rectangle* is shown at higher magnification in the *inset* on the *right*. Note the simple columnar epithelium (*SEp*) that covers the endometrial surface and its similarity to the glandular epithelium (*GI*). The endometrium is relatively thin at this phase, and over half of it consists of the stratum basale. The area inscribed by the *lower small rectangle*, located in the region of the stratum basale, is shown at higher magnification in the *inset* in the next figure. The glandular epithelium of the deep portion of the glands is similar to that of the endometrial surface. Below the endometrium is the myometrium (*M*), in which a number of large blood vessels (*BV*) are present.

Endometrium, proliferative phase, uterus, human, H&E $\times 25$; inset $\times 120$.

Under the influence of estrogen, the various components of the endometrium proliferate (proliferative phase) so that the total thickness of the endometrium is increased. As shown in this figure, the endometrial glands (*GI*) become rather long and follow a fairly straight course within the **stratum functionale** (*SF*) to reach the surface. Several profiles of blood vessels (*BV*) that represent spiral arteries are visible in the lower two-thirds of the stratum functionale. The **stratum basale** (*SB*) remains essentially unaffected by the estrogen and appears much the same as in the previous figure. Below the stratum basale is the myometrium (*M*). In this figure, the stratum functionale (*SF*), on the other hand, has increased in thickness and constitutes about four-fifths of the endometrial thickness.

BV, blood vessels
GI, endometrial glands
M, myometrium

SEp, surface epithelium
SF, stratum functionale

PLATE 23.6 ■ UTERUS II

After **estrogen** brings about the uterine events designated the proliferative phase, another hormone, **progesterone**, influences uterine changes that constitute the secretory phase of the uterine cycle. This hormone brings the endometrium to a state of readiness for implantation, and as a consequence of its actions, the thickness of the endometrium increases further. There are conspicuous changes in the glands, primarily in the stratum functionale, where the glands take on a more pronounced corkscrew shape and secrete mucus that accumulates in sacculations along their length.

The **vasculature** of the endometrium also proliferates and degenerates in each menstrual cycle. **Radial arteries** enter the stratum basale of the endometrium from the myometrium and give rise to small, straight arteries that supply the stratum basale and continue into the endometrium to become the highly coiled **spiral arteries**. Arterioles derived from the spiral arteries supply the stratum functionale. The distal portion of the spiral arteries and the arterioles are sloughed with the stratum functionale during menstruation. Alternating contraction and relaxation of the basal portions of the spiral arteries prevent excessive blood loss during menstruation.

Uterus, human, hematoxylin and eosin (H&E) ×25.

This view of the endometrium in the secretory phase shows the **stratum functionale** (*SF*), the **stratum basale** (*SB*), and, in the *lower left* of the photomicrograph, a small amount of the **myometrium** (*M*). The uterine glands have been cut in a plane that is close to their long axes, and one gland (*arrow*) is seen opening at the uterine surface. Except for a few glands *near the center* of the figure that resemble those of the proliferative phase, most of the glands (*GI*) in this figure, including those that are labeled, show numerous shallow sacculations that give the profile of the glandular epithelium a serrated appearance. This is one of the distinctive features of the secretory phase. It is seen most advantageously in areas where the plane of section is close to the long axis of the gland. In contrast to the characteristic sinuous course of the glands in the stratum functionale, glands of the stratum basale more closely resemble those in the proliferative phase. They are not oriented in any noticeable relationship to the uterine surface, and many of their long profiles are even parallel to the plane of the surface.

**Endometrium, secretory phase, uterus,
human, H&E $\times 30$; inset $\times 120$.**

This slightly higher magnification view of the **stratum functionale** shows essentially the same characteristics of the **endometrial glands (Gl)** described earlier; it also shows other modifications that occur during the secretory phase. One of these is that the endometrium becomes edematous. The increase in endometrial thickness because of edema is reflected by the presence of empty spaces between cells and other formed elements. Thus, many areas of this figure, especially the area within and near the *rectangle*, show histologic signs of edema. In addition, in this phase, the glandular epithelial cells begin to secrete a mucoid fluid that is rich in glycogen. This product is secreted into the lumen of the glands, causing them to dilate. Typically, the glands of the secretory endometrium are more dilated than those of the proliferative endometrium.

The *rectangle* in this figure highlights two glands that are shown at higher magnification in the *inset*. Each of these glands contains some substance within the lumen. The mucoid character of the substance within one of the glands can be surmised from its blue staining. Although not evident in routine H&E paraffin sections, the epithelial cells also contain glycogen during the secretory phase, and as mentioned earlier, this becomes part of the secretion. The *arrowheads* indicate stromal cells; some of these cells undergo enlargement late in the secretory phase. These modified stromal cells, called *decidual cells*, play a role in implantation.

Gl, endometrial glands

PLATE 23.7 ■ CERVIX

The **cervix** is the narrow or constricted inferior portion of the uterus, part of which projects into the vagina. The cervical canal traverses the cervix and provides a channel connecting the vagina and the uterine cavity. The structure of the cervix resembles the rest of the uterus in that it consists of a mucosa (endometrium) and a myometrium. There are, however, some important differences in the mucosa.

The **endometrium** of the cervix does not undergo the cyclical growth and loss of tissue that is characteristic of the body and fundus of the uterus. Rather, the amount and character of the mucus secretion of its simple columnar epithelium vary at different times in the uterine cycle under the influence of ovarian hormones. At midcycle, there is a 10-fold increase in the amount of mucus produced; this mucus is thin and provides a favorable environment for sperm migration. At other times in the cycle, the mucus is thick and restricts the passage of sperm into the uterus.

The **myometrium** forms the major thickness of the cervix. It consists of interweaving bundles of smooth muscle cells in an extensive, continuous network of fibrous connective tissue.

Cervix, uterus, human, hematoxylin and eosin (H&E) $\times 15$.

The portion of the cervix that projects into the vagina, the **vaginal part** or **ectocervix**, is represented by the upper two-thirds of the *top* figure. The lower third of the micrograph reveals the portion of the **cervical canal (CC)**. The *lower* figure shows the continuation of the cervical canal (CC). The plane of section in both figures passes through the long axis of the cervical canal, which is narrowed and cone shaped at its two ends. The upper end, the **internal os**, communicates with the uterine cavity, and the lower end, the **external os (Os)**, communicates with the vagina. (For purposes of orientation, realize that only one side of the longitudinal section of the cervix is shown in these figures and that the actual specimen, as seen in a section, would present a similar image on the other side of the cervical canal.)

The **mucosa** (*Muc*) of the cervix differs according to the cavity it faces. The *two rectangles* in the *upper* figure delineate representative areas of the mucosa that are shown at higher magnification in the *upper right* and *middle right* figures, respectively.

The *bottom* figure emphasizes the nature of the **cervical glands** (*Gl*). The glands differ from those of the uterus in that they branch extensively. They secrete mucus into the cervical canal that serves to lubricate the vagina.

Ectocervix, uterus, human, H&E $\times 240$.

The surface of the **vaginal part of the cervix**, the **ectocervix**, is covered by stratified squamous epithelium (*SSEp*). The epithelium-connective tissue junction presents a relatively even contour in contrast to the irregular profile seen in the vagina. In other respects, the epithelium has the same general features as the vaginal epithelium. Another similarity is that the epithelial surface of the ectocervix undergoes cyclical changes similar to those of the vagina in response to ovarian hormones. The mucosa of the ectocervix, like that of the vagina, is devoid of glands.

Transformation zone, cervix, uterus, human, H&E $\times 240$.

The mucosa of the cervical canal is covered with columnar epithelium. An abrupt change from **stratified squamous epithelium** (*SSEp*) to **simple columnar epithelium** (*CEp*) occurs within the **transformation zone** (*TZ*) at the vaginal opening of the cervical canal (external os). The *lower rectangle* in the *top left* figure marks this site, known as the *transformation zone*, which is shown at a higher magnification here. Note the abrupt change in the epithelium at the transformation zone as well as the large number of lymphocytes and blood vessels (*BV*) present in this region.

Cervical glands, cervix, uterus, human, H&E $\times 500$.

This figure shows, at high magnification, portions of the **cervical gland** identified in the *rectangle* in the figure on the *left*. Note the tall epithelial cells and the lightly staining supranuclear cytoplasm, a reflection of the mucin that dissolved out of the cell during tissue

preparation. The crowding and the change in shape of the nuclei (*asterisk*) seen at the *upper part* of one of the glands in this figure are due to a tangential cut through the wall of the gland as it passed out of the plane of section. (It is not uncommon for cervical glands to develop into cysts as a result of obstruction in the duct. Such cysts are referred to as **nabothian cysts**.)

BV, blood vessels
CC, cervical canal
CEp, columnar epithelium
Gl, cervical glands
Muc, mucosa
Os, ostium of the uterus
SSEp, stratified squamous epithelium
TZ, transformation zone
asterisk, tangential cut of the epithelial surface

PLATE 23.8 ■ PLACENTA I

The **placenta** is a disc-shaped organ that serves for the exchange of materials between the fetal and maternal circulations during pregnancy. It develops primarily from embryonic tissue, the **chorion frondosum**. One side of the placenta is embedded in the uterine wall at the basal plate. The other side faces the amniotic cavity that contains the fetus. After childbirth, the placenta separates from the wall of the uterus and is discharged along with the contiguous membranes of the amniotic cavity.

The **umbilical cord** connects the fetus to the placenta. It contains two arteries that carry blood from the fetus to the placenta and a vein that returns blood from the placenta to the fetus. The umbilical arteries have thick muscular walls. These are arranged as two layers, an inner longitudinal layer and an outer circular layer. Elastic lamellae are poorly developed in these vessels and, indeed, may be absent. The umbilical vein is similar to the arteries, also having a thick muscular wall arranged as an inner longitudinal and an outer circular layer.

Placenta, human, hematoxylin and eosin (H&E)
×16.

A section extending from the amniotic surface into the substance of the placenta is shown here. This includes the **amnion** (*A*), the **chorionic plate** (*CP*), and the **chorionic villi** (*CV*). The amnion consists of a layer of simple cuboidal epithelium and an underlying layer of connective tissue. The connective tissue of the amnion is continuous with the connective tissue of the chorionic plate as a result of their fusion at an earlier time. The plane of fusion, however, is not evident in H&E sections; the separation (*asterisks*) in parts of this figure in the vicinity of the fusion is an artifact.

The chorionic plate is a thick connective tissue mass that contains the ramifications of the umbilical arteries and vein. These vessels (*BVp*) do not have the distinct organizational features characteristic of arteries and veins; rather, they resemble the vessels of the umbilical cord. Although their identification as blood vessels is relatively simple, it is difficult to distinguish which vessels are branches of an umbilical artery and which are tributaries of the vein.

The main substance of the placenta consists of chorionic villi of different sizes (see Plate 23.9, page 972). These emerge from the chorionic plate as large stem villi that branch into increasingly smaller villi. Branches of the umbilical arteries and vein (*BVv*, in

the next figure) enter the stem villi and ramify through the branching villous network. Some villi extend from the chorionic plate to the maternal side of the placenta and make contact with the maternal tissue; these are called **anchoring villi**. Other villi, the **free villi**, simply arborize within the substance of the placenta without anchoring onto the maternal side.

Placenta, human, H&E $\times 70$; inset $\times 370$.

The maternal side of the placenta is shown in this figure. The **basal plate** (*BP*) is on the *right side* of the illustration. This is the part of the uterus to which the chorionic villi anchor. Along with the usual connective tissue elements, the basal plate contains specialized cells called **decidual cells** (*DC*). The same cells are shown at higher magnification in the *inset*. Decidual cells are usually found in clusters and have an epithelial appearance. Because of these features, they are easily identified.

Septa from the basal plate extend into the portion of the placenta that contains the chorionic villi. The septa do not contain the branches of the umbilical vessels and, on this basis, can frequently be distinguished from stem villi or their branches.

PLATE 23.9 ■ PLACENTA II

As the embryo develops, the invasive activity of the syncytiotrophoblast erodes the maternal capillaries and anastomoses them with the trophoblast lacunae, forming the maternal blood sinusoids. These communicate with each other and form a single blood compartment, lined by syncytiotrophoblasts, called the *intervillous space*. At the end of the second week of development, cytotrophoblast cells form **primary chorionic villi**. They project into the maternal blood space. In the third week of development, invasion of the extraembryonic mesenchyme into the primary chorionic villi creates **secondary chorionic villi**. At the end of the third week, core mesenchyme differentiates into connective tissue and blood vessels that connect with the embryonic circulation. These **tertiary chorionic villi** constitute functional units for exchange of gases, nutrients, and waste products between maternal and fetal circulation without direct contact with each other. This separation of fetal and maternal blood is referred to as the *placental barrier*. Each tertiary villus consists of a connective tissue core surrounded by two distinct layers of trophoblast-derived cells. The outermost layer consists of the syncytiotrophoblast; immediately beneath it is a layer of cytotrophoblast cells. Starting at the fourth month, these layers become very thin to facilitate the exchange of products across the placental barrier. The thinning of the wall of the villus is due to the loss of the inner, cytotrophoblastic layer. At this stage, the syncytiotrophoblast forms numerous trophoblastic buds that resemble the primary chorionic villi; however, the cytotrophoblast and the connective tissue grow very rapidly into these structures, transforming them into tertiary villi. At term, the **placental barrier** consists of the syncytiotrophoblasts; a spare, thin (or discontinuous), inner cytotrophoblast layer; the basal lamina of the trophoblast; the connective tissue of the villus; the basal lamina of the endothelium; and the endothelium of the fetal placental capillary in the tertiary villus.

Tertiary chorionic villi, placenta, full-term, human, hematoxylin and eosin (H&E) $\times 280$.

This photomicrograph shows a section through the intervillous space of the placenta at term. It includes **chorionic villi (CV)** of different sizes and the surrounding **intervillous space (IS)**. The connective tissue of the villi contains branches and tributaries of the umbilical

vein (*UV*) and arteries. The intervillous space usually contains maternal blood (only a few maternal blood cells are seen here). The outermost layer of each chorionic villus derives from the fusion of cytotrophoblast cells. This layer, known as the **syncytiotrophoblast** (*S*), has no intercellular boundaries, and its nuclei are rather evenly distributed, giving this layer an appearance similar to that of cuboidal epithelium. In some areas, nuclei are gathered in clusters forming **syncytial knots** (*SK*); in other regions, the syncytiotrophoblast layer appears relatively free of nuclei (*arrows*). These stretches of the syncytiotrophoblast may be so attenuated in places that the villous surface appears devoid of a covering. The syncytiotrophoblast contains microvilli that project into the intervillous space. In well-preserved specimens, they may appear as a striated border (see *inset below*). The cytotrophoblast consists of an irregular layer of mononucleated cells that lies beneath the syncytiotrophoblast. In immature placentas, the cytotrophoblasts form an almost complete layer of cells. In this full-term placenta, only occasional **cytotrophoblast cells** (*C*) can be discerned. Most of the cells within the core of the villus are typical connective tissue fibroblasts and endothelial cells. Other cells have a visible amount of cytoplasm that surrounds the nucleus. These are considered to be fetal placental antigen-presenting cells or placental macrophages (*PM*) historically known as *Hofbauer cells*.

Secondary chorionic villi, placenta, midterm, human, H&E X320; inset X640.

This micrograph shows the **secondary chorionic villi** in the third week of embryonic development. These villi are composed of a **mesenchymal core** (*MC*) surrounded by two distinct layers of the trophoblast. Secondary villi have a much larger number of **cytotrophoblast cells** (*C*) than the mature tertiary villi and form an almost complete layer of cells immediately deep into the **syncytiotrophoblast** (*S*) (see *inset*). The syncytiotrophoblast not only covers the surface of the chorionic villi but also extends into the chorionic plate. Maternal red blood cells are present in the intervillous space.

Tertiary chorionic villi, placenta, full-term, human, H&E X320.

This higher magnification photomicrograph shows a cross section through **immature chorionic tertiary villi** surrounded by the intervillous space (*IS*). At this stage, chorionic villi are growing by

proliferation of their core mesenchyme, syncytiotrophoblast (*S*), and fetal endothelial cells. Note a discontinued layer of cytotrophoblast cells (*C*). The syncytiotrophoblast surrounding the chorionic villus (*center of the image*) forms **syncytial knots** (*SK*), which are present in the full-term mature placenta. They represent aggregation of syncytiotrophoblast nuclei on the surface of mature terminal villi. In addition to

fibroblasts, several fetal placental **antigen-presenting cells** (**placental macrophages**) (*PM*) can be identified by the amount of cytoplasm surrounding their nuclei.

C, cytotrophoblast cells
 CV, chorionic villi
 IS, intervillous space
 MC, mesenchymal core

 S, syncytiotrophoblast
 SK, syncytial knot
 UV, umbilical vein

PLATE 23.10 ■ VAGINA

The **vagina** is the fibromuscular tube of the female reproductive tract that leads to the exterior of the body. The wall of the vagina consists of three layers: a **mucosa**, a **muscularis**, and an **adventitia**. The epithelium of the mucosa is nonkeratinized stratified squamous. It undergoes changes that correspond to the ovarian cycle. The amount of glycogen stored in the epithelial cells increases under the influence of **estrogen**, whereas the rate of desquamation increases under the influence of **progesterone**. The glycogen liberated from the desquamated cells is fermented by **lactobacilli vaginalis**, producing lactic acid that acidifies the vaginal surface and inhibits colonization by yeasts and potentially harmful bacteria.

The vagina has certain histologic similarities to the proximal portion of the alimentary canal but is distinguished by the following features: The epithelium does not keratinize, and except for the deepest layers, the cells appear to be empty in routine hematoxylin and eosin (H&E) sections; the mucosa contains neither glands nor a muscularis mucosae; and the muscle is smooth and not well ordered. This can be contrasted with the oral cavity, pharynx, and upper part of the esophagus in which the muscle is striated. The more distal portion of the esophagus, which contains smooth muscle, can be distinguished easily from the vagina because it has a muscularis mucosae.

Vagina, human, H&E $\times 90$.

The mucosa of the vagina consists of a **stratified squamous epithelium** (*Ep*) and an underlying fibrous connective tissue (*CT*) that often appears more cellular than other fibrous connective tissue. The boundary between the two is readily identified because of the conspicuous staining of the closely packed small cells of the basal layer (*B*) of the epithelium. Connective tissue papillae project into the underside of the epithelium, giving the epithelial-connective tissue junction an uneven appearance. The papillae may be cut obliquely or in cross section and thus may appear as connective tissue islands (*arrows*) within the lower portion of the epithelium. The epithelium is characteristically thick, and although keratohyalin granules may be found in the superficial cells, keratinization does not occur in the human vaginal epithelium. Thus, nuclei can be observed throughout the entire thickness of the epithelium despite the fact that the cytoplasm of most of the cells above the basal layers appears empty. These cells are normally filled with large deposits of

glycogen that are lost in the processes of fixation and embedding of the tissue. The *rectangle* outlines a portion of the epithelium and connective tissue papillae that is examined at higher magnification (next figure). The muscular layer of the vaginal wall consists of smooth muscle arranged in two ill-defined layers. The outer layer is generally said to be longitudinally arranged (*SML*), and the inner layer is generally said to be circularly arranged (*SMC*), but the fibers are more usually organized as interlacing bundles surrounded by connective tissue. Many blood vessels (*BV*) are seen in the connective tissue.

Mucosa, vagina, human, H&E $\times 110$.

This is a higher magnification of the epithelium (*Ep*) that includes the area outlined by the *rectangle* in the *upper* figure (turned 90 degree). The obliquely cut and cross-sectioned portions of connective tissue papillae that appear as connective tissue islands in the epithelium are more clearly seen here (*arrows*), in some instances, outlined by the surrounding closely packed cells of the basal epithelial cell layer. Note, again, that the epithelial cells even at the surface still retain their nuclei and there is no evidence of keratinization.

Mucosa, vagina, human, H&E $\times 225$.

This is a higher magnification micrograph of the basal portion of the epithelium (*Ep*) between connective tissue papillae. Note the regularity and dense packing of the basal epithelial cells. They are the stem cells for the stratified squamous epithelium. Daughter cells of these cells migrate toward the surface and begin to accumulate glycogen and become less regularly arranged as they move toward the surface. The highly cellular connective tissue (*CT*) immediately beneath the basal layer (*B*) of the epithelium typically contains many lymphocytes (*L*). The number of lymphocytes varies with the stage of the ovarian cycle. Lymphocytes invade the epithelium around the time of menstruation and appear along with the epithelial cells in vaginal smears.

Muscularis, vagina, human, H&E $\times 125$.

This higher magnification micrograph of the smooth muscle of the vaginal wall emphasizes the irregularity of the arrangement of the muscle bundles. At the *right edge* of the figure is a bundle of smooth

muscle cut in a longitudinal section (*SML*). Adjacent to this is a bundle of smooth muscle cut in cross section (*SMC*). This bundle abuts on a longitudinally sectioned lymphatic vessel (*LV*). To the left of the lymphatic vessel is another longitudinal bundle of smooth muscle (*SML*). A valve (*Va*) is seen in the lymphatic vessel. A small vein (*V*) is present in the circular smooth muscle close to the lymphatic vessel.

PLATE 23.11 ■ MAMMARY GLAND INACTIVE STAGE

The mammary glands are branched tubuloalveolar glands that develop from epidermis and come to lie in the subcutaneous tissue (superficial fascia). They begin to develop at puberty in the female but do not reach a fully functional state until after pregnancy. The glands also develop in the male at puberty; the development is limited, however, and the glands usually remain in a stabilized state.

Mammary gland, inactive stage, human, hematoxylin and eosin (H&E) $\times 80$.

This figure is a section through an **inactive gland**. The parenchyma is sparse and consists mainly of duct elements. Several ducts (*D*) are shown in the *center* of the field. A small lumen can be seen in each. The ducts are surrounded by loose connective tissue (see *CT[L]*, in the next figure), and together, the ducts and surrounding connective tissue constitute a lobule. Two terminal duct lobular units (*TDLU*) are bracketed in this figure. Beyond the **lobular unit**, the connective tissue is more dense (*CT[D]*) and contains adipocytes (*A*). The two types of connective tissues can be distinguished at the low magnification of this figure.

Mammary gland, inactive stage, human, H&E $\times 200$; inset $\times 400$.

Additional details are evident at higher magnification. In distinguishing between the loose and dense connective tissue, recall that both extracellular and cellular features show differences that are evident in both the figure and the *inset*. Note the thicker collagenous fibers in the dense connective tissue in contrast to the much thinner fibers of the loose connective tissue. The loose connective tissue (*CT[L]*) contains far more cells per unit area and a greater variety of cell types. This figure shows a cluster of **lymphocytes** (*L*) and, at still higher magnification (*inset*), **plasma cells** (*P*) and individual lymphocytes (*L*). Both plasma cells and lymphocytes are cells with a rounded shape, but plasma cells are larger and show more cytoplasm. In addition, regions of plasma cell cytoplasm display basophilia. Elongate nuclei in spindle-shaped cells belong to fibroblasts. In contrast, although the cell types in the

dense connective tissue may also be diverse, a simple examination of equal areas of loose and dense connective tissue will, by far, show fewer cells in the dense connective tissue. Characteristically, the dense connective tissue contains numerous aggregates of adipocytes (*A*).

The epithelial cells within the resting lobular units are regarded as being chiefly duct elements (*D*). Usually, alveoli are not found; their precursors, however, are represented as cellular thickenings of the duct wall. The epithelium of the resting lobule is cuboidal; in addition, myoepithelial cells are present. Reexamination of the *inset* shows a thickening of the epithelium in one location, presumably the precursor of an alveolus, and **myoepithelial cells** (*M*) at the base of the epithelium. As elsewhere, the myoepithelial cells are on the epithelial side of the basement membrane. During pregnancy, the glands begin to proliferate. This can be thought of as a dual process in which ducts proliferate and alveoli grow from the ducts.

A, adipocytes
CT(D), dense connective tissue
CT(L), loose connective tissue
D, ducts
L, lymphocytes
M, myoepithelial cells
P, plasma cells
TDLU, terminal duct lobular unit

PLATE 23.12 ■ MAMMARY GLAND, LATE PROLIFERATIVE AND LACTATING STAGES

Mammary glands exhibit a number of changes during pregnancy in preparation for lactation. Lymphocytes and plasma cells infiltrate the loose connective tissue as the glandular tissue develops. As the cells of the glandular portion proliferate by mitotic division, the ducts branch and alveoli begin to develop at their growing ends. Alveolar development becomes most prominent in the later stages of pregnancy, and accumulation of secretory product takes place in the alveoli. At the same time, lymphocytes and plasma cells become prominent in the loose connective tissue of the developing lobules. Myoepithelial cells proliferate between the base of the epithelial cells and the basal lamina in both the alveolar and the ductal portion of the glands. They are most prominent in the larger ducts.

Both **merocrine** and **apocrine** secretion are involved in the production of milk. The protein component is synthesized, concentrated, and secreted by exocytosis in a manner typical for protein secretion. The lipid component begins as droplets in the cytoplasm that coalesce into large droplets in the apical cytoplasm of the alveolar cells and cause the apical plasma membrane to bulge into the alveolar lumen. The droplets are surrounded by a thin layer of cytoplasm and are enveloped in plasma membrane as they are released.

The initial secretion in the first days after birth is called **colostrum**. This premilk is an alkaline secretion with a higher protein, vitamin A, sodium, and chloride content than milk and a lower lipid, carbohydrate, and potassium content. Considerable amounts of antibodies are contained in colostrum, and these provide the newborn with passive immunity to many antigens. The antibodies are produced by the plasma cells in the stroma of the breast and are carried across the glandular cells in a manner similar to that for secretory immunoglobulin A (IgA) in the salivary glands and intestine. A few days after parturition, the secretion of colostrum stops and lipid-rich milk is produced.

Mammary gland, late proliferative stage, human, hematoxylin and eosin (H&E) $\times 90$; inset $\times 560$.

Whereas the development of the duct elements in the mammary gland occurs during the **early proliferative stage**, the development of the alveolar elements becomes

conspicuous in the late proliferative stage. This figure shows the **terminal duct lobular units (TDLU)** at the late proliferative stage. Individual lobular units are separated by narrow, dense **connective tissue septa (S)**. The connective tissue within the lobular unit is a typical loose connective tissue that is now more cellular, containing mostly plasma cells and lymphocytes. The alveoli are well developed, and many exhibit precipitated secretory product. Each of the alveoli is joined to a duct, although that relationship can be difficult to identify. The epithelium of the intralobular ducts is similar in appearance to the alveolar epithelium. The cells of both components are secretory. The alveoli as well as the intralobular ducts consist of a single layer of cuboidal epithelial cells subtended by myoepithelial cells. Often, what appear to be several alveoli are seen merging with one another (*asterisks*). Such profiles represent alveolar units opening into a duct. **Interlobular ducts (D)** are easy to identify as they are surrounded by dense connective tissue. In one instance, an intralobular duct can be seen emptying into an interlobular duct (*arrow*). The *inset* shows the secretory epithelium at a much higher magnification. Note that it is a simple columnar epithelium. The nucleus of a **myoepithelial cell (M)** is seen at the base of the epithelium. Generally, these cells are difficult to recognize. Also, as noted earlier, numerous plasma cells (*P*) and lymphocytes (*Ly*) are present in the loose connective tissue of the lobule.

Mammary gland, lactating stage, human, methyl green - osmium $\times 90$; inset $\times 700$.

The specimen shown here is from a **lactating mammary gland**. It is similar in appearance to the gland at the late proliferative stage but differs mainly to the extent that the alveoli are more uniform in appearance and their lumina are larger. As in the late proliferative stage, several alveoli can be seen merging with one another (*asterisks*). The use of osmium in this specimen stains the lipid component of the secretion. The *inset* reveals the lipid droplets within the epithelial cell cytoplasm as well as lipid that has been secreted into the lumen of the alveolus. The lipid first appears as small droplets within the epithelial cells. These droplets become larger and ultimately are secreted into the alveolar lumen along with milk proteins. The milk proteins are present in small vacuoles in the apical part of the cell but cannot be seen by light microscopic methods. They are secreted by exocytosis. The lipid droplets, in contrast, are large and surrounded by the apical cell membrane as they are pinched off to enter the lumen; thus, it is an apocrine secretion. Several **interlobular ducts**

(*D*) are evident. One of these ducts reveals a small branch, an ending intralobular duct (*arrows*) joining the interlobular duct.

HISTOLOGY

■ OVERVIEW OF THE EYE

The **eye** is a complex sensory organ that provides the sense of sight. In many ways, the eye is similar to a digital camera. Like the optical system of a camera, the **cornea** and **lens** of the eye capture and automatically focus light, whereas the iris automatically adjusts the diameter of the pupil to differences in illumination. The light detector in a digital camera, the charge-coupled device (CCD), consists of closely spaced photodiodes that capture, collect, and convert the light image into a series of electrical impulses. Similarly, the **photoreceptor cells** in the **retina** of the eye detect light intensity and color (wavelengths

of visible light that are reflected by different objects) and encode these parameters into electrical impulses for transmission to the brain via the **optic nerve**. The retina has other capabilities beyond those of a CCD: It can extract and modify specific impulses from the visual image before sending them to the central nervous system (CNS).

In other ways, the optical system of the eye is far more elaborate and complex than a camera. For example, the eye is able to track moving objects with coordinated eye movements. The eye can also protect, maintain, self-repair, and clean its transparent optical system.

Because the eyes are paired and spatially separated, two slightly different and overlapping views (visual fields) are sent to the brain. The brain integrates these two slightly different images from each eye into a single **three-dimensional (3D) image** in a process called **stereopsis**. The primary visual cortex located in the occipital lobes processes the differences between the two images to create the perception of depth. The final image is then projected onto the visual cortex. In addition, other complex neural mechanisms coordinate eye movements, enabling refinements in the perception of depth and distance. Therefore, the way in which we see the world around us largely depends on impulses processed within the retina and the analysis and interpretation of these impulses by the CNS.

■ GENERAL STRUCTURE OF THE EYE

The eye measures approximately 25 mm in diameter. It is suspended in the bony orbital socket by six extrinsic muscles that control its movement. A thick layer of adipose tissue partially surrounds and cushions the eye as it moves within the orbit. The extraocular muscles are coordinated so that the eyes move symmetrically around their own central axes.

Layers of the Eye

The wall of the eye consists of three concentric layers or coats.

The eyeball is composed of three concentric structural layers (Fig. 24.1):

FIGURE 24.1. Schematic diagram of the layers of the eye. The wall of the eyeball is organized in three separate concentric layers: an outer supporting fibrous layer, the corneoscleral coat; a middle vascular coat or uvea; and an inner layer consisting of the retina. Note that the retina has two layers: a neural retina (*yellow*) and a retinal pigment epithelium (*orange*). The photosensitive and nonphotosensitive parts of the neural retina occupy different regions of the eye. The photosensitive part of the retina is found in the posterior part of the eye and terminates anteriorly along the ora serrata. The nonphotosensitive region of the retina is located anterior to the ora serrata and lines the inner aspect of the ciliary body and the posterior surface of the iris. The vitreous body (*partially removed*) occupies considerable space within the eyeball.

- The **corneoscleral coat**, the outer or fibrous layer, includes the **sclera**, the white portion, and the **cornea**, the transparent portion.
- The **vascular coat**, the middle layer, or **uvea**, includes the **choroid** and the stroma of the **ciliary body** and **iris**.
- The **retina**, the inner layer, includes an outer pigment epithelium, the inner neural retina, and the epithelium of the

ciliary body and iris. The neural retina is continuous with the CNS through the **optic nerve**.

The corneoscleral coat consists of the transparent cornea and the white opaque sclera.

The **cornea** covers the anterior one-sixth of the eye (see Fig. 24.1). In this window-like region, the surface of the eye has a prominence or convexity. The cornea is continuous with the **sclera** [*Gr. skleros, hard*]. The sclera is composed of dense fibrous connective tissue that provides attachment for the extrinsic muscles of the eye. The corneoscleral coat encloses the inner two layers, except where it is penetrated by the optic nerve. The sclera constitutes the “white” of the eye. In children, it has a slightly blue tint because of its thinness; in elderly people, it is yellowish because of the accumulation of lipofuscin in its stromal cells. A noticeable feature of patients with jaundice is a yellow discoloration of the sclera (**scleral icterus**) caused by a high level of circulating bilirubin.

The uvea consists principally of the choroid, the vascular layer that provides nutrients to the retina.

Blood vessels and melanin pigment give the **choroid** an intense dark brown color. The pigment absorbs scattered and reflected light to minimize glare within the eye. The choroid contains numerous venous plexuses and layers of capillaries and is firmly attached to the retina (see Fig. 24.1). The anterior rim of the uveal layer continues forward, where it forms the stroma of the **ciliary body** and **iris**.

The **ciliary body** is a ring-like thickening that extends inward just posterior to the level of the corneoscleral junction. Within the ciliary body is the **ciliary muscle**, a smooth muscle that is responsible for lens **accommodation**. Contraction of the ciliary muscle changes the shape of the lens, which enables it to bring light rays from different distances to focus on the retina.

The **iris** is a contractile diaphragm that extends over the anterior surface of the lens. It also contains smooth muscle and melanin-containing pigment cells scattered in the connective tissue. The **pupil** is the central circular aperture of the iris. It appears black because one looks through the lens toward the

heavily pigmented back of the eye. In the process of **adaptation**, the iris contracts or expands, changing the size of the pupil in response to the amount of light that passes through the lens to reach the retina.

The retina consists of two components: the neural retina and pigment epithelium.

The **retina** is a thin, delicate layer (see Fig. 24.1) consisting of two components:

- The **neural retina** is the inner layer that contains light-sensitive receptors and complex neuronal networks.
- The **retinal pigment epithelium (RPE)** is the outer layer composed of simple cuboidal melanin-containing cells.

Externally, the retina rests on the choroid; internally, it is associated with the vitreous body. The neural retina consists largely of **photoreceptor cells**, called retinal **rods** and **cones**, and interneurons. Visual information encoded by the rods and cones is sent to the brain via impulses conveyed along the optic nerve.

Chambers of the Eye

The layers of the eye and the lens serve as boundaries for three chambers within the eye.

The chambers of the eye are as follows:

- The **anterior chamber** is the space between the cornea and the iris.
- The **posterior chamber** is the space between the posterior surface of the iris and the anterior surface of the lens.
- The **vitreous chamber** is the space between the posterior surface of the lens and the neural retina (Fig. 24.2). The cornea, the anterior and posterior chambers, and their contents constitute the anterior segment of the eye. The vitreous chamber, visual retina, RPE, posterior sclera, and uvea constitute the posterior segment.

FIGURE 24.2. Schematic diagram illustrating the internal structures of the human eye. This diagram shows the relationship between the layers of the eye and internal structures. The lens is suspended between the edges of the ciliary body. Note the posterior chamber of the eye, which is a narrow space between the anterior surface of the lens and the posterior surface of the iris. It communicates through the pupil with the larger anterior chamber that is bordered by the iris and the cornea. These spaces are filled with the aqueous humor produced by the ciliary body. The large cavity posterior to the lens, the vitreous chamber, is filled with a transparent jelly-like substance called the *vitreous body*. In this figure, most of the vitreous body has been removed to illustrate the distribution of the central retinal vessels on the surface of the retina. The other layers of the eyeball and the attachment of two of the extraocular muscles to the sclera are also shown.

The refractile media components of the eye alter the light path to focus it on the retina.

As light rays pass through the components of the eye, they are refracted. Refraction focuses the light rays on the photoreceptor cells of the retina. Four transparent components of the eye,

called the **refractile (or dioptric) media**, alter the path of the light rays:

- The **cornea** is the anterior window of the eye.
- The **aqueous humor** is the watery fluid located in the anterior and posterior chambers.
- The **lens** is a transparent, crystalline, biconvex structure suspended from the inner surface of the ciliary body by a ring of radially oriented fibers, the **zonule of Zinn**.
- The **vitreous body** is composed of a transparent gel-like substance that fills the vitreous chamber. It acts as a “shock absorber” that protects the fragile retina during rapid eye movement and helps maintain the shape of the eye. The vitreous body is almost 99% water with soluble proteins, hyaluronan, glycoproteins, widely dispersed collagen fibrils, and traces of other insoluble proteins. The fluid component of the vitreous body is called the **vitreous humor**.

The **cornea** is the chief refractive element of the eye. It is the single most powerful focusing element of the eye and has a refractive index of 1.376 (air has a refractive index of 1.0). The cornea provides about 80% of the eye's refractive power and is almost twice as powerful as the lens. The lens is second in importance to the cornea in refracting light rays. It is responsible for fine-tuning and focusing light onto the retina. Because of its elasticity, the shape of the **lens** can undergo slight changes in response to the tension of the ciliary muscle. These changes are important in **accommodation** for proper focusing on near objects. The aqueous humor and vitreous body have only minor roles in refraction. However, the aqueous humor plays an important role in providing nutrients to two avascular structures, the lens and cornea. In addition to transmitting light, the vitreous body helps maintain the position of the lens and helps keep the neural retina in contact with the RPE.

Development of the Eye

To appreciate the unusual structural and functional relationships in the eye, it is helpful to understand how it forms in the embryo.

The tissues of the eye are derived from neuroectoderm, surface ectoderm, and mesoderm.

By the 22nd day of development, the **eyes** are evident as shallow grooves—the **optic sulci** or **optic grooves**—located in the neural folds at the cranial end of the embryo. As the neural tube closes, the paired grooves form outpocketings called **optic vesicles** (Fig. 24.3a). As each optic vesicle grows laterally, the connection to the forebrain becomes constricted into an optic stalk, and the overlying surface ectoderm thickens and forms a **lens placode**. These events are followed by concomitant invagination of the optic vesicles and the lens placodes. The invagination of the optic vesicle results in the formation of a double-layered **optic cup** (Fig. 24.3b). The inner layer becomes the **neural retina**. The outer layer becomes the **RPE**. The mesenchyme surrounding the optic cup gives rise to the **sclera**.

FIGURE 24.3. Schematic drawing illustrating the development of the eye. a. Forebrain and developing optic vesicles as seen in a 4-mm

embryo. b. Bilayered optic cup and invaginating lens vesicle as seen in a 7.5-mm embryo. The optic stalk connects the developing eye to the brain. c. The eye as seen in a 15-week fetus. All the layers of the eye are established, and the hyaloid artery traverses the vitreous body from the optic disc to the posterior surface of the lens.

Invagination of the central region of each **lens placode** results in the formation of the **lens vesicle**. By the fifth week of development, the lens vesicle loses contact with the surface ectoderm and comes to lie in the mouth of the optic cup. After the lens vesicle detaches from the surface ectoderm, this same site again thickens to form the corneal epithelium. **Mesenchymal cells** from the periphery then give rise to the **corneal endothelium** and the **corneal stroma**.

Grooves containing blood vessels derived from mesenchyme develop along the inferior surface of each optic cup and stalk. Called the **choroid fissures**, the grooves enable the hyaloid artery to reach the inner chamber of the eye. This artery and its branches supply the inner chamber of the optic cup, lens vesicle, and mesenchyme within the optic cup. The hyaloid vein returns blood from these structures. The distal portions of the hyaloid vessels degenerate, but the proximal portions remain as the **central retinal artery** and **central retinal vein**. By the end of the seventh week, the edges of the choroid fissure fuse, and a round opening, the future pupil, forms over the lens vesicle.

The **outer layer of the optic cup** forms a single layer of pigmented cells (Fig. 24.3c). Pigmentation begins at the end of the fifth week. The **inner layer** undergoes a complex differentiation into the nine layers of the **neural retina**. The photoreceptor cells (rods and cones) as well as the bipolar, amacrine, and ganglion cells and nerve fibers are present by the seventh month. The macular depression, a future site of fovea centralis, begins to develop during the eighth month and is not complete until about 6 months after birth.

During the third month, the growth of the optic cup gives rise to the **ciliary body** and the future **iris**, which forms a double row of epithelium in front of the lens. The mesoderm located external to this region becomes the stroma of the ciliary body and iris. Both epithelial layers of the iris become pigmented. In the ciliary body, however, only the outer layer is pigmented. At birth, the iris is light blue in fair-skinned people because the

pigment is usually not present. The dilator and sphincter pupillary muscles develop during the sixth month as derivatives of the neuroectoderm of the outer layer of the optic cup.

The embryonic origins of the individual eye structures are summarized in Table 24.1.

TABLE 24.1

Embryonic Origins of the Individual Structures of the Eye

Source	Derivative
Surface ectoderm	Lens Epithelium of the cornea, conjunctiva, and lacrimal gland and its drainage system
Neural ectoderm	Vitreous body (derived partly from neural ectoderm of the optic cup and partly from mesenchyme) Epithelium of the retina, iris, and ciliary body Sphincter pupillae and dilator papillae muscles Optic nerve
Mesoderm	Sclera Stroma of the cornea, ciliary body, iris, and choroids Extraocular muscles Eyelids (except epithelium and conjunctiva) Hyaloid system (most of which degenerates before birth) Coverings of the optic nerve Connective tissue and blood vessels of the eye, bony orbit, and vitreous body

■ MICROSCOPIC STRUCTURE OF THE EYE

The three layers of the eye—the **corneoscleral coat**, the **vascular coat**, and the **retina**—are in turn composed of complex molecular layers and structures that reflect their various functions.

Corneoscleral Coat

The cornea is a unique tissue and the most powerful focusing element of the eye. It forms part of the anterior segment of the eye, protecting structures within the eye from the external environment. The most important characteristics of the cornea

include its mechanical strength and transparency to incoming light.

The cornea consists of five layers: three cellular layers and two noncellular layers.

The transparent **cornea** (see Figs. 24.1 and 24.2) is only 0.5 mm thick at its center and about 1 mm thick peripherally. It consists of three cellular layers that are distinct in both appearance and origin. These layers are separated by two important membranes that appear homogeneous when viewed in the light microscope. Thus, the **five layers of the cornea** seen in a transverse section are the following:

- **Corneal epithelium**
- **Bowman membrane** (anterior basement membrane)
- **Corneal stroma**
- **Descemet membrane** (posterior basement membrane)
- **Corneal endothelium**

The corneal epithelium is a nonkeratinized stratified squamous epithelium.

The **corneal epithelium** (Fig. 24.4) represents **nonkeratinized stratified squamous epithelium** that consists of approximately five layers of cells and measures about 50 μm in average thickness. It is continuous with the conjunctival epithelium that overlies the adjacent sclera. The epithelial cells adhere to neighboring cells via desmosomes that are present in short interdigitating processes. Like other stratified epithelia, such as that of the skin, the cells proliferate from a basal layer and become squamous at the surface. The basal cells are low columnar with round, ovoid nuclei; the surface cells acquire a squamous or discoid shape, and their nuclei are flattened and pyknotic (Fig. 24.4b). As the cells migrate to the surface, the cytoplasmic organelles gradually disappear, indicating a progressive decline in metabolic activity. The corneal epithelium has a remarkable regenerative capacity with a turnover time of approximately 7 days.

FIGURE 24.4. Photomicrograph of the cornea. **a.** This photomicrograph of a section through the full thickness of the cornea shows the corneal stroma and the two corneal surfaces covered by different types of epithelia. The corneal stroma does not contain blood or lymphatic vessels. $\times 140$. **b.** A higher magnification of the anterior surface of the cornea showing the *corneal stroma* covered by a stratified squamous (corneal) *epithelium*. The basal cells that rest on *Bowman membrane*, which is a homogeneous condensed layer of corneal stroma, are low columnar in contrast to the squamous surface cells. Note that one of the surface cells is in the process of desquamation (*arrow*). $\times 280$. **c.** A higher magnification photomicrograph of the posterior surface of the cornea covered by a thin layer of simple squamous epithelium (corneal *endothelium*). These cells are in direct contact with the aqueous humor of the anterior chamber of the eye. Note the very thick *Descemet membrane* (basal lamina) of the corneal endothelial cells. $\times 280$.

The actual stem cells for the corneal epithelium, called **corneolimbic stem cells**, reside at the **corneoscleral limbus**, the junction of the cornea and sclera. The microenvironment of this stem cell niche is important in maintaining the stem cell population. It also acts as a barrier that prevents migration of conjunctival epithelial cells to the corneal surface. **The corneolimbic stem cells may be partially or totally depleted by disease or extensive injury, resulting in abnormalities of the corneal surface that lead to conjunctivalization of the cornea, which is characterized by vascularization, appearance of goblet**

cells, and an irregular and unstable epithelium. These changes cause ocular discomfort and reduced vision. Minor injuries of the corneal surface heal rapidly by inducing stem cell proliferation and migration of cells from the corneoscleral limbus to fill the defect.

Numerous free nerve endings in the corneal epithelium provide it with extreme sensitivity to touch. Stimulation of these nerves (e.g., by small foreign bodies) elicits blinking of the eyelids, flow of tears, and, sometimes, severe pain. Microvilli present on the surface epithelial cells help retain the tear film over the entire corneal surface. Drying of the corneal surface may cause ulceration.

DNA in the corneal epithelial cells is protected from UV light damage by nuclear ferritin.

Despite constant exposure of the corneal epithelium to ultraviolet (UV) light, cancer of the corneal epithelium is extremely rare. Unlike the epidermis, which is also exposed to UV light, melanin is not present as a defense mechanism in the corneal epithelium. The presence of melanin in the cornea would diminish light transmission. Instead, it has recently been shown that corneal epithelial cell nuclei contain **ferritin**, an iron-storage protein. Experimental studies with avian corneas have shown that nuclear ferritin protects the DNA in the corneal epithelial cells from free radical damage caused by UV light exposure.

Bowman membrane is a homogeneous-appearing layer on which the corneal epithelium rests.

Bowman membrane (anterior basement membrane) is a homogeneous, faintly fibrillar lamina that is approximately 8–10 μm thick. It lies between the corneal epithelium and the underlying corneal stroma and ends abruptly at the corneoscleral limbus. The collagen fibrils of Bowman membrane have a diameter of about 18 nm and are randomly oriented. Bowman membrane imparts some strength to the cornea, but more significantly, it acts as a barrier to the spread of infections. It does not regenerate. Therefore, if damaged, an opaque scar forms that may impair

vision. In addition, changes in Bowman membrane are associated with recurrent corneal erosions.

The corneal stroma constitutes 90% of the corneal thickness.

The **corneal stroma**, also called **substantia propria**, is composed of about 60 thin lamellae. Each lamella consists of parallel bundles of collagen fibrils. Located between the lamellae are nearly complete sheets of slender, flattened fibroblasts. The collagen fibrils are very uniform, measuring approximately 23 nm in diameter and as long as 1 cm in length, and are arranged at approximately right angles to those in adjacent lamellae (Fig. 24.5). The ground substance of cornea contains **small leucine-rich proteoglycans (SLRPs)**, which comprise sulfated glycosaminoglycans—chiefly, keratan sulfate proteoglycan (**lumican**) and chondroitin sulfate proteoglycan (**decorin**). They are responsible for the 3D organization of collagen fibrils. Lumican regulates the normal collagen fibril assembly in the cornea and is critical to the development of a highly organized collagenous matrix.

FIGURE 24.5. Electron micrograph of the corneal stroma. This electron micrograph shows parts of three lamellae and a portion of a corneal fibroblast (*CF*) between two of the lamellae. Note that the collagen fibrils in adjacent lamellae are oriented at right angles to one another. $\times 16,700$.

Corneal transparency is achieved by the regular arrangement of small collagen fibrils and the spaces between them that are smaller than one-half of a wavelength of visible light.

The **transparency of the cornea** is directly related to the spaces between collagen fibrils containing glycosaminoglycans and the size of the collagen fibrils. If these spaces are smaller than one-half of a wavelength of visible light, the cornea is clear and transparent. The uniform spacing of type I collagen fibrils and lamellae, as well as the **orthogonal array** of the lamellae

(alternating layers at right angles), helps maintain corneal transparency. Proteoglycans (**lumican**), along with **type V collagen**, regulate the precise diameter and spacing of the type I collagen fibrils, maintaining corneal clarity. The necessity for uniformity of collagen fibrils explains the ratio of type V to type I collagen, which is much higher in the corneal stroma than in other tissues. **Corneal swelling after injury to the epithelium or endothelium** disrupts this precise array and leads to translucency or opacity of the cornea. The hazy appearance of the cornea is related to the enlargement of the spaces between collagen fibers. Lumican is overexpressed during the wound healing process following corneal injury. Normally, the cornea contains no blood vessels or pigments. During an inflammatory response involving the cornea, large numbers of neutrophils and lymphocytes migrate from the blood vessels of the corneoscleral limbus and penetrate the stromal lamellae.

Descemet membrane is an unusually thick basal lamina.

Descemet membrane (posterior basement membrane) is the basal lamina of corneal endothelial cells. It is intensely positive to periodic acid-Schiff (PAS) and can be as thick as 10 μm . Descemet membrane has a felt-like appearance and consists of an interwoven meshwork of fibers and pores. It separates the corneal endothelium from the adjacent corneal stroma. **Unlike Bowman membrane, Descemet membrane readily regenerates after injury.** It is produced continuously but slowly thickens with age. Descemet membrane also contributes to the diagnosis of **Wilson disease**, a rare inherited disorder of copper metabolism that causes excessive deposition of copper in organs and other tissues. A common ophthalmologic finding in individuals with Wilson disease is the presence of **Kayser-Fleischer rings**. These are caused by increased depositions of copper within Descemet membrane. A Kayser-Fleischer ring usually appears as a gold brown ring located in the periphery of the cornea.

Descemet membrane extends peripherally beneath the sclera as a trabecular meshwork forming the **pectinate ligament**. Strands from the pectinate ligament penetrate the ciliary muscle and sclera and may help maintain the normal curvature of the cornea by exerting tension on Descemet membrane.

The corneal endothelium provides for metabolic exchange between the cornea and the aqueous humor.

The **corneal endothelium** is a single layer of squamous cells covering the surface of the cornea that faces the anterior chamber (Fig. 24.4c). The cells are joined by well-developed zonulae adherentes, relatively leaky zonulae occludentes, and desmosomes. Virtually, all of the metabolic exchanges of the cornea occur across the endothelium. The endothelial cells contain many mitochondria and vesicles and an extensive rough-surfaced endoplasmic reticulum (rER) and Golgi apparatus. They demonstrate endocytotic activity and are engaged in active transport. Na^+/K^+ -activated ATPase is located on the lateral plasma membrane.

Transparency of the cornea requires precise regulation of the water content of the stroma. Physical or metabolic damage to the endothelium leads to rapid corneal swelling and, if the damage is severe, corneal opacity. Restoration of endothelial integrity is usually followed by deturgescence (dehydration necessary to maintain the transparency), although corneas can swell beyond their ability for self-repair. Such swelling can result in permanent focal opacities caused by aggregation of collagen fibrils in the swollen cornea. Essential sulfated glycosaminoglycans that normally separate the corneal collagen fibers are extracted from the swollen cornea.

Human corneal endothelium has a limited proliferative capacity. Severely damaged endothelium can be repaired only by transplantation of a donor cornea. Recent studies indicate that the periphery of the cornea represents a regenerative zone of the corneal endothelial cells. However, soon after corneal transplantation, endothelial cells exhibit contact inhibition when exposed to the extracellular matrix of Descemet membrane. The discovery that inhibitory factors released by Descemet membrane prevent proliferation of endothelial cells has focused current corneal research on the reversal or prevention of this inhibition with exogenous growth factors.

The sclera is an opaque layer that consists predominantly of dense connective tissue.

The **sclera** is a thick fibrous layer containing flat collagen bundles that pass in various directions and in planes parallel to its surface. Both the collagen bundles and the fibrils that form them are irregular in diameter and arrangement. Interspersed between the collagen bundles are fine networks of elastic fibers and a moderate amount of ground substance. Fibroblasts are scattered among these fibers (Plate 24.4, page 1016).

The opacity of the sclera, like that of other dense connective tissues, is primarily attributable to the irregularity of its structure. The sclera is pierced by blood vessels, nerves, and the optic nerve (see Fig. 24.2). It is 1 mm thick posteriorly, 0.3–0.4 mm thick at its equator, and 0.7 mm thick at the corneoscleral margin or limbus.

The sclera is divided into three rather ill-defined layers:

- The **episcleral layer (episclera)**, the external layer, is the loose connective tissue adjacent to the periorbital fat.
- The **substantia propria (sclera proper, also called Tenon capsule)** is the investing fascia of the eye and is composed of a dense network of thick collagen fibers.
- The **suprachoroid lamina (lamina fusca)**, the inner aspect of the sclera, is located adjacent to the choroid and contains thinner collagen fibers and elastic fibers as well as fibroblasts, melanocytes, macrophages, and other connective tissue cells.

In addition, the **episcleral space (Tenon space)** is located between the episcleral layer and substantia propria of the sclera. This space and the surrounding periorbital fat allow the eye to rotate freely within the orbit. The tendons of the extraocular muscles attach to the substantia propria of the sclera.

The corneoscleral limbus is the transitional zone between the cornea and the sclera that contains corneolimbal stem cells.

At the **junction of the cornea and sclera** (Fig. 24.6 and Plate 24.4, page 1016), Bowman membrane ends abruptly. The overlying epithelium at this site thickens from the 5 cell layers of the cornea to the 10–12 cell layers of the conjunctiva. The surface of the limbus is composed of two distinct types of epithelial

cells: One type constitutes the conjunctival cells, and the other constitutes the corneal epithelial cells. The basal layer of the limbus contains the **corneolimbal stem cells** that generate and maintain the corneal epithelium. These cells proliferate, differentiate, and migrate to the surface of the limbus and then toward the center of the cornea to replace damaged epithelial cells. As mentioned previously, this movement of cells at the corneoscleral limbus also creates a barrier that prevents conjunctival epithelium from migrating onto the cornea. At this junction, the corneal lamellae become less regular as they merge with the oblique bundles of collagen fibers of the sclera. An abrupt transition from the avascular cornea to the well-vascularized sclera also occurs here.

FIGURE 24.6. Schematic diagram of the structure of the eye. This drawing shows a horizontal section of the eyeball with color-coded layers of its wall. **Upper inset.** Enlargement of the anterior and posterior chambers is shown in more detail. Note the location of the iridocorneal angle and canal of Schlemm (scleral venous sinus), which

drains the aqueous humor from the anterior chamber of the eye. Lower inset. Typical organization of the cells and nerve fibers of the fovea.

The limbus region, specifically, the **iridocorneal angle**, contains the apparatus for the outflow of aqueous humor (Fig. 24.7). In the stromal layer, endothelium-lined channels called the **trabecular meshwork** (or **spaces of Fontana**) merge to form the **scleral venous sinus (canal of Schlemm)**. This sinus encircles the eye (see Figs. 24.6 and 24.7). The aqueous humor is produced by the ciliary processes that border the lens in the posterior chamber of the eye. The fluid passes from the posterior chamber into the anterior chamber through the valve-like potential opening between the iris and lens. The fluid then passes through the openings in the trabecular meshwork in the limbus region as it continues its course to enter the scleral venous sinus. Collecting vessels in the sclera, called **aqueous veins** (of Ascher) because they convey aqueous humor instead of blood, transport the aqueous humor to episcleral and conjunctival (blood) veins located in the sclera. **Changes in the iridocorneal angle** may lead to blockage in the drainage of aqueous humor, causing **glaucoma** (see Folder 24.1, page 990). The iridocorneal angle can be visualized during eye examination using a **gonioscope**, a specialized optical device that uses mirrors or prisms to reflect the light from the iridocorneal angle into the direction of the observer. In conjunction with a slit lamp or operating microscope, the ophthalmologist can examine this region to monitor various eye conditions associated with glaucoma. The iridocorneal angle can be also visualized using the **ultrasound biomicroscopy (UBM)**. This high-resolution imaging technique utilizes a high-frequency ultrasound transducer to visualize the narrowed iridocorneal angle in primary angle-closure glaucoma.

FIGURE 24.7. Photomicrograph of the ciliary body and iridocorneal angle. This photomicrograph of the human eye shows the anterior portion of the ciliary body and parts of the *iris* and *sclera*. The inner surface of the ciliary body forms radially arranged, ridge-shaped elevations, the *ciliary processes*, to which the *zonular fibers* are anchored. The ciliary body contains the *ciliary muscle*, connective tissue with blood vessels of the vascular coat, and the ciliary epithelium, which is responsible for the production of aqueous humor. Anterior to the ciliary body, between the iris and the cornea, is the *iridocorneal angle*. The scleral venous sinus (*canal of Schlemm*) is located in close proximity to this angle and drains the aqueous humor to regulate intraocular pressure. $\times 120$. The *inset* shows that the ciliary epithelium consists of two layers, the outer pigmented layer and the inner nonpigmented layer. $\times 480$.

FOLDER 24.1

CLINICAL CORRELATION: GLAUCOMA

Glaucoma is a clinical condition resulting from increased intraocular pressure over a sustained period of time. It can be caused by excessive secretion of aqueous humor or impedance of the drainage of aqueous humor from the anterior chamber. The internal tissues of the eye, particularly the retina, are nourished by the diffusion of oxygen and nutrients from the intraocular vessels. Blood flows normally through these vessels (including the capillaries and veins) when the hydrostatic pressure within the vessels exceeds the intraocular pressure. If the drainage of the aqueous humor is impeded, the intraocular pressure increases because

the layers of the eye do not allow the wall to expand. This increased pressure interferes with normal retinal nourishment and function, causing the retinal nerve fiber layer to atrophy (Fig. F24.1.1).

FIGURE F24.1.1. Glaucoma. This image shows a view of the fundus of the left eye in a patient with advanced glaucoma. As a result of the increased intraocular pressure, retinal nerve fibers undergo atrophy and shrink in size. Note a pale optic disc in the *center* of the image with a less pronounced rim due to atrophy of nerve fibers. Enlargement of the optic nerve cup (central area of the optic disc) is also visible and a characteristic finding for glaucoma. Compare this image to a normal retina in Figure 24.15. (Courtesy of Dr. Renzo A. Zaldivar.)

There are two major types of glaucoma:

- **Open-angle glaucoma** is the most common type of glaucoma and the leading cause of blindness among adults. The removal of aqueous humor is obstructed because of reduced flow through the trabecular

meshwork of the iridocorneal angle into the scleral venous sinus (canal of Schlemm).

- **Angle-closure glaucoma (acute glaucoma)** is less common and is characterized by a narrowed iridocorneal angle that obstructs the inflow of the aqueous humor into the scleral venous sinus. Usually, it is associated with a sudden, painful, complete blockage of the scleral venous sinus and can result in permanent blindness if not treated promptly.

Visual deficits associated with glaucoma include blurring of vision and impaired dark adaptation (symptoms that indicate loss of normal retinal function) and halos around lights (a symptom indicating corneal endothelial damage). If the condition is not treated, the retina will be permanently damaged, and blindness will occur. Treatment is directed toward lowering the intraocular pressure by decreasing the rate of production of aqueous humor or eliminating the cause of the obstruction of normal drainage. Topical **prostaglandin analogs** (i.e., latanoprost, bimatoprost, travoprost) are the first line of treatment for open-angle glaucoma. They are very effective in reducing intraocular pressure by increasing the drainage of aqueous humor into the canal of Schlemm.

Carbonic anhydrase inhibitors, which were used in the past to decrease the production of aqueous humor, have largely been replaced by prostaglandin analogs that have fewer systemic side effects.

There are two main types of laser surgery to treat glaucoma. They facilitate drainage of aqueous humor from the iridocorneal angle.

Laser **trabeculoplasty** utilizes a laser beam to induce focal scarring of the trabecular meshwork. This results in mechanical stretching of the surrounding untreated regions of the meshwork, which facilitates drainage of the aqueous humor. Trabeculoplasty is often used in open-angle glaucoma when medications are not effective or cause intolerable side effects. **Iridotomy** is used in patients with angle-closure glaucoma. The laser beam incises a small opening at the base of the iris, which widens the iridocorneal angle to allow better drainage of aqueous humor.

Vascular Coat (Uvea)

The iris, the most anterior part of the vascular coat, forms a contractile diaphragm in front of the lens.

The **iris** arises from the anterior border of the ciliary body (see Fig. 24.7) and is attached to the sclera about 2 mm posterior to the corneoscleral junction. The **pupil** is the central aperture of this thin disc. The iris is pushed slightly forward as it changes in size in response to light intensity. It consists of a highly vascularized connective tissue stroma that is covered on its

posterior surface by highly pigmented cells, the **posterior pigment epithelium** (Fig. 24.8). The basal lamina of these cells faces the posterior chamber of the eye. The degree of pigmentation is so great that neither the nucleus nor the character of the cytoplasm can be seen in the light microscope. Located beneath this layer is a layer of myoepithelial cells, the **anterior pigment myoepithelium**. The apical (posterior) portions of these myoepithelial cells are laden with melanin granules, which effectively obscure their boundaries with the adjacent posterior pigment epithelial cells. The basal (anterior) portions of myoepithelial cells possess processes containing contractile elements that extend radially and collectively make up the **dilator pupillae muscle** of the iris. The contractile processes are enclosed by a basal lamina that separates them from the adjacent stroma.

FIGURE 24.8. Structure of the iris. **a.** This schematic diagram shows the layers of the iris. Note that the pigmented epithelial cells are reflected as occurs at the pupillary margin of the iris. The two layers of pigmented epithelial cells are in contact with the dilator pupillae muscle. The incomplete layer of fibroblasts and stromal melanocytes is indicated on the anterior surface of the iris. **b.** Photomicrograph of the iris showing the histologic features of this structure. The *lens*, which

lies posterior to the iris, is included for orientation. The iris is composed of a *connective tissue* stroma covered on its posterior surface by the posterior pigment epithelium. The basal lamina (not visible) faces the posterior chamber of the eye. Because of intense pigmentation, the histologic features of these cells are not discernible. Just anterior to these cells is the anterior pigment myoepithelium layer (the *dashed line* separates the two layers). Note that the posterior portion of the myoepithelial cells contains melanin, whereas the anterior portion contains contractile elements forming the dilator pupillae muscle of the iris. The sphincter pupillae muscle is evident in the stroma. The color of the iris depends on the number of *stromal melanocytes* scattered throughout the connective tissue stroma. At the *bottom*, note the presence of the lens. ×570.

Constriction of the pupil is produced by smooth muscle cells located in the stroma of the iris near the pupillary margin of the iris. These circumferentially oriented cells collectively compose the **sphincter pupillae muscle**.

The anterior surface of the iris reveals numerous ridges and grooves that can be seen in clinical examination with the ophthalmoscope. When this surface is examined in the light microscope, it appears as a discontinuous layer of fibroblasts and melanocytes. The number of melanocytes in the stroma is responsible for variation in eye color. **The function of these pigment-containing cells in the iris is to absorb light rays. If there are few melanocytes in the stroma, the color of the iris is derived from light reflected from the pigment present in the cells of the iris's posterior surface, giving it a blue appearance. With increasing amounts of pigment present in the stroma, the iris color changes from blue to shades of greenish blue, gray, and, finally, brown.**

The sphincter pupillae is innervated by parasympathetic nerves; the dilator pupillae muscle is under sympathetic nerve control.

The **size of the pupil** is controlled by contraction of the sphincter pupillae and dilator pupillae muscles. The process of **adaptation** (increasing or decreasing the size of the pupil) ensures that only the appropriate amount of light enters the eye. Two muscles are actively involved in adaptation:

- The **sphincter pupillae muscle**, a circular band of smooth muscle cells (Plate 24.3, page 1014), is innervated by

parasympathetic nerves carried in the oculomotor nerve (cranial nerve III) and is responsible for reducing pupillary size in response to bright light. Failure of the pupil to respond when light is shined into the eye—“pupil fixed and dilated”—is an important clinical sign showing a lack of nerve or brain function.

- The **dilator pupillae muscle** is a thin sheet of radially oriented contractile processes of pigmented myoepithelial cells constituting the anterior pigment epithelium of the iris. This muscle is innervated by sympathetic nerves from the superior cervical ganglion and is responsible for increasing pupillary size in response to dim light.

Just before ophthalmoscopic examination, mydriatic agents such as atropine are given as eye drops to cause dilation of the pupil. Acetylcholine (ACh) is the neurotransmitter of the parasympathetic nervous system (it innervates the sphincter pupillae muscle); the addition of atropine blocks muscarinic acetylcholine receptors, temporally blocking the action of the sphincter muscle, and leaving the pupil wide open and unreactive to light originating from ophthalmoscope.

The ciliary body is the thickened anterior portion of the vascular coat and is located between the iris and the choroid.

The **ciliary body** extends about 6 mm from the root of the iris posterolaterally to the **ora serrata** (see Fig. 24.2). As seen from behind, the lateral edge of the ora serrata bears 17–34 grooves or crenulations. These grooves mark the anterior limit of both the retina and the choroid. The anterior third of the ciliary body has approximately 75 radial ridges or **ciliary processes** (see Fig. 24.7). The fibers of the zonule arise from the grooves between the ciliary processes.

The layers of the ciliary body are similar to those of the iris and consist of a stroma and an epithelium. The stroma is divided into two layers:

- An **outer layer** of smooth muscle, the **ciliary muscle**, makes up the bulk of the ciliary body.
- An **inner vascular region** extends into the ciliary processes.

The epithelial layer covering the internal surface of the ciliary body is a direct continuation of the two layers of the retinal epithelium (see Fig. 24.1).

The ciliary muscle is organized into three functional portions or groups of smooth muscle fibers.

The smooth muscle of the ciliary body has its origin in the scleral spur, a ridge-like projection on the inner surface of the sclera at the corneoscleral junction. The muscle fibers spread out in several directions and are classified into three functional groups on the basis of their direction and insertion:

- The **meridional (or longitudinal) portion** consists of the outer muscle fibers that pass posteriorly into the stroma of the choroid. These fibers function chiefly in stretching the choroid. It also may help open the iridocorneal angle and facilitate drainage of the aqueous humor.
- The **radial (or oblique) portion** consists of deeper muscle fiber bundles that radiate in a fan-like manner to insert into the ciliary body. Its contraction causes the lens to flatten and thus focus on distant vision.
- The **circular (or sphincteric) portion** consists of inner muscle fiber bundles oriented in a circular pattern that forms a sphincter. It reduces the tension on the lens, causing the lens to accommodate for near vision.

Examination of a histologic preparation does not clearly reveal the arrangement of the muscle fibers. Rather, the organizational grouping is based on microdissection techniques.

Ciliary processes are ridge-like extensions of the ciliary body from which zonular fibers emerge and extend to the lens.

Ciliary processes are thickenings of the inner vascular region of the ciliary body. They are continuous with the vascular layers of the choroid. Scattered macrophages containing melanin pigment granules and elastic fibers are present in these processes (Plate 24.3, page 1014). The processes and the ciliary body are covered by a double layer of columnar epithelial cells, the **ciliary epithelium**, which was originally derived from the two layers of

the optic cup. The ciliary epithelium has three principal functions:

- Secretion of **aqueous humor**
- Participation in the **blood - aqueous barrier** (part of the **blood - ocular barrier**)
- Secretion and anchoring of the **zonular fibers** that form the **suspensory ligament of the lens**

The inner cell layer of the ciliary epithelium has a basal lamina facing the posterior and vitreous chambers. The cells in this layer are nonpigmented. The cell layer that has its basal lamina facing the connective tissue stroma of the ciliary body is heavily pigmented and is directly continuous with the pigmented epithelial layer of the retina. The **double-layered ciliary epithelium** continues over the iris, where it becomes the posterior pigmented epithelium and anterior pigmented myoepithelium. The zonular fibers extend from the basal lamina of the nonpigmented epithelial cells of the ciliary processes and insert into the lens capsule (the thickened basal lamina of the lens).

The blood - aqueous barrier separates the interior environment of the eye from the blood entering the ciliary body.

The **cells of the nonpigmented layer** have all the characteristics of a fluid-transporting epithelium, including complex cell-to-cell junctions with a well-developed zonula occludens, extensive lateral and basal plications, and localization of Na^+/K^+ -ATPase in the lateral plasma membrane. In addition, they have an elaborate rER and Golgi complex, consistent with their role in the secretion of zonular fibers. Tight junctions (zonulae occludentes) between the nonpigmented ciliary epithelial cells are responsible for maintaining the **blood - aqueous barrier**. This barrier restricts free diffusion across the ciliary epithelium to maintain the unique environment of the aqueous humor, which is quite different from that of blood vessels and stroma of the ciliary body. The blood - aqueous barrier contributes to the nutrition and function of the cornea and the lens. **Disruption of the blood - aqueous barrier may be observed in ocular inflammation, intraocular surgery, trauma, or vascular diseases.**

The aqueous humor becomes cloudy because of the leakage of plasma proteins (fibrinogen) and migration of inflammatory cells from the stroma of the ciliary body and iris into the posterior and anterior chambers of the eye.

The **cells of the pigmented layer** have a less developed junctional zone and often exhibit large, irregular lateral intercellular spaces. Both desmosomes and gap junctions hold together the apical surfaces of the two cell layers, creating discontinuous “luminal” spaces called **ciliary channels**.

The aqueous humor is derived from plasma and maintains intraocular pressure.

The **aqueous humor** is secreted by the double-layered ciliary epithelium and originates from blood capillaries. It is similar in ionic composition to plasma but contains less than 0.1% protein (compared to 7% protein in plasma). The main functions of the aqueous humor are to maintain **intraocular pressure** and to provide nutrients and remove metabolites from the avascular tissues of the cornea and lens. The aqueous humor passes from the ciliary body toward the lens and then between the iris and the lens, before it reaches the anterior chamber of the eye (see Fig. 24.6). In the anterior chamber of the eye, the aqueous humor passes laterally to the angle formed between the cornea and the iris. Here, it penetrates the tissues of the limbus as it enters the labyrinthine spaces of the limbus' s trabecular meshwork in the iridocorneal angle and finally reaches the **canal of Schlemm**, which communicates with the veins of the sclera (see Folder 24.1). Normal turnover of the aqueous humor in the human eye is approximately once every 1.5 - 2 hours.

The choroid is the portion of the vascular coat that lies deep into the retina.

The **choroid** is a dark brown vascular sheet only 0.25 mm thick posteriorly and 0.1 mm thick anteriorly. It lies between the sclera and the retina (see Fig. 24.1).

Two layers can be identified in the choroid:

- **Choriocapillary layer**, an inner vascular layer
- **Bruch membrane**, a thin, amorphous hyaline membrane

The choroid is attached firmly to the sclera at the margin of the optic nerve. A potential space, the **perichoroidal space** (between the sclera and the retina), is traversed by thin, ribbon-like branching lamellae or strands that pass from the sclera to the choroid. These lamellae originate from the **suprachoroid lamina** (lamina fusca) and consist of large, flat melanocytes scattered between connective tissue elements, including collagen and elastic fibers, fibroblasts, macrophages, lymphocytes, plasma cells, and mast cells. The lamellae pass inward to surround the vessels in the remainder of the choroid layer. Free smooth muscle cells, not associated with blood vessels, are present in this tissue. Lymphatic channels called **epichoroid lymph spaces**, long and short posterior ciliary vessels, and nerves on their way to the front of the eye are also present in the suprachoroid lamina.

Most of the blood vessels decrease in size as they approach the retina. The largest vessels continue forward beyond the ora serrata into the ciliary body. These vessels can be seen with an ophthalmoscope. The large vessels are mostly veins that course in whorls before passing obliquely through the sclera as vortex veins. The inner layer of vessels, arranged in a single plane, is called the **choriocapillary layer**. The vessels of this layer provide nutrients to the cells of the retina. The fenestrated capillaries have lumina that are large and irregular in shape. In the region of the fovea, the choriocapillary layer is thicker, and the capillary network is denser. This layer ends at the ora serrata.

Bruch membrane, also called the **lamina vitrea**, measures 1-4 μm in thickness and lies between the choriocapillary layer and the pigment epithelium of the retina. It runs from the optic nerve to the ora serrata, where it undergoes modifications before continuing into the ciliary body. Bruch membrane is a thin, amorphous refractile layer. The transmission electron microscope (TEM) reveals that it consists of a multilaminar sheet containing a center layer of elastic and collagen fibers. Five different layers are identified in Bruch membrane:

- The basal lamina of the endothelial cells of the choriocapillary layer
- A layer of collagen fibers approximately 0.5 μm thick

- A layer of elastic fibers approximately 2 μm thick
- A second layer of collagen fibers (thus forming a “sandwich” around the intervening elastic tissue layer)
- The basal lamina of the RPE cells

At the ora serrata, the collagenous and elastic layers disappear into the ciliary stroma, and Bruch membrane becomes continuous with the basal lamina of the RPE of the ciliary body.

Retina

The retina represents the innermost layer of the eye.

The **retina**, derived from the inner and outer layers of the optic cup, is the innermost of the three concentric layers of the eye (see Fig. 24.1). It consists of two basic layers:

- The **neural retina** or **retina proper** is the inner layer that contains the photoreceptor cells.
- The **retinal pigment epithelium (RPE)** is the outer layer that rests on and is firmly attached through the Bruch membrane to the choriocapillary layer of the choroid.

A potential space exists between the two layers of the retina. The two layers may be separated mechanically in the preparation of histologic specimens. Separation of the layers, “**retinal detachment**” (see Folder 24.2), also occurs in the living state because of eye disease or trauma.

FOLDER 24.2

CLINICAL CORRELATION: RETINAL DETACHMENT

A potential space exists in the retina as a vestige of the space between the apical surfaces of the two epithelial layers of the optic cup. If this space expands, the neural retina separates from the retinal pigment epithelium (RPE), which remains attached to the choroid layer. This condition is called **retinal detachment**. As a result of retinal detachment, the photoreceptor cells are no longer supplied by nutrients from the underlying vessels in the choriocapillary plexus of the choroid.

Clinical symptoms of retinal detachment include visual sensations commonly described as a “shower of pepper” or floaters. These are caused by red blood cells extravasated from the capillary vessels

that have been injured during the retinal tear or detachment. In addition, some individuals describe sudden flashes of light as well as a “web” or “veil” in front of the eye in conjunction with the onset of floaters. A detached retina can be observed and diagnosed during ophthalmoscopic eye examination (Fig. F24.2.1).

FIGURE F24.2.1. Retinal detachment. This image shows a view of the fundus of the right eye in a patient with retinal detachment. The central retinal vessels emerging from the optic disc are in focus, but in the *area of the retinal detachment*, they appear to be out of focus. Because the area of retinal detachment is elevated (note multiple ridges and shadows), it is located anterior to the plane of focus of the ophthalmoscope. (Courtesy of Dr. Renzo A. Zaldivar.)

Another common retinal condition occurs with aging. As the vitreous body ages (in the sixth and seventh decades of life), it tends to shrink and pull away from the neural retina, which causes single or multiple tears in the neural retina.

If not repositioned quickly, the detached area of the retina will undergo necrosis, resulting in blindness. An argon laser is often used to repair retinal detachment by photocoagulating the edges of the detachment and producing scar tissue. This method prevents the

retina from further detachment and facilitates the repositioning of photoreceptor cells.

In the neural retina, two regions or portions that differ in function are recognized:

- The **nonphotosensitive region** (nonvisual part), located anterior to the ora serrata, lines the inner aspect of the ciliary body and the posterior surface of the iris (this portion of the retina is described in the sections on the iris and ciliary body).
- The **photosensitive region** (optic part) lines the inner surface of the eye posterior to the ora serrata, except where it is pierced by the optic nerve (see Fig. 24.1).

The site where the optic nerve joins the retina is called the **optic disc** or **optic papilla**. Because the optic disc is devoid of photoreceptor cells, it is a blind spot in the visual field. The **fovea centralis** is a shallow depression located about 2.5 mm lateral to the optic disc. It is the area of greatest visual acuity. The visual axis of the eye passes through the fovea. A yellow-pigmented zone called the **macula lutea** surrounds the fovea. In relative terms, the fovea is the region of the retina that contains the highest concentration and most precisely ordered arrangement of visual elements. The region of the retina surrounding the macula lutea may be affected in older individuals by age-related macular degeneration (see Folder 24.3).

FOLDER 24.3

CLINICAL CORRELATION: AGE-RELATED MACULAR DEGENERATION

Age-related macular degeneration (ARMD) is the most common cause of blindness in older individuals. Although the cause of this disease is still unknown, evidence suggests both genetic and environmental (ultraviolet [UV] irradiation, drugs) components. The disease causes loss of central vision, although peripheral vision remains unaffected. Two forms of ARMD are recognized: a dry (atrophic, nonexudative) form and a wet (exudative, neovascular) form. The latter is considered a complication of the first. **Dry ARMD** is the most common form (90% of all cases) and involves degenerative lesions localized in the area of the macula lutea. The degenerative lesions include **drusen**, which are focal thickenings of

Bruch membrane, atrophy, depigmentation of the RPE, and obliteration of capillaries in the underlying choroid layer. These changes lead to the deterioration of the overlying photosensitive retina, resulting in the formation of blind spots in the visual field (Fig. F24.3.1). **Wet ARMD** is a complication of dry ARMD caused by neovascularization of blind spots of the retina in the large drusen. These newly formed, thin, fragile vessels frequently leak and produce exudates and hemorrhages in the space just beneath the retina, resulting in fibrosis and scarring. These changes are responsible for the progressive loss of central vision over a short time. The treatment of wet ARMD includes conventional **laser photocoagulation** therapy and pharmacologic therapy with intravitreal injection of ranibizumab, a **vascular endothelial growth factor (VEGF) inhibitor**. Other surgical methods, such as **macular translocation**, have been recently introduced. In this procedure, the retina is detached, translocated, and reattached in a new location, away from the choroid neovascular tissue. Conventional laser treatment is then applied to destroy pathologic vessels without destroying central vision.

FIGURE F24.3.1. Photograph depicting the visual field in individuals with age-related macular degeneration. Note that central vision is absent because of the changes in the macula region of the retina. To maximize their remaining vision, individuals with this condition are instructed to use eccentric fixation of their eyes.

Layers of the retina

Ten layers of cells and their processes constitute the retina.

Before discussing the **ten layers of the retina**, it is important to identify the types of cells found there. This identification will aid in understanding the functional relationships of the cells. Studies of the retina in primates have identified at least 15 types of neurons that form at least 38 different types of synapses. For convenience, neurons and supporting cells can be classified into four groups of cells (Fig. 24.9):

FIGURE 24.9. Schematic drawing and photomicrograph of the layers of the retina. On the basis of histologic features that are evident in the photomicrograph *on right*, the retina can be divided into 10 layers. The layers correspond to the diagram *on left*, which shows the distribution of major cells of the retina. Note that light enters the retina and passes through its inner layers before reaching the photoreceptors of the rods and cones that are closely associated with

the retinal pigment epithelium. Also, the interrelationship between the bipolar neurons and ganglion cells that carry electrical impulses from the retina to the brain is clearly visible. Bruch membrane (lamina vitrea) separates the inner layer of the vascular coat (choroid) from the retinal pigment epithelium. $\times 440$.

- **Photoreceptor cells**—the retinal rods and cones
- **Conducting neurons**—bipolar neurons and ganglion cells
- **Association neurons** and others—horizontal, centrifugal, interplexiform, and amacrine neurons
- **Supporting (neuroglial) cells**—Müller cells, microglial cells, and astrocytes

The specific arrangement and associations of the nuclei and processes of these cells form 10 retinal layers that can be seen with the light microscope. [The layers of the retina can also be imaged and examined in living individuals using spectral-domain optical coherence tomography \(see Folder 24.4\).](#) The 10 layers of the retina, from outside inward, are as follows (see Fig. 24.9):

FOLDER 24.4

CLINICAL CORRELATION: CLINICAL IMAGING OF THE RETINA

The standard ophthalmoscopic examination of the eye has been recently supplemented by a new examination technique that utilizes **spectral-domain optical coherence tomography** (SD OCT). This noninvasive and noncontact examination is not only useful in visualizing the retinal surface, but it also provides a high-resolution cross-sectional image of the retina in vivo. All histologic layers of the retina can be easily differentiated with SD OCT (Fig. F24.4.1), and they can be objectively measured for tissue thickness and change. SD OCT technology is based on comparisons of spectral characteristics of the reflected light beam from the retina with those of the reference beam. For this purpose, an infrared laser beam (~ 840 nm wavelength with 50 nm bandwidth) is used that is able to produce images at 5- μ m resolution. The laser beam passes through the structures of the eye and is partially absorbed and partially reflected depending on tissue characteristics. The reflected light is detected by a multichannel spectrometer, and the interference pattern is compared to the reference beam using complex computer algorithms. The spectral differences are used to construct the cross-sectional (line) scans as shown in Figure F24.4.1 or the three-dimensional images of the retina as shown in Figure F24.4.2. Introduced in the 1990s, the SD OCT has revolutionized the management and diagnosis of many eye diseases. SD OCT established itself as an imaging modality of choice in **glaucoma** (measurement of

optic nerve and retinal nerve fiber layer) and retinal diseases. It is used for the early and accurate detection of **macular degeneration**, **retinal detachment**, **macular holes**, **epiretinal membranes**, and **optic disc pits** and for the detection of fluid accumulation within the retina that occurs in conditions such as **diabetic retinopathy**, **cystoid macular edema**, and **central serous choroidopathy**.

FIGURE F24.4.1. Spectral-domain optical coherence tomography (SD OCT) cross-sectional (line) image of the retina in a healthy eye. The *upper* image represents a normal cross-sectional image of the retina containing fovea and optic disc on the *right* side of the image. The optically transparent vitreous body is invisible and appears as the *black* region in the upper part of the image. Hyperreflective and hyporeflective bands of retinal tissue correspond to the histologic layers of the retina. Note the photoreceptor layer containing rods and cones as well the retinal pigment epithelium are well defined and are separated from the choroid layer containing blood vessels. (Courtesy of Drs. Andrew J. Barkmeier and Denise M. Lewison.)

FIGURE F24.4.2. Spectral-domain optical coherence tomography (SD OCT) three-dimensional image of the retina of a healthy right eye. The scan area is $\sim 12 \text{ mm} \times 9 \text{ mm}$ in size and includes a portion of the optic disc (*on the left*) and fovea (*on the right*). A three-dimensional data set is acquired from four scans (two vertical and two horizontal), which is then processed with a motion-correction technology (MCT) algorithm. The MCT algorithm analyzes and compares the vascular pattern in each of the scans and reduces artifacts and image distortions associated with eye movement. This image has two parts. The upper false-color image (optical densities are coded in different colors) shows the surface and thickness of all layers of the retina and represents a motion-corrected, three-dimensional volume rendering of the entire data set. The lower grayscale vascular map image (optical densities are coded in grayscale) is a two-dimensional image created by summing all the pixels in each column. It is curved to match the curvature of the eye. The letters S (for superior) and T (for temporal) on the eye orientation icon in the *lower right corner* provide reference to the positioning of the scan in the patient's eye. (Image courtesy of Dr. Pravin Dugel, Phoenix, Arizona.)

1. **Retinal pigment epithelium (RPE)**—the outer layer of the retina, actually not part of the neural retina but intimately associated with it
2. **Layer of rods and cones**—contains the outer and inner segments of photoreceptor cells
3. **Outer limiting membrane**—the apical boundary of Müller cells
4. **Outer nuclear layer**—contains the cell bodies (nuclei) of retinal rods and cones
5. **Outer plexiform layer**—contains the processes of retinal rods and cones and processes of the horizontal, amacrine, and bipolar cells that connect to them
6. **Inner nuclear layer**—contains the cell bodies (nuclei) of horizontal, amacrine, bipolar, and Müller cells
7. **Inner plexiform layer**—contains the processes of horizontal, amacrine, bipolar, and ganglion cells that connect to each other
8. **Ganglion cell layer**—contains the cell bodies (nuclei) of ganglion cells
9. **Layer of optic nerve fibers**—contains processes of ganglion cells that lead from the retina to the brain
10. **Inner limiting membrane**—composed of the basal lamina of Müller cells

Each of the layers is more fully described in the following sections (see corresponding numbers).

The cells of the retinal pigment epithelium (layer 1) have extensions that surround the processes of the rods and cones.

The **RPE** is a single layer of cuboidal cells about 14 μm wide and 10–14 μm tall. The cells rest on Bruch membrane of the choroid layer. The pigment cells are tallest in the fovea and adjacent regions, which account for the darker color of this region.

Adjacent RPE cells are connected by a junctional complex consisting of gap junctions and elaborate zonulae occludentes and adherentes. This junctional complex is the site of the **blood-retina barrier**. This barrier makes the retinal vessels impermeable to molecules larger than 20–30 kDa.

The pigment cells have cylindrical sheaths on their apical surface that are associated with, but do not directly contact, the tip of the photoreceptor processes of the adjacent rod and

cone cells. Complex cytoplasmic processes project for a short distance between the photoreceptor cells of the rods and cones. Numerous elongated melanin granules, unlike those found elsewhere in the eye, are present in many of these processes. They aggregate on the side of the cell nearest the rods and cones and are the most prominent feature of the cells. The nucleus with its many convoluted infoldings is located near the basal plasma membrane adjacent to Bruch membrane.

The cells also contain material phagocytosed from the processes of the photoreceptor cells in the form of lamellar debris (lipofuscin) contained in residual bodies or phagosomes. These lipofuscin granules reside in the basal cytoplasm of the RPE cell and are relatively difficult to detect in routine hematoxylin and eosin (H&E) preparation. Because the lipofuscin pigment is fluorescent, it can be clearly seen in the UV fluorescent microscope. A supranuclear Golgi apparatus and an extensive network of smooth-surfaced endoplasmic reticulum (sER) surround the melanin granules and residual bodies that are present in the cytoplasm.

The **RPE** serves several important functions, including the following:

- It **absorbs light** passing through the neural retina to **prevent reflection** and resultant glare.
- It isolates the retinal cells from blood-borne substances. It serves as a major component of the **blood-retina barrier** via tight junctions between RPE cells.
- It participates in **restoring photosensitivity** to visual pigments that were dissociated in response to light. The metabolic apparatus for visual pigment resynthesis is present in the RPE cells.
- It **phagocytoses and disposes of membranous discs** from the rods and cones of the retinal photoreceptor cells.

The rods and cones of the photoreceptor cell (layer 2) extend from the outer layer of the neural retina to the pigment epithelium.

The **rods** and **cones** are the outer segments of photoreceptor cells whose nuclei form the outer nuclear layer of the retina (Figs.

24.9 and 24.10). The light that reaches the photoreceptor cells must first pass through all of the internal layers of the neural retina. The rods and cones are arranged in a palisade manner; therefore, in the light microscope, they appear as vertical striations.

FIGURE 24.10. Schematic diagram of the ultrastructure of rod and cone cells. The outer segments of the rods and cones are closely

associated with the adjacent pigment epithelium.

The retina contains approximately 120 million rods and 7 million cones. They are not distributed equally throughout the photosensitive part of the retina. The highest density of cones is detected in the fovea centralis, which corresponds to the highest visual acuity and best color vision (Fig. 24.11). The highest density of rods is outside the fovea centralis, and their density steadily decreases toward the periphery of the retina. Rods are not present in the fovea centralis nor at the optic disc, which is devoid of any photoreceptors (see Fig. 24.11). The rods are about 2 μm thick and 50 μm long (ranging from about 60 μm at the fovea to 40 μm peripherally). The cones vary in length from 85 μm at the fovea to 25 μm at the periphery of the retina.

FIGURE 24.11. Distribution of rods and cones in the human eye. This graph shows the density of rods and cones per mm² across the retina. The peak number of cones occurs in the fovea centralis, where it reaches ~150,000 cones/mm². Rod density peaks about 20 degrees from the visual axis and is roughly the same as that of cones. Rods density decreases toward the periphery of the retina. Note that there are no photoreceptors at the optic disc.

Rods are sensitive in low light and produce black-and-white images; cones are less sensitive in low light and produce color images.

Functionally, the **rods** are more **sensitive to light** and are the receptors used during periods of low light intensity (e.g., at dusk or at night). The rod pigments have a maximum absorption at 496 nm of visual spectrum, and the image provided is one composed of gray tones (a “black-and-white picture”). In contrast, the **cones** exist in **three classes: L, M, and S** (long-, middle-, and short-wavelength sensitive, respectively) that cannot be distinguished morphologically. They are less sensitive to low light but more sensitive to red, green, and blue regions of the visual spectrum. Each class of cones contains a different visual pigment molecule that is activated by the absorption of light at the **blue** (420 nm), **green** (531 nm), and **red** (588 nm) ranges in the color spectrum. Cones provide a visual image composed of color by mixing the appropriate proportion of red, green, and blue light. For a description of different types of color blindness, see Folder 24.5.

FOLDER 24.5

CLINICAL CORRELATION: COLOR BLINDNESS

In individuals with normal color vision, the three primary colors (red, green, and blue) are combined to achieve the full spectrum of color vision. These individuals are called **trichromats** and possess three independent channels for conveying color information that are derived from three different classes of cones (L—red sensitive; M—green sensitive; and S—blue sensitive). Approximately 90% of trichromats can apperceive any given color from impulses generated in all three classes of cones. Some individuals have an impairment of normal color vision, which occurs when one of the cones is altered in its spectral sensitivity. For example, about 6% of trichromats matches colors with an unusual proportion of red and green. These individuals are called **anomalous trichromats**.

Color blindness is a condition in which individuals are missing or have a defect in a specific class of cones. True color-blind individuals are **dichromats** and have a defect either in the L, M, or S cones. In this condition, the affected cones are completely missing. Dichromats can only distinguish different colors by matching the impulses generated by the two remaining normal classes of cones.

Three major types of color blindness have been identified:

- **Protanopia** is characterized as a defect affecting the long-wavelength L cones responsible for red vision. The genes encoding L cone photoreceptor proteins are located on the X chromosome; therefore, protanopia is a sex-linked disorder affecting mainly

males (1% of the male population). These individuals have difficulty distinguishing between blue and green as well as red and green colors; thus, this color vision deficiency is a serious risk factor in driving (Fig. F24.5.1).

Normal color vision with all three L, M, and S cones

Protanopia, color vision with loss of L cones (loss of red vision)

Deuteranopia, color vision with loss of M cones (loss of green vision)

Tritanopia, color vision with loss of S cones (loss of blue vision)

FIGURE F24.5.1. Color blindness. This chart shows the six-color spectrum in normal color vision and in individuals with the three types of color blindness.

- **Deuteranopia** is characterized as a defect affecting the middle-wavelength M cones responsible for green vision. Deuteranopia is the most common form of color blindness, affecting about 5% of the male population. It is also a sex-linked disorder because the genes encoding M cone photoreceptor proteins are located in the same region of the X chromosome as the genes for L cones. Similar to protanopia, red and green are the main problem colors (see Fig. F24.5.1).
- **Tritanopia** is characterized as a defect affecting the short-wavelength S cones responsible for blue vision (see Fig. F24.5.1). The defect is autosomal and involves mutation of a single gene encoding S cone photoreceptor proteins that reside on chromosome 7. This color blindness occurs very rarely (1 in 10,000) and affects women and men equally.

Each rod and cone photoreceptor consists of three parts:

- The **outer segment** of the photoreceptor is roughly cylindrical or conical (hence, the descriptive name **rod** or **cone**). This portion of the photoreceptor is intimately related to microvilli projecting from the adjacent pigment epithelial cells.
- The **connecting stalk** contains a cilium composed of nine peripheral microtubule doublets extending from a basal body. The connecting stalk appears as the constricted region of the cell that joins the inner to the outer segment. In this region, a thin, tapering process called the **calyceal process** extends from the distal end of the inner segment to surround the proximal portion of the outer segment (see Fig. 24.10).
- The **inner segment** is divided into an outer **ellipsoid** and an inner **myoid portion**. This segment contains a typical complement of organelles associated with a cell that actively synthesizes proteins. A prominent Golgi apparatus, rER, and free ribosomes are concentrated in the myoid region. Mitochondria are most numerous in the ellipsoid region. Microtubules are distributed throughout the inner segment. In the outer ellipsoid portion, cross-striated fibrous rootlets may extend from the basal body among the mitochondria.

The outer segment is the site of photosensitivity, and the inner segment contains the metabolic machinery that supports the activity of the photoreceptor cells. The outer segment is considered a highly modified cilium because it is joined to the inner segment by a short connecting stalk containing a basal body (Fig. 24.12a).

FIGURE 24.12. Electron micrographs of portions of the inner and outer segments of cones and rods. **a.** This electron micrograph shows the junction between the inner and outer segments of the rod cell. The outer segments contain the horizontally flattened discs. The plane of this section passes through the connecting stalk and cilium. A centriole, a cilium and its basal body, and a calyceal process are identified. $\times 32,000$. **b.** Another electron micrograph shows a similar section of a cone cell. The interior of the discs in the outer segment of the cone is continuous with the extracellular space (*arrows*). $\times 32,000$. (Courtesy of Dr. Toichiro Kuwabara.)

With the TEM, 600 - 1,000 regularly spaced horizontal **membranous discs** are seen in the outer segment (Fig. 24.12). In rods, these discs are membrane-bound structures measuring about 2 μm in diameter. They are enclosed within the plasma membrane of the outer segment (see Fig. 24.12a). The parallel membranes of the discs are about 6 nm thick and are continuous at their ends. The central enclosed space is about 8 nm across. In both rods and cones, the membranous discs are formed from repetitive transverse infolding of the plasma membrane in the region of the outer segment near the cilium. Autoradiographic studies have demonstrated that rods form new discs by infolding of the plasma membrane throughout their life span. Discs are formed in cones in a similar manner but are not replaced on a regular basis.

Rod discs lose their continuity with the plasma membrane from which they are derived soon after they are formed. They then pass like a stack of plates, proximally to distally, along the length of the cylindrical portion of the outer segment until they are eventually shed and phagocytosed by the pigment epithelial cells. Thus, each rod disc is a membrane-enclosed compartment within the cytoplasm. Discs within the cones retain their continuity with the plasma membrane (Fig. 24.12b).

Rod cells contain the visual pigment rhodopsin; cone cells contain the visual pigment iodopsin.

Rhodopsin (also called **visual purple**) is a 39-kDa protein in rod cells that initiates the visual stimulus when it is bleached by light. Rhodopsin is present in globular form on the outer surface of the lipid bilayer (on the cytoplasmic side) of the membranous discs. In the cone cells, the visual pigment protein on the membranous discs is the photopigment **iodopsin**. Each cone cell is specialized to respond maximally to one of three colors: red, green, or blue. Both rhodopsin and iodopsin contain a membrane-bound subunit called an **opsin** and a second small light-absorbing component called a **chromophore**. The opsin of rods is **scotopsin**; the opsins of cones are **photopsins**. The chromophore of rods is a vitamin A-derived carotenoid called **retinal**. Thus, an adequate intake of vitamin A is essential for normal vision. Prolonged dietary deficiency of vitamin A leads to the inability to see in dim light (night blindness).

The interior of the discs of cones is continuous with the extracellular space.

The basic difference in the structure of the rod and cone discs—that is, continuity with the plasma membrane—is correlated with the slightly different means by which the visual pigments are renewed in rods and cones. Newly synthesized rhodopsin is incorporated into the membrane of the rod disc as the disc is being formed at the base of the outer segment. It then takes several days for the disc to reach the tip of the outer segment. In contrast, although visual proteins are constantly produced in retinal cones, the proteins are incorporated into cone discs located anywhere in the outer segment.

Vision is a process by which light striking the retina is converted into electrical impulses that are transmitted to the brain.

The impulses produced by light reaching the photoreceptor cells are conveyed to the brain by an elaborate network of nerves. The conversion of the incident light into electrical nerve impulses is called **visual processing** and involves several steps:

- A photochemical reaction occurs in the outer segment of the rods and cones. In the dark, **rhodopsin** molecules contain a chromophore called retinal in its isometric form of **11-*cis*-retinal**. When rods are exposed to light, the 11-*cis*-retinal undergoes a conformational change from a bent to a more linear molecule called **all-*trans*-retinal**. The conversion of 11-*cis*-retinal to all-*trans*-retinal activates opsin, which results in the release of all-*trans*-retinal into the rod's cytoplasm (a reaction called **bleaching**).
- The activated **opsin** interacts with a G-protein called **transducin**, which subsequently activates phosphodiesterase that breaks down **cyclic guanosine monophosphate (cGMP)**. In the dark, high levels of cGMP molecules produced in the photoreceptor cells by guanylyl cyclase are bound to the cytoplasmic surface of **cGMP-gated Na⁺ channels**, causing them to stay open. Steady influx of Na⁺ into the cells results in **depolarization** of the plasma membrane and continuous **release**

of the neurotransmitter (glutamate) at the synaptic junction with the bipolar neurons (Fig. 24.13).

FIGURE 24.13. Schematic diagram of visual processing in the photoreceptor cell. **a.** In the dark, high levels of cGMP generated by guanylyl cyclase are present in the cytoplasm of the rod. Some of the cGMP molecules are bound to the cytoplasmic surface of cGMP-gated Na⁺ channels, causing them to stay open and resulting in continuous influx of Na⁺ and depolarization of the plasma membrane. This results in a steady release of glutamate, a neurotransmitter, in the synaptic junctions with bipolar neurons. Also in the dark, rhodopsin molecules that contain 11-*cis*-retinal are inactive. **b.** After exposure to light, 11-*cis*-retinal undergoes a conformational change to all-*trans*-retinal. This conversion activates opsin (a reaction called *bleaching*) and releases all-*trans*-retinal into the rod's cytoplasm. The activated opsin interacts with G-protein, which subsequently activates phosphodiesterase that breaks down cGMP, effectively lowering the concentration of cGMP in the cell. In this condition, cGMP molecules dissociate from Na⁺ channels, resulting in their closing and hyperpolarization of the plasma membrane. This results in a decrease in glutamate secretion, which is detected by the bipolar neurons and conveyed as electrical impulses to the brain. The released retinal from opsin is converted to its original conformation in retinal pigment epithelial (RPE) cells by the RPE65 enzymatic complex and is recycled to the photoreceptor cell. *cGMP*, cyclic guanosine

monophosphate; *GDP*, guanosine diphosphate; *GMP*, guanosine monophosphate; *GTP*, guanosine triphosphate.

- A decrease in the concentration of cGMP within the cytoplasm of the inner segment of the photoreceptor cells is due to the action of phosphodiesterase. Dissociation of cGMP from Na⁺ channels effectively closes the channels and reduces the influx of Na⁺ into the cell, resulting in **hyperpolarization** of the plasma membrane. The hyperpolarization causes a **decrease of glutamate secretion** at the synapses with bipolar cells, which is detected and conveyed as electrical impulses (see Fig. 24.13).

Released retinal from opsin is converted back to its original conformation in the RPE cells and Müller cells.

After release, all-*trans*-retinal is converted to all-*trans*-retinol in the cytoplasm of rods and cones and then transported to the cytoplasm of RPE cells (from rods) or both RPE cells and Müller cells (from cones). The energy for this process is provided by the mitochondria located in the inner segment of these photoreceptors. Both Müller cells and RPE cells participate in a multistep conversion of all-*trans*-retinol to 11-*cis*-retinal, which is transported back to the photoreceptor cells for the resynthesis of rhodopsin. The **retinal pigment epithelium-specific protein 65 kDa (RPE65)** is involved in this conversion; thus, the visual cycle can begin again.

During the normal functioning of the photoreceptor cells, the membranous discs of the outer segment are shed and phagocytosed by the pigment epithelial cells (Fig. 24.14). It is estimated that each of these cells is capable of phagocytosing and disposing of about 7,500 discs per day. The discs are constantly turning over, and the production of new discs must equal the rate of disc shedding.

FIGURE 24.14. Electron micrograph of the retinal pigment epithelium in association with the outer segments of rods and cones. Retinal pigment epithelial (*RPE*) cells contain numerous elongated *melanin granules* that are aggregated in the apical portion of the cell, where the *microvilli* extend from the surface toward the outer segments of the rod and cone cells. The *retinal pigment epithelial* cells contain numerous mitochondria and *phagosomes*. The *arrow* indicates the location of the junctional complex between two adjacent cells. $\times 20,000$. (Courtesy of Dr. Toichiro Kuwabara.)

Discs are shed from both rods and cones.

In rods, after a period of sleep, a burst of **disc shedding** occurs as light first enters the eye. The time of disc shedding in cones is more variable. The shedding of discs in cones also enables the receptors to eliminate superfluous membrane. Although not fully understood, the shedding process in cones also alters the size of the discs so that the conical form is maintained as discs are released from the distal end of the cone.

The outer limiting membrane (layer 3) is formed by a row of zonulae adherentes between Müller cells.

The **outer limiting membrane** is not a true membrane. It is a row of zonulae adherentes that attaches the apical ends of Müller cells (i.e., the end that faces the pigment epithelium) to each other and to the rods and cones (see Fig. 24.9). Because Müller cells end at the base of the inner segments of the receptors,

they mark the location of this layer. Thus, the supporting processes of Müller cells, on which the rods and cones rest, are pierced by the inner and outer segments of the photoreceptor cells. This layer is thought to be a metabolic barrier that restricts the passage of large molecules into the inner layers of the retina.

The outer nuclear layer (4) contains the nuclei of the retinal rods and cones.

The region of the rod cytoplasm that contains the nucleus is separated from the inner segment by a tapering process of the cytoplasm. In cones, the nuclei are located close to the outer segments, and no tapering is seen. The cone nuclei stain lightly and are larger and more oval than rod nuclei. Rod nuclei are surrounded by only a thin rim of cytoplasm. In contrast, a relatively thick investment of cytoplasm surrounds the cone nuclei (see Fig. 24.10).

The outer plexiform layer (5) is formed by the processes of the photoreceptor cells and neurons.

The **outer plexiform layer** is formed by the processes of retinal rods and cones and the processes of horizontal, interplexiform, amacrine, and bipolar cells. The processes allow the electrical coupling of photoreceptor cells to these specialized interneurons via synapses. A thin process extends from the region of the nucleus of each rod or cone to an inner expanded portion with several lateral processes. The expanded portion is called a **spherule** in a rod and a **pedicle** in a cone. Normally, many photoreceptor cells converge onto one bipolar cell and form interconnecting neural networks. Cones located in the fovea, however, synapse with a single bipolar cell. The fovea is also unique in that the compactness of the inner neural layers of the retina causes the photoreceptor cells to be oriented obliquely. Horizontal cell dendritic processes synapse with photoreceptor cells throughout the retina and further contribute to the elaborate neuronal connections in this layer.

The inner nuclear layer (6) consists of the nuclei of horizontal, amacrine, bipolar, interplexiform, and Müller cells.

Müller cells form the scaffolding for the entire retina. Their processes invest the other cells of the retina so completely that they fill most of the extracellular space. The basal and apical ends of Müller cells form the inner and outer limiting membranes, respectively. Microvilli extending from their apical border lie between the photoreceptor cells of the rods and cones. Capillaries from the retinal vessels extend only to this layer. The rods and cones carry out their metabolic exchanges with extracellular fluids transported across the blood-retina barrier of the RPE.

The four types of conducting cells—bipolar, horizontal, interplexiform, and amacrine—found in this layer have distinct orientations (see Fig. 24.9):

- **Bipolar cells** and their processes extend to both the inner and outer plexiform layers. In the peripheral regions of the retina, the axons of bipolar cells pass to the inner plexiform layer where they synapse with several ganglion cells. Through these connections, the bipolar cells establish communication with multiple cells in each layer, except in the fovea, where they may synapse only with a single ganglion cell to provide greater visual acuity in this region.
- **Horizontal cells** and their processes extend to the outer plexiform layer where they intermingle with processes of bipolar cells. The cells have synaptic connections with rod spherules, cone pedicles, and bipolar cells. This electrical coupling of cells is thought to affect the functional threshold between rods and cones and bipolar cells.
- **Amacrine cells'** processes pass inward, contributing to a complex interconnection of cells. Their processes branch extensively to provide sites of synaptic connections with axonal endings of bipolar cells and dendrites of ganglion cells. Besides bipolar and ganglion cells, the amacrine cells synapse in the inner plexiform layer with interplexiform and other amacrine cells (see Fig. 24.9).
- **Interplexiform cells** and their processes have synapses in both inner and outer plexiform layers. These cells convey impulses from the inner plexiform to the outer plexiform layer.

The inner plexiform layer (7) consists of a complex array of intermingled neuronal cell processes.

The **inner plexiform layer** consists of synaptic connections between axons of the bipolar neurons and dendrites of ganglion cells. It also contains synapses between intermingling processes of amacrine cells and bipolar neurons, ganglion cells, and interplexiform neurons. The course of these processes is parallel to the inner limiting membrane, thus giving the appearance of horizontal striations to this layer (see Fig. 24.9).

The ganglion cell layer (8) consists of the cell bodies of large multipolar neurons.

The cell bodies of large **multipolar nerve cells**, measuring as much as 30 μm in diameter, constitute the ganglion cell layer. These nerve cells have lightly staining round nuclei with prominent nucleoli and Nissl bodies in their cytoplasm. An axonal process emerges from the rounded cell body, passes into the **nerve fiber layer**, and then enters **the optic nerve**. The dendrites extend from the opposite end of the cell to ramify in the inner plexiform layer. In the peripheral regions of the retina, a single ganglion cell may synapse with 100 bipolar cells. In marked contrast, in the macular region surrounding the fovea, the bipolar cells are smaller (some authors refer to them as *midget bipolar cells*), and they tend to make one-to-one connections with ganglion cells. Over most of the retina, the ganglion cells are only a single layer of cells. At the macula, however, they are piled as many as eight deep, although they are absent over the fovea itself. Scattered among the ganglion cells are small neuroglial cells with densely staining nuclei (see Fig. 24.9).

The layer of optic nerve fibers (9) contains axons of the ganglion cells.

The axonal processes of the ganglion cells form a flattened layer running parallel to the retinal surface. This layer increases in depth as the axons converge at the **optic disc** (Fig. 24.15). The axons are thin, nonmyelinated processes measuring as much as 5 μm in diameter (see Fig. 24.9). The retinal vessels, including the superficial capillary network, are primarily located in this layer.

FIGURE 24.15. Normal view of the fundus in ophthalmoscopic examination of the right eye. The site where the axons converge to form the optic nerve is called the *optic disc*. Because the optic disc is devoid of photoreceptor cells, it is a blind spot in the visual field. From the center of the optic nerve (clinically called the *optic cup*), *central retinal vessels* emerge. The artery divides into upper and lower branches, each of which further divides into nasal and temporal branches (note the nasal and temporal directions on the image). Veins have a similar pattern of tributaries. Approximately 17 degree or 2.5 times optic disc diameters lateral to the disc, the slightly oval-shaped, blood vessel-free, and pigmented area represents the *macula lutea*. The *fovea centralis*, a shallow depression in the center of the *macula lutea*, is also visible. (Courtesy of Dr. Renzo A. Zaldivar.)

The inner limiting membrane (layer 10) consists of a basal lamina separating the retina from the vitreous body.

The **inner limiting membrane** forms the innermost boundary of the retina. It serves as the basal lamina of Müller cells (see Fig. 24.9). In younger individuals, reflections from the internal limiting membrane produce a **retinal sheen** that is seen during ophthalmoscopic examination of the eye. In older individuals, a semitranslucent sheet of cells and extracellular matrix can be formed on the inner surface of the retina in conjunction with the

inner limiting membrane. This condition is called **epiretinal membrane (ERM)** or **macular pucker** and is responsible for variable clinical symptoms, including optical distortion and blurred vision. ERM is initially formed by cells from within the retina (RPE cells, Müller cells, and astrocytes) that begin proliferating and migrating onto the surface of the internal limiting membrane. Later, the membrane is infiltrated by macrophages, fibroblasts, and myofibroblasts. To prevent damage to the underlying retina, surgical removal of the ERM may be performed.

Specialized regions of the retina

The **fovea (fovea centralis)** appears as a small (1.5 mm in diameter), shallow depression located at the posterior pole of the visual axis of the eye. Its central region, known as the **foveola**, is about 200 μm in diameter (see Fig. 24.15). Except for the photoreceptor layer, most of the layers of the retina are markedly reduced or absent in this region (see Fig. 24.6). Here, the photoreceptor is composed entirely of cones (~4,000) that are longer and more slender and rod like than they are elsewhere. The fovea is the area of the retina specialized for the discrimination of details and color vision. The ratio between cones and ganglion cells is close to 1:1. Retinal vessels are absent in the fovea, allowing light to pass unobstructed into the cones' outer segments. The adjacent pigment epithelial cells and choriocapillaris are also thickened in this region.

The **macula lutea** is the area surrounding the fovea and is approximately 5.5 mm in diameter. It is yellowish because of the presence of yellow pigment (xanthophyll). The macula lutea contains approximately 17,000 cones and gains rods at its periphery. Retinal vessels are also absent in this region. Here, the retinal cells and their processes, especially the ganglion cells, are heaped up on the sides of the fovea so that light may pass unimpeded to this most sensitive area of the retina.

Vessels of the retina

The **central retinal artery** and **central retinal vein**, the vessels that can be seen and assessed with an ophthalmoscope, pass through the center of the optic nerve to enter the bulb of the eye at the optic disc (see Fig. 24.2 and pages 982–983, the

section on the development of the eye). The central retinal artery provides nutrients to the inner retinal layers. The artery branches immediately into the upper and lower branches, each of which divides again into nasal and temporal branches (see Fig. 24.15). Veins undergo a similar pattern of branching. The vessels initially lie between the vitreous body and the inner limiting membrane. As the vessels pass laterally, they also move deeper within the inner retinal layers. Branches from these vessels form a capillary plexus that reaches the inner nuclear layer and, therefore, provides nutrients to the inner retinal layers (layers 6-10; see pages 993-994). Nutrients to the remaining layers (layers 1-5) are provided by diffusion from the vascular choriocapillary layer of the choroid. The branches of the central retinal artery do not anastomose and, therefore, are classified as anatomic end arteries. Evaluation of the retinal vessels and appearance of the optic disc during ophthalmoscopy not only gives important information on the state of the eye but also may reveal early clinical signs of a number of conditions, including increased intracranial pressure, hypertension, glaucoma, and diabetes.

Crystalline Lens

Like the lens in a camera, the basic function of the eye lens is to transmit and focus light onto the retina.

The **lens** is a transparent, biconvex structure that has no vessels or nerves and is almost totally devoid of connective tissue, except for an enveloping capsule of basal lamina. It is suspended between the edges of the ciliary body by the **zonular fibers**. The pull of the zonular fibers keeps the lens in a flattened condition. Release of tension causes the lens to widen or **accommodate** to bend light rays originating close to the eye so that they focus on the retina.

The lens has three principal components (Fig. 24.16):

FIGURE 24.16. Structure of the lens. **a.** This schematic drawing of the lens suspended from ciliary processes by zonular fibers indicates its structural components. Note that the capsule of the lens is formed by the basal lamina of the lens fibers and the subcapsular epithelium located on the anterior surface of the lens. A strip of capsule was removed on this drawing to show underlying epithelium. Also note the location of the germinal zone (*yellow*) at the lens equator, where cells divide and differentiate into the lens fiber cells. The organelle-free center of the lens is occupied by the lens nucleus. **b.** This high-magnification photomicrograph of the germinal zone of the lens (near its equator) shows the active process of lens fiber formation from the *subcapsular epithelium*. Note the thick *lens capsule* and the underlying layer of nuclei of lens fibers during their differentiation. The *mature lens fibers* do not possess nuclei. $\times 570$.

- The **lens capsule** is a thick basal lamina that surrounds the outer surface of the lens. It originates as the basal lamina of the embryonic lens vesicle. The anterior part of the capsule is thick, measuring approximately 10–20 μm , and is produced by the anterior lens cells. The posterior part of the capsule is much thinner, measuring approximately 5–10 μm . The lens capsule, composed primarily of type IV collagen and proteoglycans (i.e., laminin, entactin, perlecan), is elastic. It is thickest at the equator where the zonular fibers attach to it.

- The **subcapsular epithelium** is derived from the epithelial cells of the anterior part of the embryonic lens vesicle. It represents a single cuboidal layer of **lens epithelial cells** present only on the anterior surface of the lens. The epithelial cells of the posterior part of the vesicle elongate anteriorly and form the **primary lens fibers** that fill the cavity of the optic vesicle.
- **Secondary lens fibers (lens fiber cells)** are formed at the periphery near the **lens equator**. Here, epithelial cells proliferate and migrate along the posterior lens capsule to differentiate into mature lens fiber cells. In the center of the lens, epithelial cells are quiescent. As lens fiber cells differentiate, they undergo massive elongation and lose all of their organelles, including nuclei, forming the **organelle-free zone**.

Gap junctions connect the cuboidal cells of the subcapsular epithelium. They have few cytoplasmic organelles and stain faintly. The apical region of the cell is directed toward the internal aspect of the lens and the **lens fibers**, with which they form **junctional complexes**. The lens increases in size during normal growth and then continues to produce new lens fibers at an ever-decreasing rate throughout life. The new lens fibers develop from the subcapsular epithelial cells located near the equator (see Fig. 24.16) are laid down peripherally as concentric lamellae in an onion-like arrangement. Cells in this region increase in height and then differentiate into lens fibers.

As the lens fibers develop, they become highly elongated and appear as thin, flattened structures. They lose their nuclei and other organelles as they become filled with proteins called **crystallins**. Mature lens fibers attain a length of 7–10 mm, a width of 8–10 μm , and a thickness of 2 μm . In the adult lens, only lens fibers in the outermost region maintain their nuclei and organelles. Near the center, in the **lens nucleus**, the fibers are compressed and condensed to such a degree that individual fibers are impossible to recognize. The lens nucleus is an organelle-free zone and is composed of primary lens fiber cells laid down during embryonic and fetal development. The lens fibers are joined at their apical and basal ends by specialized junctions called **sutures**. Despite its density and protein

content, the lens is normally transparent (see Fig. 24.16). The high density of lens fibers makes it difficult to obtain routine histologic sections of the lens that are free from artifacts.

Changes in the lens are associated with aging.

With increasing age, the lens gradually loses its elasticity and ability to accommodate. This condition, called **presbyopia**, usually occurs in the fourth decade of life. It is easily corrected by wearing reading glasses or using a magnifying lens.

Loss of transparency of the lens or its capsule is also a relatively common condition associated with aging. This condition, called **cataract**, may be caused by conformational changes or cross-linking of proteins. The development of a cataract may also be related to disease processes, metabolic or hereditary conditions, trauma, or exposure to a deleterious agent (such as ultraviolet radiation). Cataracts that significantly impair vision can usually be corrected surgically by removing the lens and replacing it with a plastic lens implanted in the posterior chamber.

Vitreous Body

The vitreous body is the transparent jelly-like substance that fills the vitreous chamber in the posterior segment of the eye.

The **vitreous body** is loosely attached to the surrounding structures, including the inner limiting membrane of the retina. The main portion of the vitreous body is a homogeneous gel containing approximately 99% water (the vitreous humor), collagen, glycosaminoglycans (principally hyaluronan), and a small population of cells called **hyalocytes**. These cells are believed to be responsible for the synthesis of collagen fibrils and glycosaminoglycans. Hyalocytes in routine H&E preparations are difficult to visualize. Often, they exhibit a well-developed rER and Golgi apparatus. Fibroblasts and tissue macrophages are sometimes seen in the periphery of the vitreous body. The **hyaloid canal** (or **Cloquet canal**), which is not always visible, runs through the center of the vitreous body from the optic disc to the posterior lens capsule. It is the remnant of the pathway of the hyaloid artery of the developing eye.

■ ACCESSORY STRUCTURES OF THE EYE

The primary functions of the eyelids are to cover, protect, and lubricate the eyes.

The **eyelids** represent folds of modified skin containing highly modified epidermal appendages to cover, protect, and lubricate the anterior portions of the eyes. The anterior surface of the eyelid is covered by thin **skin**, and its posterior surface is lined by a specialized mucous membrane, the **conjunctiva**. The skin of the eyelids is loose and elastic to accommodate their movement. Within each eyelid is a flexible support, the **tarsal plate**, consisting of dense fibrous and elastic tissue. In the upper eyelid, the lower free edge of the tarsal plate extends to the lid margin, and its superior border serves for the attachment of smooth muscle fibers of the **superior tarsal muscle (of Müller)**. The undersurface of the tarsal plate is covered by the conjunctiva (Fig. 24.17). The striated **orbicularis oculi muscle**, a facial expression muscle, forms a thin oval sheet of circularly oriented skeletal muscle fibers overlying the tarsal plate. In addition, the connective tissue of the upper eyelid contains tendon fibers of the **levator palpebrae superioris muscle** that open the eyelid (see Fig. 24.17). A mucocutaneous junction between eyelid skin and conjunctiva occurs near the lid margin. The **eyelashes** emerge from the most anterior edge of the lid margin. They are short, stiff, curved hairs and may occur in double or triple rows. The lashes on the same eyelid margin may have different lengths and diameters.

FIGURE 24.17. Structure of the eyelid. **a.** This schematic drawing of the eyelid shows the skin, associated skin appendages, muscles, tendons, connective tissue, and conjunctiva. Note the distribution of multiple small glands associated with the eyelid and observe the reflection of the palpebral conjunctiva in the fornix of the lacrimal sac to become the bulbar conjunctiva. **b.** Photomicrograph of a sagittal section of the eyelid stained with picric acid for better visualization of epithelial components of the skin and the numerous glands. In this preparation, muscle tissue (i.e., *orbicularis oculi muscle*) stains yellow, and the epithelial cells of the skin, conjunctiva, and glandular epithelium are green. Note the presence of numerous glands within the eyelid. The *tarsal (Meibomian) gland* is the largest gland, and it is located within the dense connective tissue of the tarsal plates. This sebaceous gland secretes into ducts opening onto the eyelids. $\times 20$. Inset. Higher magnification of a tarsal gland from the boxed area showing the typical structure of a holocrine gland. $\times 60$.

The conjunctiva lines the space between the inner surface of the eyelids and the anterior surface of the eye without covering the cornea.

The **conjunctiva** is a thin, transparent mucous membrane that extends from the corneoscleral limbus located on the peripheral margin of the cornea across the sclera (**bulbar conjunctiva**) and covers the internal surface of the eyelids (**palpebral conjunctiva**). The palpebral conjunctiva merges with the bulbar conjunctiva at the fornices of the conjunctival sac; this part is

called the **forniceal conjunctiva** (Fig. 24.18). Bulbar, palpebral, and forniceal conjunctiva form a conjunctival sac, a space between the eyelid and eyeball that opens anteriorly at the palpebral fissure. The conjunctival sac can hold fluid up to 30 μL . Because a standard eyedropper dispenses about 50 μL of suspended medicine per drop, one drop is more than enough to overfill the conjunctival sac.

FIGURE 24.18. Conjunctiva and conjunctival sac. This photograph of the lower part of the eyeball with a reflected lower eyelid shows different regions of the conjunctiva that line the conjunctival sac. The area shown is located between the inner surface of the eyelid and the anterior surface of the eye. The bulbar conjunctiva extends from the corneoscleral limbus covering the sclera of the eye (it does not cover the cornea) to its reflections onto the internal surface of the eyelid, at which point it is called the *palpebral conjunctiva*. This photograph shows the inferior point of reflection onto the lower eyelid (called the *inferior fornix* of the conjunctival sac). The conjunctiva in these regions is recognized as the forniceal conjunctiva.

The conjunctiva consists of a **stratified columnar epithelium** containing numerous **goblet cells** and rests on a lamina propria composed of loose connective tissue. The goblet cells secrete a

component of the tears that bathe the eye. Melanocytes are present in the basal epithelial layer and, like melanocytes in the skin, transfer melanosomes into neighboring epithelial cells. Accumulation of diffuse lymphatic tissue is evident, especially deep to the forniceal conjunctiva (Fig. 24.19). These specialized collections of T and B lymphocytes underlying the conjunctiva are called **conjunctiva-associated lymphatic tissue (CALT)** (Fig. 24.20). It functions to recognize and process antigens and trigger an appropriate immune response against the microbial invasion of the ocular surface. The conjunctiva is supplied with blood by the branches of arteries of the eyelid (marginal tarsal arcades) and from the eyeball (anterior ciliary arteries). The conjunctiva receives sensory innervation from the branches of the trigeminal nerve. **Conjunctivitis, an inflammation of the conjunctiva, commonly called pinkeye, is characterized by redness, irritation, and watering of the eyes. For more clinical information about this condition, see Folder 24.6.**

FIGURE 24.19. Superior fornix of the conjunctival sac. This low-magnification hematoxylin and eosin (H&E)-stained specimen was obtained from the superior fornix of the conjunctival sac as indicated by the *rectangle* in the inset. The palpebral conjunctiva lines the inner surface of the eyelid, and in the superior fornix of the conjunctival sac, it reflects onto the eyeball (bulbar conjunctiva). This reflection

is identified as the forniceal conjunctiva and is composed of stratified columnar epithelium containing numerous goblet cells. Accumulations of lymphatic tissue called *conjunctiva-associated lymphatic tissue* (CALT) are clearly visible. There are numerous blood vessels (BV) underlying the palpebral conjunctiva. $\times 120$. (Courtesy of Dr. Nick Mamalis, University of Utah, Moran Clinical Ophthalmology Resource for Education [CORE], Salt Lake City, Utah.)

FIGURE 24.20. Forniceal conjunctiva. This high-magnification hematoxylin and eosin (H&E)-stained specimen shows the fornix of the conjunctival sac. The forniceal conjunctiva shows a typical pattern of the stratified columnar epithelium containing goblet cells that rests on a lamina propria composed of loose connective tissue. The stratified columnar epithelium farther away from the fornix may change into columnar stratified or squamous stratified nonkeratinized epithelium (*lower right corner of conjunctival sac*). Note the accumulations of diffuse lymphatic tissue deep into the conjunctiva known as *conjunctiva-associated lymphatic tissue* (CALT). $\times 220$. (Courtesy of Dr. Nick Mamalis, University of Utah, Moran Clinical Ophthalmology Resource for Education [CORE], Salt Lake City, Utah.)

CLINICAL CORRELATION: CONJUNCTIVITIS

Conjunctivitis, otherwise known as pinkeye, is an inflammation of the conjunctiva. It may be localized in either the palpebral conjunctiva or the bulbar conjunctiva. Individuals may present with relatively nonspecific symptoms and signs that include redness, irritation, and watery discharge from the eye (Fig. F24.6.1). The symptoms can also mimic a foreign-body sensation. Extended use of contact lenses can cause allergic or bacterial conjunctivitis and may be the first sign of more serious ocular disease (i.e., corneal ulcer). In general, symptoms that last <4 weeks are classified as **acute conjunctivitis**, and those extending for a longer period are referred to as **chronic conjunctivitis**.

FIGURE F24.6.1. Conjunctivitis. This photograph of the lower part of the eyeball with reflected lower eyelid shows an infected conjunctiva. The enlarged blood vessels of the conjunctiva are responsible for moderate redness of the eye with conjunctival swelling. Moderately, clear (in allergic conjunctivitis) or purulent (in bacterial conjunctivitis) discharge is visible. (Courtesy of Dr. Renzo A. Zaldivar.)

Acute conjunctivitis is most commonly caused by bacteria; a variety of viruses, including HIV, varicella-zoster virus (VZV), and herpes simplex virus (HSV); or allergic reactions. Bacterial

conjunctivitis often causes an opaque purulent discharge containing white cells and desquamated epithelial cells. On eye examination, the purulent discharge and conjunctival papillae help differentiate between bacterial and viral etiology. Viral conjunctivitis is most common in adults. Clinically, it presents as a diffuse pinkness of the conjunctiva with particularly numerous lymphoid follicles on the palpebral conjunctiva, often accompanied by enlarged preauricular lymph nodes. Viral conjunctivitis is very contagious and usually associated with a recent upper respiratory infection. Patients need to be advised to avoid touching their eyes, to wash their hands frequently, and to avoid sharing towels and washcloths.

Bacterial conjunctivitis is usually treated with antibiotic eye drops or ointments. For viral conjunctivitis, no antimicrobial therapy is needed. However, conservative management with artificial tears to keep the eye lubricated may relieve symptoms. For severe cases, topical corticosteroid drops may be prescribed to reduce the discomfort of inflammation. However, prolonged use of corticosteroid drops increases the risk of side effects. Antibiotic drops may also be used for the treatment of secondary infections. Viral conjunctivitis usually resolves within 3 weeks. However, in the worst cases, it may take more than a month.

Secretions from modified glands in the eyelid provide additional protection to the eye.

In addition to eccrine sweat glands, which discharge their secretions directly onto the skin, the eyelid contains four other major types of glands (see Fig. 24.17):

- The **tarsal glands (Meibomian glands)**, long sebaceous glands embedded in the tarsal plates, appear as vertical yellow streaks in the tissue deep into the conjunctiva. Their elongated ducts open at the lid margin behind rows of eyelashes. About 25 tarsal glands are present in the upper eyelid, and 20 are present in the lower eyelid. The sebaceous secretion of the tarsal glands produces an oily layer on the surface of the tear film that retards the evaporation of the normal tear layer. Blockage of the tarsal gland secretion leads to chalazion (tarsal gland lipogranuloma), an inflammation of the tarsal gland. It presents as a painless cyst usually on the upper eyelid that disappears after a few months without therapeutic intervention.
- **Sebaceous glands of eyelashes (glands of Zeis)** are small, modified sebaceous glands that are connected with and empty

their secretion into the follicles of the eyelashes. Bacterial infection of these sebaceous glands causes a sty (also called a hordeolum), a painful tenderness and redness of the affected area of the eyelid.

- Apocrine glands of eyelashes (glands of Moll) are small sweat glands with unbranched sinuous tubules that begin as a simple spiral.
- Accessory lacrimal glands are compound serous tubuloalveolar glands that have distended lumina. They are located on the inner surface of the upper eyelids (glands of Wolfring) and in the fornix of the conjunctival sac (glands of Krause).

All glands of the human eyelid are innervated by neurons of the autonomic nervous system, and their secretion is synchronized with the lacrimal glands by a common neurotransmitter, vasoactive intestinal polypeptide (VIP).

The lacrimal gland produces tears that moisten the cornea and flow to the nasolacrimal duct.

Tears are produced by the lacrimal glands and, to a lesser degree, by the accessory lacrimal glands. The lacrimal gland is located beneath the conjunctiva on the upper lateral side of the orbit (Fig. 24.21). The lacrimal gland consists of several separate lobules of tubuloacinar serous glands. The acini have large lumina lined with columnar cells. Myoepithelial cells, located below the epithelial cells within the basal lamina, aid in the release of tears (Fig. 24.22). Approximately 12 ducts drain from the lacrimal gland into the reflection of conjunctiva just beneath the upper eyelid, known as the fornix of the conjunctival sac.

FIGURE 24.21. Schematic diagram of the eye and lacrimal apparatus. This drawing shows the location of the lacrimal gland and components of the lacrimal apparatus, which drains the lacrimal fluid into the nasal cavity.

FIGURE 24.22. Photomicrograph of lacrimal gland. The lacrimal gland consists of tubuloacinar serous secretory units. The acini are lined with serous secretory columnar cells. Myoepithelial cells (*MEp*) are present below the epithelial cells within the basal lamina. Cytoplasm of the secretory cells contains small lipid droplets and mucin-containing granules. Intralobular ducts (*D*) lined by serous cells also contain myoepithelial cells. Occasional plasma cells (*P*) and lymphocytes are present between acini of the lacrimal gland. *BV*, blood vessels. $\times 450$.

Tears drain from the eye through **lacrimal puncta**, the small openings of the **lacrimal canaliculi**, located at the medial angle. The upper and lower canaliculi join to form the **common canaliculus**, which opens into the lacrimal sac. The sac is continuous with the **nasolacrimal duct**, which opens into the nasal cavity below the inferior nasal conchae. A pseudostratified ciliated epithelium lines the lacrimal sac and the nasolacrimal duct. **Dacryocystitis** is an inflammation of the lacrimal sac that is frequently caused by an obstruction of the nasolacrimal duct. It can be acute, chronic, or congenital. It usually affects older individuals and is most often secondary to stenosis (narrowing) of the lacrimal canaliculi.

Tears protect the corneal epithelium and contain antibacterial and UV-protective agents.

Tears keep the conjunctiva and corneal epithelium moist and wash foreign material from the eye as they flow across the corneal surface toward the medial angle of the eye (see Fig. 24.21). The thin film of tears covering the corneal surface is not homogeneous but a mixture of products secreted by the lacrimal glands, the accessory lacrimal glands, the goblet cells of the conjunctiva, and the tarsal glands of the eyelid. The tear film contains proteins (tear albumins and lactoferrin), enzymes (lysozyme), lipids, metabolites, electrolytes, and medications, the latter secreted during therapy.

The tear cationic protein lactoferrin increases the activity of various natural antimicrobial agents, such as lysozyme.

The eye is moved within the orbit by coordinated contraction of extraocular muscles.

Six muscles of the eyeball (also called **extraocular** or **extrinsic muscles**) attach to each eye. These are the medial, lateral, superior, and inferior rectus muscles and the superior and inferior oblique muscles. The superior oblique muscle is innervated by the trochlear nerve (cranial nerve IV). The lateral rectus muscle is innervated by the abducens nerve (cranial nerve VI). All of the remaining extraocular muscles are innervated by the oculomotor nerve (cranial nerve III). The combined, precisely controlled action of these muscles allows vertical, lateral, and rotational movement of the eye. **Normally, the actions of the muscles of both eyes are coordinated so that the eyes move in parallel (called conjugate gaze).**

EYE

OVERVIEW OF THE EYE

- The eye is a paired, specialized sensory organ that provides the sense of sight.
- The tissues of the eye are derived from **neuroectoderm** (retina), **surface ectoderm** (lens, corneal epithelium), and **mesoderm** (sclera, corneal stroma, vascular coat).
- The eyeball is composed of three structural layers: the outer **corneoscleral (fibrous) coat** consisting of the transparent cornea and the opaque white sclera; the middle **vascular coat** consisting of the choroid, ciliary body, and iris; and the inner layer, the **retina**.
- The layers of the eye and the lens serve as boundaries for three chambers: the **anterior chamber** and **posterior chamber**, which are filled with **aqueous humor**, and the **vitreous chamber**, which is occupied by a transparent gel, the **vitreous body**.
- **Aqueous humor** is secreted by the ciliary processes into the posterior chamber. From there it flows through the pupil into the anterior chamber, where it drains inside the **iridocorneal angle** to the **scleral venous sinus** (canal of Schlemm).

COATS IN THE WALL OF THE EYE

- The **cornea** is transparent and consists of five layers (beginning from the anterior surface): **corneal epithelium** (nonkeratinized stratified squamous epithelium), **Bowman membrane** (anterior basement membrane for corneal epithelium), a thick avascular **corneal stroma**, **Descemet membrane** (posterior basement membrane for corneal endothelium), and **corneal endothelium**.
- The **sclera** is opaque and consists predominantly of dense connective tissue. It communicates with the cornea at the **corneoscleral limbus**, which contains **corneolimbic stem cells**.
- The **iris** arises from the ciliary body, and the diameter of its opening (**pupil**) is controlled by smooth muscle fibers of the **sphincter pupillae muscle** and the myoepithelial cell layer of the **dilator pupillae muscle**. Its posterior

surface is covered by pigment epithelium and contains a stroma that is abundant with melanocytes.

- The **ciliary body** is located between the iris and the choroid. It contains **ciliary processes** that secrete aqueous humor, anchors **zonular fibers** that suspend the lens, and contains **ciliary muscle** that alters the shape of the lens during **lens accommodation**.
- The **lens** is a transparent, avascular, biconvex structure that is suspended between the edges of the ciliary body. It consists of a **lens capsule**, **subcapsular epithelium**, and **lens fiber cells**.
- The **choroid** is part of the vascular coat and has an inner **choriocapillary layer** containing blood vessels that provide nutrients to the retina and an outer **Bruch membrane** that serves as the basal lamina for both the endothelial and RPE cells.
- The **retina** is derived from the inner and outer layers of the optic cup. It consists of two basic layers: the **neural retina** is the inner layer containing photoreceptor cells, and the **retinal pigment epithelium (RPE)** is the outer layer that attaches to the choroid.

RETINA

- The **retina** contains 10 layers of cells and their processes. Major cells in the retina include **photoreceptors** (rods and cones), **conducting neurons** (bipolar neurons and ganglion cells), **association neurons**, and **supporting cells** (e.g., Müller cells).
- **Retinal pigment epithelium** (layer 1) is the outermost layer of the retina and **absorbs scattered light**, contributes to the **blood-retina barrier**, **restores photosensitivity** to visual pigments, and **phagocytoses membranous discs** from the rods and cones.
- **Rods** (layer 2) are most numerous (120 million) in the retina and detect light intensity with their cylindrical outer segments. **Cones** (layer 2) are less numerous (7 million) and, with their conical outer segment, detect

three different wavelengths of light corresponding to the primary colors: blue, green, and red.

- Rods contain the visual pigment **rhodopsin** that consists of **opsin** and a small light-absorbing compound, **retinal**. Cone cells contain the visual pigment **iodopsin**.
- Conversion of light into nerve impulses in the photoreceptors is called **visual processing**. It involves a photochemical reaction based on the conversion of **11-cis-retinal** into **all-trans-retinal** in the rhodopsin. This results in the activation of opsin, which, in turn, activates G-protein and initiates hyperpolarization of the photoreceptor cell membrane that is detected by the bipolar neurons as a nerve impulse.
- The **outer limiting membrane** (layer 3) is formed by a row of zonulae adherentes between Müller cells.
- The **outer nuclear layer** (layer 4) contains the nuclei of rods and cones, and the **outer plexiform layer** (layer 5) contains their processes, which synapse with the horizontal, amacrine, and bipolar cells (the nuclei of which reside in the **inner nuclear layer** [layer 6]).
- Axons from cells in the outer plexiform layer synapse in the **inner plexiform layer** (layer 7) with ganglion cells, the cell bodies of which reside in the **ganglion cell layer** (layer 8). These cells send axons to the **layer of optic nerve fibers** (layer 9), which forms the optic nerve.
- The **inner limiting membrane** (layer 10) consists of a basal lamina separating the retina from the vitreous body.

ACCESSORY STRUCTURES OF THE EYE

- The **eyelids** consist of skin, tarsal plates, part of the **orbicularis oculi muscle**, tendon fibers of the **levator palpebrae superioris muscle** (in the upper eyelid), and the palpebral conjunctiva.
- The **conjunctiva** consists of **stratified columnar epithelium** with **goblet cells**. It lines the space between the inner surface of the eyelid and the anterior surface of the eye lateral to the cornea.

- A diffuse lymphatic tissue called **conjunctiva-associated lymphatic tissue (CALT)** is underlying conjunctiva at the superior and inferior fornices of the conjunctival sac.
- The **tarsal glands (Meibomian glands)** are long sebaceous glands embedded in the tarsal plates of the upper and lower eyelids.
- The **lacrimal gland** produces tears that moisten the cornea and flow to the nasolacrimal duct and into the nasal cavity.

PLATE 24.1 ■ EYE I

The human eye is a complex sensory organ that provides sight. The wall of the eye consists of **three concentric layers or coats**: the **retina**, the inner layer; the **uvea**, the middle or vascular layer; and the **corneosclera**, the outer fibrous layer. The eye is often compared to a simple camera with a lens to capture and focus light, a diaphragm to regulate the amount of light, and film to record the image. In the eye, the **cornea** and **lens** concentrate and focus light on the **retina**. The **iris**, located between the cornea and lens, regulates the size of the pupil through which light enters the eye. **Photoreceptor cells (rods and cones)** in the retina detect the intensity (rods) and color (cones) of the light that reaches them and encode the various parameters for transmission to the brain via the optic nerve (cranial nerve II).

The eye measures 25 mm in diameter. It is suspended in the bony orbit by six extrinsic striated muscles that control its movement. The extraocular muscles are coordinated so that both eyes move synchronously, with each moving symmetrically around its own central axis. A thick layer of adipose tissue partially surrounds and cushions the eye as it moves within the orbit.

Modified drawing of human eye, meridional perspective by E. Sobotta.

The innermost layer is the **retina** (*R*), which consists of several layers of cells. Among these are receptor cells (rods and cones), neurons (e.g., bipolar and ganglion cells), supporting cells, and a pigment epithelium (see Plate 24.2, page 1012). The receptor components of the retina are situated in

the posterior three-fifths of the eyeball. At the anterior boundary of the receptor layer, the **ora serrata** (*OS*), the retina becomes reduced in thickness, and nonreceptor components of the retina continue forward to cover the posterior or inner surface of the **ciliary body** (*CB*) and the **iris** (*I*). This anterior nonreceptor extension of the inner layer is highly pigmented, and the pigment (melanin) is evident as the black inner border of these structures.

The **uvea**, the middle layer of the eyeball, consists of the choroid, the ciliary body, and the iris. The choroid is a vascular layer; it is relatively thin and difficult to distinguish in the accompanying figure, except by location. On this basis, the **choroid** (*Ch*) is identified as being just external to the pigmented layer of the retina. It is also highly pigmented; the choroidal pigment is evident as a discrete layer in several parts of the section.

Anterior to the ora serrata, the uvea is thickened; here, it is called the ciliary body (*CB*). This contains the ciliary muscle (see Plate 24.3, page 1014), which brings about adjustments of the lens to focus light. The ciliary body also contains processes to which the zonular fibers are attached. These fibers function as suspensory ligaments of the lens (*L*). The iris (*I*) is the most anterior component of the uvea and contains a central opening, the pupil.

The outermost layer of the eyeball, the **fibrous layer**, consists of the **sclera** (*S*) and the **cornea** (*C*). Both of these contain collagenous fibers as their main structural element; however, the cornea is transparent, and the sclera is opaque. The extrinsic muscles of the eye insert into the sclera and affect the movements of the eyeball. These are not included in the preparation, except for two small pieces of a muscle insertion (*arrows*) in the *lower left* and *top center* of the illustration. Posteriorly, the sclera is pierced by the emerging **optic nerve** (*ON*). A deep depression in the neural retina lateral to the optic nerve (above the *ON* in this figure) is the fovea centralis (*FC*), the thinnest and most sensitive portion of the neural retina.

The lens is considered in Plate 24.4 (page 1016). Just posterior to the lens is the large cavity of the eye, the **vitreal cavity** (*V*), which is filled with a thick jelly-like material, the vitreous humor or body. Anterior to the lens are two additional, fluid-filled chambers of the eye, the **anterior chamber** (*AC*) and the **posterior chamber** (*PC*), separated by the iris.

AC, anterior chamber
C, cornea
CB, ciliary body
Ch, choroid
FC, fovea centralis
I, iris

L, lens
ON, optic nerve
OS, ora serrate
PC, posterior chamber
R, retina
S, sclera
V, vitreous cavity
arrows, muscle insertions

PLATE 24.2 ■ EYE II: RETINA

The **retina** and **optic nerve** are projections of the forebrain. The fibrous cover of the optic nerve is an extension of the meninges of the brain. The neural retina is a multilayered structure consisting of photoreceptors (rods and cones); neurons, some of which are specialized as conducting and associating neurons; and supporting cells (**Müller cells**). External to the neural retina is a layer of simple columnar **retinal pigment epithelium (RPE)**. The Müller cells are comparable to neuroglia in the rest of the central nervous system. Processes of Müller cells ramify virtually through the entire thickness of the retina. The internal limiting membrane is the basal lamina of these cells; the external limiting membrane is actually a line formed by the junctional complexes between processes of these cells and the **photoreceptor cells**.

The neurons of the retina are arranged sequentially in three layers: (1) a deep layer of rods and cones; (2) an intermediate layer of **bipolar, horizontal, and amacrine cells**; and (3) a superficial layer of **ganglion cells**. Nerve impulses originating in the rods and cones are transmitted to the intermediate layer and then to the ganglion cells. Synaptic connections occur in the **outer plexiform layer** (between the rods and cones and the intermediate neuronal layer) and the **inner plexiform layer** (between the intermediate layer and the ganglion cells), resulting in summation and neuronal integration. Finally, the ganglion cells send their axons to the brain as components of the optic nerve.

Optic disc and nerve, eye, human, hematoxylin and eosin (H&E) $\times 65$.

The site where the optic nerve leaves the eyeball is called the **optic disc (OD)**. It is characteristically marked by a depression, evident here. Receptor cells are not present at the optic disc, and because it is not sensitive to light stimulation, it is sometimes referred to as the *blind spot*.

The fibers that give rise to the optic nerve originate in the retina, more specifically, in the ganglion cell layer (see later). They traverse the sclera through a number of openings (*arrows*) to form the **optic nerve (ON)**. The region of the sclera that contains these openings is called the **lamina cribrosa (LC)** or cribriform plate. The optic nerve contains a central artery and vein (not seen here) that also traverse the lamina cribrosa. Branches of these blood vessels (*BN*) supply the inner portion of the retina.

Retina, eye, human, H&E $\times 325$.

On the basis of structural features that are evident in histologic sections, the retina is divided into 10 layers, from posterior to anterior, as listed herein and labeled in this figure:

1. Retinal pigment epithelium (*RPE*), the outermost layer of the retina
2. Layer of rods and cones (*R&C*), the photoreceptor layer of the retina
3. External limiting membrane (*ELM*), a line formed by the junctional complexes of the photoreceptor cells
4. Outer nuclear layer (*ONL*), containing nuclei of rod and cone cells
5. Outer plexiform layer (*OPL*), containing neural processes and synapses of rod and cone cells with bipolar, amacrine, interplexiform, and horizontal cells
6. Inner nuclear layer (*INL*), containing nuclei of bipolar, horizontal, interplexiform, amacrine, and Müller cells
7. Inner plexiform layer (*IPL*), containing processes and synapses of bipolar, horizontal, interplexiform, amacrine, and ganglion cells
8. Layer of ganglion cells (*GC*), containing cell bodies and nuclei of ganglion cells
9. Nerve fiber layer (*NFL*), containing axons of ganglion cells
10. Internal limiting membrane (*ILM*), consisting of the external (basal) lamina of Müller cells

This figure also shows the innermost layer of the choroid (*Ch*), a cell-free membrane, the lamina vitrea (*LV*), also called Bruch membrane. Electron micrographs reveal that it corresponds to the basement membrane of the pigment epithelium. Immediately external to the lamina vitrea is the capillary layer of the choroid (lamina choriocapillaris). These vessels supply the outer part of the retina.

BV, blood vessels
Ch, choroid

ELM, external limiting membrane
GC, layer of ganglion cells
ILM, internal limiting membrane
INL, inner nuclear layer (nuclei of bipolar, horizontal, amacrine,
and Müller cells)
IPL, inner plexiform layer
LC, lamina cribrosa
LV, lamina vitrea
NFL, nerve fiber layer
OD, optic disc
ON, optic nerve
ONL, outer nuclear layer (nuclei of rod and cone cells)
OPL, outer plexiform layer
RPE, retinal pigment epithelium
R&C, layer of rods and cones
arrows, openings in sclera (lamina cribrosa)

PLATE 24.3 ■ EYE III: ANTERIOR SEGMENT

The **anterior segment** is that part of the eye anterior to the **ora serrata**, the most anterior extension of the neural retina, and includes the **anterior** and **posterior chambers** and the structures that define them. These include the cornea and sclera, the iris, the lens, the ciliary body, and the connections between the basal lamina of the ciliary processes and the lens capsule (thick basal lamina of the lens epithelium) that form the suspensory ligament of the lens, the **zonular fibers**. The posterior chamber is bounded posteriorly by the anterior surface of the lens and anteriorly by the posterior surface of the iris. The ciliary body forms the lateral boundary. Aqueous humor flows through the pupil into the anterior chamber, which occupies the space between the cornea and the iris, and drains into the **canal of Schlemm**.

Anterior segment, eye, human, hematoxylin and eosin (H&E) $\times 45$; inset $\times 75$.

A portion of the **anterior segment** of the eye, shown in this figure, includes parts of the cornea (*C*), sclera (*S*), iris (*I*), ciliary body (*CB*), anterior chamber (*AC*), posterior chamber (*PC*), lens (*L*), and zonular fibers (*ZF*).

The relationship of the cornea to the sclera is illustrated to advantage here. The junction between the two (*arrows*) is marked by a change in staining, with the substance of the cornea appearing lighter than that of the sclera. The **corneal epithelium** (*CEp*) is continuous with the **conjunctival epithelium** (*CjEp*) that covers the sclera. Note that the epithelium thickens considerably at the corneoscleral junction and resembles that of the oral mucosa. The conjunctival epithelium is separated from the dense fibrous component of the sclera by a loose vascular connective tissue. Together, this connective tissue and the epithelium constitute the conjunctiva (*Cj*). The epithelial-connective tissue junction of the conjunctiva is irregular; in contrast, the undersurface of the corneal epithelium presents an even profile.

Just lateral to the junction of the cornea and sclera is the **canal of Schlemm** (*CS*; see also the next figure). This canal takes a circular route about the perimeter of the cornea. It communicates with the anterior chamber through a loose trabecular meshwork of tissue, the spaces of Fontana. The canal of Schlemm also communicates with episcleral veins. By means of its communications, the canal of Schlemm

provides a route for the fluid in the anterior and posterior chambers to reach the bloodstream.

The *inset* shows the tip of the iris. Note the heavy pigmentation on the posterior surface of the iris, which is covered by the same double-layered epithelium as the ciliary body and ciliary processes. In the ciliary epithelium, the outer layer is pigmented and the inner layer is nonpigmented. In the iris, both layers of the iridial epithelium (*IEp*) are heavily pigmented. A portion of the iridial constrictor muscle (*M*) is seen beneath the epithelium.

Anterior segment, eye, human, H&E $\times 90$; inset $\times 350$.

Immediately internal to the anterior margin of the sclera (*S*) is the **ciliary body** (*CB*). The **iris** (*I*) arises from the anterior border of the ciliary body. The inner surface of the ciliary body forms radially arranged, ridge-shaped elevations, the **ciliary processes** (*CP*), to which the zonular fibers (*ZF*) are anchored. From the outside, the components of the ciliary body are the ciliary muscle (*CM*), the connective tissue (vascular) layer (*VL*) containing small arteries (*A*, *inset*) and veins (*V*, *inset*) representing the choroid coat in the ciliary body, the lamina vitrea (*LV*, *inset*), and the ciliary epithelium (*CiEp*, *inset*). The ciliary epithelium consists of two layers (*inset*), the pigmented layer (*PE*) and the nonpigmented layer (*npE*). The lamina vitrea is a continuation of the same layer of the choroid; it is the basement membrane of the pigmented ciliary epithelial cells.

The **ciliary muscle** is arranged in three patterns. The outer layer is immediately deep into the sclera and contains the meridionally arranged fibers of Brücke. The outermost of these fibers continues more posteriorly into the choroid and is referred to as the *tensor muscle of the choroid*. The middle layer is the radial group. It radiates from the region of the sclerocorneal junction into the ciliary body. The innermost layer of muscle cells is circularly arranged. These are seen in cross section. The circular artery (*CA*; barely discernible) and vein (*CV*) for the iris, also cut in cross section, are just anterior to the circular group of muscle cells.

A, artery
AC, anterior chamber
C, cornea
CA, circular artery
CB, ciliary body
CEp, corneal epithelium
CiEp, ciliary epithelium
Cj, conjunctiva

CjEp, conjunctival epithelium
CM, ciliary muscle
CP, ciliary processes
CS, canal of Schlemm
CV, circular vein
I, iris
IEp, iridial epithelium
L, lens
LV, lamina vitrea
M, iridial constrictor muscle
npE, nonpigmented layer of ciliary epithelium
PC, posterior chamber
PE, pigmented layer of ciliary epithelium
S, sclera
V, vein
VL, vascular layer (of ciliary body)
ZF, zonular fibers
arrows, junction between cornea and sclera

PLATE 24.4 ■ EYE IV: SCLERA, CORNEA, AND LENS

The transparent **cornea** is the primary dioptric (refractive element) of the eye and is covered with nonkeratinized stratified squamous epithelium. Its stroma consists of alternating lamellae of collagen fibrils and fibroblasts (**keratocytes**). The fibrils in each lamella are extremely uniform in diameter and uniformly spaced; fibrils in adjacent lamellae are arranged at approximately right angles to each other. This orthogonal array of highly regular fibrils is responsible for the transparency of the cornea. The posterior surface is covered with a single layer of low cuboidal cells, the **corneal endothelium**, which rests on a thickened basal lamina called **Descemet membrane**. Nearly all of the metabolic exchanges of the avascular cornea occur across the endothelium. Damage to this layer leads to corneal swelling and can produce temporary or permanent loss of transparency.

The **lens** is a transparent, avascular, biconvex epithelial structure suspended by the zonular fibers. Tension on these fibers keeps the lens flattened; reduced tension allows it to fatten or **accommodate** to bend light rays originating close to the eye to focus them on the retina.

Corneoscleral junction, eye, human, hematoxylin and eosin (H&E) $\times 130$.

This low-magnification micrograph shows the full thickness of the sclera just lateral to the **corneoscleral junction** or limbus. To the *left* of the *arrow* is sclera; to the *right* is a small amount of corneal tissue. The **conjunctival epithelium** (*CjEp*) is irregular in thickness and rests on a loose vascular connective tissue. Together, this epithelium and underlying connective tissue represent the **conjunctiva** (*Cj*). The white opaque appearance of the sclera is due to the irregular dense arrangement of the collagen fibers that make up the stroma (*S*). The **canal of Schlemm** (*CS*) and small blood vessels (*BV*) are seen at the *left* close to the inner surface of the sclera near the border with anterior chamber (*AC*) of the eye.

Corneoscleral junction and canal of Schlemm, eye, human, H&E $\times 360$.

Uppermost figure is a higher magnification micrograph showing the transition from the corneal epithelium (*CEp*) to the irregular and

thicker conjunctival epithelium (*CjEp*) covering the sclera. Note that Bowman membrane (*B*), lying under the corneal epithelium, is just discernible but disappears beneath the conjunctival epithelium. The next figure shows a higher magnification of the canal of Schlemm (*CS*) than does the *top left* figure. That the space shown here is not an artifact is evidenced by the endothelial lining cells (*En*) that face the

lumen.

Cornea, eye, human, H&E $\times 175$.

This low-magnification micrograph shows the full thickness of the **cornea** (*C*) and can be compared with the sclera shown in the figure at the *left*. The **corneal epithelium** (*CEp*) presents a uniform thickness, and the underlying stroma (*S*) has a more homogeneous appearance than the stroma of the sclera (the white spaces seen here and in the figure at the *left* are artifacts). Nuclei (*N*) of the keratocytes of the stroma lie between lamellae. The corneal epithelium rests on a thickened anterior basement membrane called **Bowman membrane** (*B*). The posterior surface of the cornea facing the anterior chamber (*AC*) is lined by a simple squamous epithelium called the **corneal endothelium** (*CEn*); its thick posterior basement membrane is called **Descemet membrane** (*D*).

Corneal epithelium and endothelium, eye, human, H&E $\times 360$.

Uppermost is a higher magnification micrograph showing the **corneal epithelium** (*CEp*) with its squamous surface cells, the very thick homogeneous-appearing **Bowman membrane** (*B*), and the underlying stroma (*S*). Note that the stromal tissue has a homogeneous appearance, a reflection of the dense packing of its collagen fibrils. The flattened nuclei belong to the keratocytes. Lowermost figure shows the posterior surface of the cornea. Note the thick homogeneous **Descemet membrane** (*D*) and the underlying **corneal endothelium** (*CEn*).

Lens, eye, human, H&E $\times 360$.

This micrograph shows a portion of the lens near its equator. The lens consists entirely of epithelial cells surrounded by a homogeneous-appearing **lens capsule** (*LC*) to which the zonular fibers attach. The lens capsule is a very thick basal lamina of the epithelial cells. Simple cuboidal lens

epithelial cells are present on the anterior surface of the lens, but at the lateral margin, they become extremely elongated and form layers that extend toward the center of the lens. These elongated columns of epithelial cytoplasm are referred to as **lens fibers** (*LF*). New cells are produced at the margin of the lens and displace the older cells inwardly. Eventually, the older cells lose their nuclei, as evidenced by the deeper portion of the cornea in this micrograph.

AC, anterior chamber
B, Bowman membrane
BV, blood vessels
C, cornea
CEn, corneal endothelium
CEp, corneal epithelium
Cj, conjunctiva
CjEp, conjunctival epithelium
CS, canal of Schlemm
D, Descemet membrane
En, endothelial lining cells
LC, lens capsule
LF, lens fibers
N, nuclei
S, stroma

HISTOLOGY

■ OVERVIEW OF THE EAR

The **ear** is a three-chambered sensory organ that functions as an **auditory system** for sound perception and as a **vestibular system** for balance. Each of the three divisions of the ear—the **external ear**, **middle ear**, and **internal ear**—is an essential part of both systems (Fig. 25.1). The external and middle ears collect and conduct acoustic energy to the internal ear, where auditory sensory receptors convert that energy into electrical impulses. The sensory receptors of the vestibular system respond to gravity and movement of the head. They are responsible for the sense of balance and equilibrium and help coordinate movements of the head and eyes.

FIGURE 25.1. Three divisions of the ear. The three divisions of the ear are represented by different colors and consist of the external ear (auricle and external acoustic meatus; *pink*), the middle ear (tympanic cavity, auditory ossicles, tympanic membrane, and auditory tube; *green*), and the internal ear containing the bony labyrinth (semicircular canals, vestibule, and cochlea; *blue*) and the membranous labyrinth (not visible).

The ear develops from surface ectoderm and components of the first and second pharyngeal arches.

The internal ear is the first of the three ear divisions to begin development. At the end of the third week, a thickening of **surface ectoderm** that appears on each side of the myelencephalon develops into the **otic placode**. Early in the fourth week, the otic placode invaginates and then pinches off to form the **otic vesicle (otocyst)**, which sinks deep to the surface ectoderm into the underlying mesenchyme (Fig. 25.2). The otic vesicle serves as a primordium for the development of the epithelia that line the membranous labyrinth of the internal ear. Later, development of the first and part of the second pharyngeal arch provides structures that augment

hearing. The endodermal component of the **first pouch** gives rise to the **tubotympanic recess**, which ultimately develops into the **auditory tube (Eustachian tube)** and the **middle ear** and its epithelial lining. The corresponding ectodermal outgrowth of the **first pharyngeal groove** gives rise to the **external acoustic meatus** and its epithelial lining (see Fig. 25.2). The connective tissue part of the pharyngeal arches produces the ossicles (“ear bones”). The **malleus** and **incus** develop from the first pharyngeal arch and the **stapes** from the second pharyngeal arch. The sensory epithelia of the membranous labyrinth that originates from the otic vesicle link with cranial nerve VIII, which is an outgrowth of the central nervous system. The auricle of the external ear develops from six **auricular hillocks** located at the dorsal ends of the first and second pharyngeal arches surrounding the first pharyngeal cleft. The cartilaginous, bony, and muscular structures of the ear develop from the mesenchyme surrounding these early epithelia.

FIGURE 25.2. Schematic drawings showing development of the ear. **a.** This drawing shows the relationship of the surface ectoderm-derived otic vesicle to the first pharyngeal arch during the fourth week of development. **b.** The otic vesicle sinks deep into the mesenchymal tissue and develops into the membranous labyrinth. Note the development of the tubotympanic recess lined by endoderm into the future middle ear cavity and auditory tube. In addition, accumulation of mesenchyme from the first and second pharyngeal arches gives rise to the auditory ossicles. **c.** At this later stage of development, the first pharyngeal groove grows toward the developing tubotympanic recess. The auditory ossicles assume a location inside the tympanic cavity. **d.** This final stage of development shows how the tympanic membrane develops from all three germ layers: surface ectoderm, mesoderm, and endoderm. Note that the wall of the otic vesicle develops into the membranous labyrinth.

■ EXTERNAL EAR

The auricle is the external component of the ear that collects and amplifies sound.

The **auricle (pinna)** is the oval appendage that projects from the lateral surface of the head. The characteristic shape of the auricle is determined by an internal supporting structure of elastic cartilage. Thin skin with hair follicles, sweat glands, and sebaceous glands cover the auricle. The auricle is considered a nearly vestigial structure in humans, compared with its development and function in other animals. Nevertheless, it is essential in collecting the sound and directing it into the external acoustic meatus.

The external acoustic meatus conducts and amplifies sounds on the way to the tympanic membrane.

The **external acoustic meatus** is an air-filled tubular space that follows a slightly S-shaped course for about 25 mm to the **tympanic membrane (eardrum)**. Because of its length, the external acoustic meatus can amplify sounds with frequencies of 2,000 – 5,000 Hz. By passively conducting sounds at this frequency and acting as a **resonator**, the external acoustic meatus increases the sound pressure at the tympanic membrane by approximately a **factor of 2**.

The wall of the meatus is continuous externally with the auricle. The wall of the lateral one-third of the meatus is cartilaginous and is continuous with the elastic cartilage of the auricle. The medial two-thirds of the meatus are contained within the temporal bone. Both parts of the meatus are lined by skin, which is also continuous with that of the auricle.

The skin in the lateral part of the meatus contains hair follicles, sebaceous glands, and **ceruminous glands**, but no eccrine sweat glands. The coiled tubular ceruminous glands closely resemble the apocrine glands found in the axillary region. Their secretion mixes with that of the sebaceous glands and desquamated cells to form **cerumen**, or **earwax**. Because the external acoustic meatus is the only blind pouch of the skin in the body, the earwax provides the means to evacuate desquamating cells from the stratum corneum, thus preventing their accumulation in the meatus. **The cerumen lubricates the skin and coats the meatal hairs to impede the entry of foreign particles into the ear. It also provides some antimicrobial**

protection from bacteria, fungi, and insects. Excessive accumulation of cerumen (impacted cerumen) can plug the meatus, resulting in conductive hearing loss. The medial part of the meatus located within the temporal bone has thinner skin and fewer hairs and glands.

■ MIDDLE EAR

The middle ear is an air-filled space that contains three small bones, the ossicles.

The middle ear is located in an air-filled space, called the tympanic cavity, within the temporal bone (Fig. 25.3). It is spanned by three small bones, the auditory ossicles, which are connected by two movable joints. The middle ear also contains the auditory tube (Eustachian tube), which opens to the nasopharynx as well as the muscles that attach to the ossicles.

FIGURE 25.3. Horizontal section of a human temporal bone. The relationships of the three divisions of the ear within the petrous part of the temporal bone are shown. Note the orientation icon that shows the plane of section. The *tympanic membrane* separates the *external acoustic meatus* from the tympanic cavity. Within the tympanic cavity, sections of the malleus (*M*) and incus (*I*) can be seen. The posterior wall of the tympanic cavity is associated with the mastoid air cells (*AC*). The lateral wall of the cavity is formed principally by the tympanic membrane. The opening to the internal ear or oval window (*OW*) is seen in the medial wall of the cavity (the stapes has been removed). The facial nerve (*F*) can be observed near the oval window. The *cochlea*, vestibule, and a portion of the lateral semicircular canal (*LSC*) of the bony labyrinth are identified. The *cochlear* and *vestibular nerves* are divisions of cranial nerve VIII and can also be observed within the *internal acoustic meatus*. *Inset* in the upper left of the photomicrograph shows the plane of the section through the bony labyrinth. $\times 65$.

The tympanic cavity has a roof, floor, and four walls: anterior, posterior, lateral, and medial. The tympanic cavity contains an opening of the auditory tube and is bound

anteriorly by a thin layer of bone that separates it from the internal carotid artery. The posterior wall of the tympanic cavity is formed by the spongy bone of the **mastoid process**, which contains the **mastoid antrum** and other, smaller, air-filled spaces called **mastoid air cells**. The middle ear is bound laterally by the **tympanic membrane** and medially by the bony wall of the internal ear. The floor and roof of the tympanic cavity are both formed by a thin layer of bone, which separates them from the internal jugular vein and middle cranial fossa, respectively.

The middle ear is a mechanical energy transformer. Its primary function is to convert sound waves (air vibrations) arriving from the external acoustic meatus into mechanical vibrations that are transmitted to the internal ear. Two openings in the medial wall of the middle ear, the **oval (vestibular) window** and the **round (cochlear) window**, are essential components in this conversion process.

The tympanic membrane separates the external acoustic meatus from the middle ear.

The intact **tympanic membrane** is a semitransparent, thin (about 0.1 mm) membrane approximately 1 cm in diameter that has an average surface area in humans of about 65 mm². It is shaped like an irregular flat cone, the apex of which is located at the **umbo** that corresponds to the tip of the manubrium of the malleus. The tympanic membrane at the end of the external acoustic meatus is tilted anteriorly and inferiorly. Thus, orientation of the tympanic membrane has been compared to the position of a miniature satellite dish tuned to receive signals coming from the ground in front of the body and to the side of the head. During otoscopic examination of a normal ear, the tympanic membrane is a semitransparent light gray color and has a visible concavity toward the external acoustic meatus. Owing to its concavity, light from the otoscope reflects off the tympanic membrane as a triangular **cone of light** (light reflex) that radiates anteriorly and inferiorly from the umbo (Fig. 25.4). The malleus is one of three small auditory ossicles

residing in the middle ear and is the only one that attaches to the tympanic membrane (see Fig. 25.1).

FIGURE 25.4. The tympanic membrane in otoscopic examination of the external ear. This diagram and photograph show the left tympanic membrane seen with an otoscope during examination of the external acoustic meatus. The landmarks of the tympanic membrane include the manubrium of the malleus with its visible attachment to the tense part of the membrane, umbo at the tip of the manubrium, and projecting lateral process of the malleus. A small, flaccid part of the tympanic membrane is located above the lateral process of the malleolus. Note the cone of light (light reflex) that is usually seen extending anteroinferiorly from the umbo of the tympanic membrane. (Courtesy of Dr. Eric J. Moore.)

The **tympanic membrane** forms the medial boundary of the external acoustic meatus and the lateral wall of the middle ear (Fig. 25.5). From outside to inside, the three layers of the tympanic membrane are

FIGURE 25.5. Cross section through a human tympanic membrane. This photomicrograph shows the *tympanic membrane*, *external acoustic meatus*, and *tympanic cavity*. $\times 9$. Inset. Higher magnification of the tympanic membrane. The outer epithelial layer of the membrane consists of stratified squamous keratinized epithelium (*SSE*), and the inner epithelial layer of the mucous membrane consists of low simple cuboidal epithelium (*SCE*). A middle layer of connective tissue core (*CTC*) lies between the two epithelial layers. The dense irregular connective tissue core is formed by two layers: the outer layer in which fibers are radially arranged (*rad*) and the inner layer with circumferentially arranged fibers (*cir*). $\times 190$.

- the skin of the external acoustic meatus (epidermis composed of stratified squamous keratinized epithelium)
- a core of connective tissue with an outer layer of radially and inner layer of circularly arranged collagen fibers, and
- the mucous membrane of the middle ear (composed of simple cuboidal epithelium).

The larger, lower part of the tympanic membrane (**tense part** or **pars tensa**) is tightly stretched and has a thick middle core that contains radial and circular collagen fibers and gives the membrane its shape and smooth appearance. The smaller, upper part of the tympanic membrane that lies superior to the lateral

process of the malleolus is loose (**flaccid part** or **pars flaccida**) and lacks a prominent middle fibrous layer (see Fig. 25.4). Sound waves cause the tympanic membrane to vibrate, and these vibrations are transmitted through the ossicular chain of three small bones that link the external ear to the internal ear.

Tympanic membrane perforations are caused by a rupture in the tympanic membrane that creates a connection between the external auditory meatus and the middle ear. This rupture can be attributed to infections, mechanical injury, or rapid changes in pressure, leading to sudden ear pain (otalgia), ear discharge (otorrhea), ringing in the ears (tinnitus), and a sensation of feeling off-balance (vertigo). Most perforations resolve spontaneously without complications; however, some may cause transient or permanent **hearing impairment**.

The auditory ossicles connect the tympanic membrane to the oval window.

The **three auditory ossicles** or bones—the malleus, the incus, and the stapes—cross the space of the middle ear in series and connect the tympanic membrane to the oval window (Fig. 25.6). These bones work like a lever system that increases the force transmitted from the vibrating tympanic membrane to the stapes by decreasing the ratio of their oscillation amplitudes. The ossicles help convert sound waves to mechanical vibrations (hydraulic waves) in tissues and fluid-filled chambers. Movable synovial joints connect the bones, which are named according to their approximate shape:

FIGURE 25.6. Photograph of the three articulated human auditory ossicles. The three ossicles are the malleus, the incus, and the

stapes. $\times 30$.

- The **malleus (hammer)** attaches to the tympanic membrane and articulates with the incus.
- The **incus (anvil)** is the largest of the ossicles and links the malleus to the stapes.
- The **stapes (stirrup)**, the footplate of which fits into the oval window. The footplate in the human stapes measures approximately $3\text{ mm} \times 1\text{ mm}$ and has an average surface area of 3 mm^2 . It acts like a small piston on the cochlear fluid, creating hydraulic waves to represent the air-pressure fluctuations of the sound wave.

Diseases that affect the external acoustic meatus, tympanic membrane, or ossicles are responsible for **conductive hearing loss** (see Folders 25.1 and 25.2).

FOLDER 25.1

CLINICAL CORRELATION: OTOSCLEROSIS

Otosclerosis is one of the most common causes of acquired hearing loss. It is reported that $\sim 13\%$ of the U.S. population has nonclinical otosclerosis (histologic otosclerosis); however, the incidence of clinical disease ranges from 0.5% to 1.0%. Individuals with clinical otosclerosis have progressive hearing loss. Symptoms usually become apparent between ages 20 and 45 years. Otosclerosis is characterized by the abnormal overgrowth of bone that uniquely affects the temporal bone and ossicles. Although the cause of bone overgrowth in otosclerosis is unknown, recent studies suggest an association with measles virus infection. In otosclerosis, mature bone in the area of the oval window on the medial wall of the tympanic cavity, which separates the middle ear from the internal ear, is removed by osteoclasts and replaced with much thicker immature (woven) bone. Because the footplate of the stapes normally resides and freely vibrates within the oval window to allow the transmission of sound into the internal ear, bone remodeling in this area results in fixation of the stapes into the surrounding bone. The “frozen” stapes cannot vibrate, which prevents sound waves from reaching the perilymphatic fluid space of the internal ear and causes conductive hearing loss. Treatment of otosclerosis includes several options: pharmacologic treatment to suppress bone remodeling with fluorides and bisphosphonates, amplification of sounds with hearing aids, and surgical removal of the stapes (**stapedectomy**) with subsequent implantation of a prosthesis

between the incus and the oval window. Surgery is usually the most effective method of managing otosclerosis; >90% of patients experience a complete reversal of their hearing loss.

FOLDER 25.2

CLINICAL CORRELATION: HEARING LOSS—VESTIBULAR DYSFUNCTION

Several types of disorders can affect the auditory and vestibular system and result in deafness, dizziness (vertigo), or both. Auditory disorders are classified as either sensorineural or conductive. **Conductive hearing loss** results when sound waves are mechanically impeded from reaching the auditory sensory receptors within the internal ear. This type of hearing loss principally involves the external ear or structures of the middle ear. Conductive hearing loss is the second most common type of loss after sensorineural hearing loss, and it usually involves a reduction in sound level or the inability to hear faint sounds. Conductive hearing loss may be caused by otitis media (ear infection); in fact, this is the most common cause of temporary hearing loss in children. Fluid that collects in the tympanic cavity can also cause significant hearing problems in children. Other common causes of conductive hearing loss include excess wax or foreign bodies in the external acoustic meatus or diseases that affect the ossicles in the middle ear (otosclerosis; see also Folder 25.1). In many cases, conductive hearing loss can be treated either medically or surgically and may not be permanent.

Sensorineural hearing impairment may occur after injury to the auditory sensory hair cells within the internal ear, cochlear division of cranial nerve VIII, nerve pathways in the central nervous system (CNS), or auditory cortex. Sensorineural hearing loss accounts for about 90% of all hearing loss. It may be congenital or acquired. Causes of acquired sensorineural hearing loss include infections of the membranous labyrinth (e.g., meningitis, chronic otitis media), fractures of the temporal bone, acoustic trauma (i.e., prolonged exposure to excessive noise), and administration of certain classes of antibiotics and diuretics.

Another example of sensorineural hearing loss often results from aging. Sensorineural hearing loss not only involves a reduction in sound level but also affects the ability to hear clearly or to distinguish speech. A loss of the sensory hair cells or associated nerve fibers begins in the basal turn of the cochlea and progresses apically over time. The characteristic impairment is a high-frequency hearing loss termed **presbycusis** (see presbyopia, page 1004).

In selected patients, the use of a **cochlear implant** can partially restore some hearing function. The cochlear implant is an

electronic device consisting of an external microphone, amplifier, and speech processor linked to a receiver implanted under the skin of the mastoid region. The receiver is connected to the multielectrode intracochlear implant inserted along the wall of the cochlear canal. After considerable training and tuning of the speech processor, the patient's hearing can be partially restored to various degrees ranging from recognition of critical sounds to the ability to converse.

Two muscles attach to the ossicles and affect their movement.

The **tensor tympani muscle** lies in a bony canal above the auditory tube; its tendon inserts on the malleus. Contraction of this muscle increases tension on the tympanic membrane. The **stapedius muscle** lies in a bony eminence on the posterior wall of the middle ear; its tendon inserts on the stapes. Contraction of the stapedius tends to dampen the movement of the stapes at the oval window. The stapedius is only a few millimeters long and is the smallest skeletal muscle.

The two muscles of the middle ear are responsible for a protective reflex called the **attenuation reflex** or **acoustic reflex**. In response to intense sound, involuntary contraction of the muscles makes the chain of ossicles more rigid, thus reducing the transmission of vibrations to the internal ear. The muscles will contract on both sides, regardless of which ear is stimulated. This reflex protects the internal ear from the damaging effects of very loud sounds. In certain conditions, such as impulse noise (i.e., fireworks or gun fire), the attenuation reflex is ineffective.

The auditory tube connects the middle ear to the nasopharynx.

The **auditory (Eustachian) tube** is a narrow flattened channel approximately 3.5 cm long. This tube is lined with ciliated pseudostratified columnar epithelium, about one-fifth of which is composed of goblet cells. It vents the middle ear to nasopharynx, equalizing the pressure of the middle ear with atmospheric pressure. In addition, the auditory tube is responsible for draining the secretion produced by the mucous membrane of the middle ear towards the nasopharynx with the aid of the ciliated pseudostratified columnar epithelium. The

auditory tube is normally closed; its walls are pressed together but they separate during yawning, chewing, swallowing, and when individual holds the nose and blows. Children are more vulnerable to the middle ear infections, due to the immature development of their auditory tubes which are shorter, narrower, and more horizontal than in the adults. It is common for infections to spread from the pharynx to the middle ear via the auditory tube (causing otitis media). A small mass of lymphatic tissue, the tubal tonsil, is often found at the pharyngeal orifice of the auditory tube.

The mastoid air cells extend from the middle ear into the temporal bone.

A system of air cells projects into the mastoid portion of the temporal bone from the middle ear. The epithelial lining of these air cells is continuous with that of the tympanic cavity and rests on periosteum. This continuity allows infections in the middle ear to spread into mastoid air cells, causing mastoiditis. Before the development of antibiotics, repeated episodes of otitis media and mastoiditis usually led to deafness.

The middle ear contributes to the amplification of mechanical forces generated by the vibration of the tympanic membrane.

All three ossicles in the tympanic cavity are involved in the amplification of the mechanical force that vibrates the tympanic membrane in two ways:

- The main amplification comes from differences in the surface area between the tympanic membrane and the footplate of the stapes. The tympanic membrane has a surface area of approximately 65 mm^2 , whereas the footplate of the stapes has a surface area of about 3 mm^2 . Sound waves apply force to every square millimeter of the tympanic membrane, and this energy is transferred via the chain of ossicles to the much smaller area of the footplate. Therefore, the pressure applied to the cochlear fluid by the footplate is about 22

times the pressure applied to the tympanic membrane (Fig. 25.7).

FIGURE 25.7. Summary of amplification of sound entering the ear. This drawing shows the external and middle ear structures and their contributions to the amplification of sound entering the ear. Note that the largest amplification comes from the difference in the surface area between the tympanic membrane (65 mm²) and the footplate of the stapes (3 mm²). This surface area difference results in ~22 times the amplification of the pressure applied by the footplate of the stapes. Another source of amplification comes from the external acoustic meatus and middle ear. The external acoustic meatus acts as a resonator that increases the sound pressure acting on the tympanic membrane by ~2 times. Finally, the arrangement of auditory ossicles resembles a basic lever that multiplies the applied mechanical force acting on the footplate of the stapes by ~1.3 times. By multiplying these three amplification factors, the acoustic energy entering the ear is amplified ~60 times.

- Additional amplification comes from the arrangement of **auditory ossicles** that act as **levers** that multiply the

mechanical force applied to the stapes. Because the pivot point of the ossicle chain is located farther from the tympanic membrane than from the stapes, the amplification of the mechanical force at the oval window is increased by a factor of **approximately 1.3**. This lever system is adjustable by the action of muscles in the tympanic cavity and may attenuate loud sounds to protect the ear (see Fig. 25.7).

Under normal conditions, the acoustic energy entering the ear is amplified **approximately 60 times**, allowing humans to detect frequencies between 2,000 and 5,000 Hz. The degree of amplification is calculated by multiplying the amplification factors contributed by the external acoustic meatus (~ 2 times) as described earlier on pages 1018–1019, the surface area differences between the tympanic membrane and the footplate of stapes (~ 22 times), and the basic lever action of ossicles (~ 1.3 times). However, this calculation ($2 \times 22 \times 1.3 = 57.2$) must be used with caution owing to variability in the mechanical function of the middle ear and its components, such as ossicular joints, ligaments, muscles, and air volumes, as well as varying frequencies of sound.

■ INTERNAL EAR

The internal ear consists of two labyrinthine compartments, one contained within the other.

The **bony labyrinth** is a complex system of interconnected cavities and canals in the petrous part of the temporal bone. The **membranous labyrinth** lies within the bony labyrinth and consists of a complex system of small sacs and tubules that also form a continuous space enclosed within a wall of epithelium and connective tissue.

There are three fluid-filled spaces in the internal ear:

- **Endolymphatic spaces** are contained within the membranous labyrinth. The **endolymph** of the membranous labyrinth is similar in composition to **intracellular fluid** (it has a high K^+ concentration and a low Na^+ concentration). The endolymph

is produced in the stria vascularis, a specialized area of the cochlear duct (see pages 1032–1034). It drains via the endolymphatic duct to the endolymphatic sac, which terminates in the epidural space of the posterior cranial fossa.

- The **perilymphatic space** lies between the wall of the bony labyrinth and the wall of the membranous labyrinth. The **perilymph** is similar in composition to **extracellular fluid** and **cerebrospinal fluid** (it has a low K^+ concentration and a high Na^+ concentration). Perilymph is produced as an ultrafiltrate from the periosteal microvasculature within the bony labyrinth. It drains via a narrow channel within the temporal bone, called the *cochlear aqueduct*, directly into the cerebrospinal fluid contained within the subarachnoid space of the cranial cavity.
- The **cortilymphatic space** lies within the tunnels of the organ of Corti of the cochlea. It is a true intercellular space. The cells surrounding the space loosely resemble an absorptive epithelium. The cortilymphatic space is filled with **cortilymph**, which has a composition similar to that of **extracellular fluid**.

Structures of the Bony Labyrinth

The bony labyrinth consists of three connected spaces within the temporal bone.

The three spaces of the bony labyrinth, as illustrated in Figure 25.8, are the

FIGURE 25.8. Photograph of a cast of the bony labyrinth of the internal ear. The cochlear portion of the bony labyrinth appears *blue green*; the vestibule and semicircular canals appear *orange red*. (Courtesy of Dr. Merle Lawrence.)

- **semicircular canals**,
- **vestibule**, and
- **cochlea**.

The vestibule is the central space that contains the utricle and saccule of the membranous labyrinth.

The **vestibule** is the small oval chamber located in the center of the bony labyrinth. The **utricle** and **saccule** of the membranous labyrinth lie in elliptical and spherical recesses, respectively. The **semicircular canals** extend from the vestibule posteriorly, and the **cochlea** extends from the vestibule anteriorly. The oval window into which the footplate of the stapes inserts lies in the lateral wall of the vestibule.

The semicircular canals are tubes within the temporal bone that lie at right angles to each other.

Three semicircular canals, each forming about three-quarters of a circle, extend from the wall of the vestibule and return to it. The semicircular canals are identified as anterior, posterior, and lateral and lie within the temporal bone at approximately right angles to each other. They occupy three planes in space—sagittal, frontal, and horizontal. The end of each semicircular canal closest to the vestibule is expanded to form the **ampulla** (Fig. 25.9a and b). The three canals open into the vestibule through five orifices; the anterior and posterior semicircular canals join at one end to form the **common bony limb** (see Fig. 25.9a).

FIGURE 25.9. Diagrams and photograph of the human internal ear. **a.** This lateral view of the left bony labyrinth shows its divisions: the vestibule, cochlea, and three semicircular canals. The openings of the oval window and the round window can be observed. **b.** This photograph of a cast obtained by injection of polyester resin into the human internal ear shows an authentic shape of the bony labyrinth.

Note that the cast material is pouring out of the cochlea through the oval and round windows. Also, in this image, the cast of the facial canal that contains the facial nerve is visible. $\times 5$. (Courtesy of Dr. Elsa Erixon.) c. Diagram of a membranous labyrinth of the internal ear lying within the bony labyrinth. The cochlear duct can be seen spiraling within the bony cochlea. The saccule and utricle are positioned within the vestibule, and the three semicircular ducts are lying within their respective canals. This view of the left membranous labyrinth allows the endolymphatic duct and sac to be observed. d. This view of the left membranous labyrinth shows the sensory regions of the internal ear for equilibrium and hearing. These regions are the macula of the saccule and macula of the utricle, the cristae ampullares of the three semicircular ducts, and the spiral organ of Corti of the cochlear duct.

The cochlea is a cone-shaped helix connected to the vestibule.

The spiral lumen of the cochlea, called the cochlear canal (like the semicircular canals), is continuous with that of the vestibule. It connects to the vestibule via two openings, the round window and the oval window, both of which are located on the side opposite the openings of the semicircular canals. Between its base and the apex, the cochlear canal makes approximately 2.75 turns around a central core of spongy bone called the modiolus (Plate 25.1, page 1042). A sensory ganglion, the spiral ganglion, lies in the modiolus. A thin membrane (the secondary tympanic membrane) covers the round window, whereas the footplate of the stapes is positioned within the oval window. These two openings are located at the base of the cochlear canal.

Structures of the Membranous Labyrinth

The membranous labyrinth contains the endolymph and is suspended within the bony labyrinth.

The membranous labyrinth consists of a series of communicating sacs and ducts containing endolymph. It is suspended within the bony labyrinth (Fig. 25.9c), and the remaining space is filled with perilymph. The membranous labyrinth is composed of two

divisions: the **cochlear labyrinth** and the **vestibular labyrinth** (Fig. 25.9d).

The vestibular labyrinth contains the following:

- Three **semicircular ducts** lie within the semicircular canals and are continuous with the utricle.
- The **utricle** and the **sacculle**, which are contained in recesses in the vestibule, are connected by the membranous **utrículosaccular duct**.

The cochlear labyrinth contains the **cochlear duct**, which is contained within the cochlea and is continuous with the sacculle (see Fig. 25.9c and d).

Sensory cells of the membranous labyrinth

Specialized sensory cells are located in six regions in the membranous labyrinth.

Six sensory regions of membranous labyrinth are composed of sensory **hair cells** and accessory **supporting cells**. These regions project from the wall of the membranous labyrinth into the endolymphatic space in each internal ear (see Fig. 25.9d):

- Three **cristae ampullares (ampullary crests)** are located in the membranous ampullae of the semicircular ducts. They are sensitive to the angular acceleration of the head (i.e., turning the head).
- Two maculae, one in the utricle (**macula of utricle**) and the other in the sacculle (**macula of sacculle**), sense the position of the head and its linear movement.
- The **spiral organ of Corti** projects into the endolymph of the cochlear duct. It functions as a sound receptor.

Hair cells are epithelial mechanoreceptors of the vestibular and cochlear labyrinth.

The **hair cells** of the vestibular and cochlear labyrinths function as **mechanoelectrical transducers**; they convert mechanical energy into electrical energy that is then transmitted via the vestibulocochlear nerve to the brain. The

hair cells derive their name from the organized bundle of rigid projections at their apical surface. This surface holds a **hair bundle** that is formed by rows of stereocilia called *sensory hairs*. The rows increase in height in one particular direction across the bundle (Fig. 25.10). In the vestibular system, each hair cell possesses a single true cilium called a **kinocilium**, which is located behind the row of longest stereocilia (Fig. 25.11). In the auditory system, the hair cells lose their cilium during development but retain the **basal body**. The position of the kinocilium (or basal body) behind the longest row of stereocilia defines the polarity of this asymmetric hair bundle. Therefore, movement of the stereocilia toward the kinocilium is perceived differently than movement in the opposite direction (see later).

FIGURE 25.10. Electron micrographs of the kinocilium and stereocilia of a vestibular sensory hair cell. a. Scanning electron micrograph of the apical surface of a sensory hair cell from the macula of the utricle. Note the relationship of the kinocilium (*K*) to the stereocilia (*S*). $\times 47,500$. b. Transmission electron micrograph of the kinocilium (*K*) and stereocilia (*S*) of a vestibular hair cell in cross section. The kinocilium has a larger diameter than the stereocilia. $\times 47,500$. (a. Reprinted with permission from Ryzanski AK, Schneider ME, Davies C, et al. An actin molecular treadmill and myosins maintain stereocilia functional architecture and self-renewal. *J Cell Biol.* 2004;164:887–897. b. Reprinted with permission from Hunter-Duvar IM, Hinojosa R. Vestibule: sensory epithelia. In: Friedmann I, Ballantyne J, eds. *Ultrastructural Atlas of the Inner Ear*. Butterworth; 1984.)

FIGURE 25.11. Diagram of two types of sensory hair cells in the sensory areas of the membranous labyrinth. The type I hair cell has a flask-shaped structure with a rounded base. The base is enclosed in a chalice-like afferent nerve ending containing several ribbon synapses in addition to several synaptic boutons for efferent nerve endings. Note the apical surface specializations of this cell, which include a kinocilium and hair bundle. The apical cytoplasm of hair cells contains basal bodies for the attachment of the kinocilium and a terminal web for the attachment of stereocilia. The type II hair cell is cylindrical and possesses several nerve terminals at its base for both afferent and efferent nerve fibers. The apical surface specializations are identical to those of the type I cell. The molecular organization of the stereocilia is depicted in the diagram on the *right*. The top link connects the lateral plasma membrane of the stereocilium shaft (where K^+ transduction channels are located) with the tip of the shorter stereocilium (where the mechanoelectrical transduction [*MET*] channel protein is located). Movement of the stereocilia toward the kinocilium opens the *MET* channels, causing depolarization of the hair cell, whereas movement in the opposite direction (away from the kinocilium) causes hyperpolarization. Note that the proximal end of each stereocilium is tapered and its narrow rootlets are anchored within the terminal web (cuticular plate) of the hair cell. Several other fibrillar connectors between neighboring stereocilia are also shown.

Stereocilia of hair cells are rigid structures that contain mechanoelectrical transducer channel proteins at their distal ends.

The **stereocilia of hair cells** have a molecular structure similar to those described on pages 127–128. Tightly packed **actin filaments** cross-linked by **fimbrin** and **espin** (actin-bundling proteins) form their internal core structure. Espins provide the most rigid cross-linking for stereocilia; mutations that alter their structure cause cochlear and vestibular dysfunction. The high density of actin filaments and the extensive cross-linking pattern impart rigidity and stiffness to the shaft of the stereocilium. The shaft tapers at its proximal end near the apical surface of the cell, where the core filaments of each stereocilium are anchored within the terminal web (cuticular plate). When stereocilia are deflected, they pivot at their proximal ends like stiff rods (see Fig. 25.11).

Transmission electron microscope examination of the distal free end of the stereocilium reveals an electron-dense plaque at the cytoplasmic site of the plasma membrane. This plaque represents the **mechanoelectrical transducer (MET) channel complex**. A fibrillar cross-link called the **tip link** connects the tip of the stereocilium with the shaft of an adjacent longer stereocilium (see Fig. 25.11). These tip links are anchored to mechanically gated ion channels on both ends. The upper insertion of the tip link to the shaft of neighboring stereocilium contains a cluster of motor proteins (unconventional myosin VIIa) that maintains a resting tension on the tip link. The lower insertion to the distal free end of the stereocilium is connected to the MET channel complex. The tip link is composed of **cadherin-23** (CDH23) and **protocadherin-15** (PCDH15); however, the molecular composition of the MET channel complex remains elusive. Recently, two transmembrane channel-like (TMC) proteins, TMC1 and TMC2, have been identified in the MET channels that are expressed in developing hair cells. Mutations in the genes encoding TMC1 cause deafness in humans.

The tip link plays an important role in activating the MET channel complex at the tip of the stereocilia and opening additional transduction K^+ channels at the site of its attachment to the shaft of neighboring stereocilium (see Fig. 25.11). The molecular structure of the transduction K^+ channels is unknown.

A mutation that disrupts the gene that encodes the actin-bundling protein *espin* causes cochlear and vestibular symptoms in experimental mice. They lose their hearing early in life; these animals also spend most of their time walking or spinning in circles. The stereocilia of these animals do not maintain the rigidity necessary for the proper functioning of the MET channels. In humans, mutations in a gene located on chromosome 1 that encodes *espin* are associated with deafness without vestibular involvement.

All hair cells use mechanically gated ion channels to generate action potentials.

All hair cells of the internal ear appear to function by moving (pivoting) their rigid stereocilia. Mechanoelectrical transduction occurs in stereocilia that are deflected toward its tallest edge (toward the kinocilium, if present). This movement exerts tension on the fibrillar tip links, and the generated force is used to open **mechanically gated ion channels** near the tip of the stereocilium. This allows for an influx of K^+ , causing depolarization of the receptor cell. This depolarization results in the opening of voltage-gated Ca^{2+} channels in the basolateral surface of the hair cells and the secretion of a neurotransmitter that generates an action potential in afferent nerve endings. Movement in the opposite direction (away from the kinocilium) closes the MET channels, causing hyperpolarization of the receptor cell. The means by which stereocilia are deflected varies from receptor to receptor; these are discussed in the sections describing each receptor area.

Hair cells communicate with afferent nerve fibers through ribbon synapses, a specialized type of chemical synapse.

Deflection of the stereocilia on hair cells generates a high rate of prolonged impulses that are quickly transmitted to the afferent nerve fibers. To ensure rapid release of the glutamate neurotransmitter from synaptic vesicles, hair cells possess specialized **ribbon synapses** that contain unique organelles called **ribbons**. In electron microscopy, ribbons appear as ovoid, 30-nm-thick, electron-dense plates that are anchored to the presynaptic membrane by electron-dense structures (Fig. 25.12). This arrangement allows the ribbons to float just above the presynaptic plate like balloons on a short leash. The ribbons tether a large number of synaptic vesicles on their surface that are primed for fusion with the presynaptic membrane, which contains a high density of voltage-gated Ca^{2+} channels (see Fig. 25.12). After activation of the Ca^{2+} channels, the ribbon serves as a fast-moving conveyor belt, delivering the vesicles to the presynaptic membrane for fusion. The tethered pool of synaptic vesicles is approximately fivefold greater than the pool of the remaining vesicles. The ribbons contain several proteins, including the active-zone protein RIM that interacts with rab3, a GTPase enzyme expressed on the surface of synaptic vesicles. Other proteins of the ribbon complex include presynaptic matrix proteins, such as RIBEYE, Bassoon, and Piccolo. A hair cell typically contains about 10–20 ribbons. These ribbon synapses are also found in the photoreceptors and bipolar cells of the retina.

FIGURE 25.12. Diagram and electron micrograph of a ribbon synapse in a hair cell. Diagram on the *left* shows a type I hair cell with several ribbon synapses that are specialized for transmitting long-lasting and high-volume impulses to the afferent nerve cell endings (*yellow*). **a.** This schematic view of a ribbon synapse shows the ribbon protein complex that contains several presynaptic matrix proteins (RIM, RIBEYE, and Piccolo) and is anchored into the presynaptic plate by another protein called *Bassoon*. The surface of the ribbon serves as the tethering platform for multiple synaptic vesicles. Note the presence of voltage-sensitive Ca^{2+} channels in the presynaptic membrane next to the attachment of the ribbon. Upon influx of Ca^{2+} , the ribbon accelerates movement of the attached vesicles toward the presynaptic membrane for fusion (similar to the action of a fast-moving conveyor belt). **b.** This electron micrograph of a ribbon synapse from a mouse cochlear hair cell shows the ribbon protein complex with attached synaptic vesicles. $\times 27,400$. Two types of hair cells are present in the vestibular labyrinth.

Both **hair cell** types are associated with **afferent** and **efferent nerve endings** (see Fig. 25.11). **Type I hair cells** are flask shaped, with a rounded base and thin neck, and are surrounded by an afferent nerve chalice and a few efferent nerve fibers. **Type II hair cells** are cylindrical and have afferent and efferent bouton nerve endings at the base of the cell (see Fig. 25.11).

Sensory receptors of the membranous labyrinth

The crista ampullaris senses angular movements of the head.

Each ampulla of the semicircular duct contains a **crista ampullaris**, which is a sensory receptor for angular movements of the head (Figs. 25.13 and 25.14). The crista ampullaris is a thickened transverse epithelial ridge that is oriented perpendicularly to the long axis of the semicircular canal and consists of the epithelial hair cells and supporting cells (Plate 25.1, page 1042).

FIGURE 25.13. Diagram of function and structure of the crista ampullaris within a semicircular duct. a. As shown in this drawing, the crista ampullaris functions as the sensor for angular movement of the head. For example, when the head of the individual shown in this diagram rotates toward the left side, the bony labyrinth also rotates at the same speed together with the head. However, the endolymph lags behind due to its own fluid inertia. Because the crista ampullaris is attached to the wall of the bony labyrinth, it will be swayed by the lagging endolymph in the opposite direction to the movement of the head. b. The structure of the crista ampullaris includes sensory epithelium and large cupula made of a gelatinous protein-polysaccharide mass that projects toward the nonsensory wall of the ampulla. Note that the membranous ampulla is filled with endolymph and is surrounded by perilymph. c. The sensory epithelium of the crista ampullaris is composed of both type I and type II hair cells and supporting cells. The stereocilia and kinocilium of each hair cell are embedded in the cupula. Their mechanical deflection opens the K^+ channels, causing depolarization of the cell.

FIGURE 25.14. Photomicrograph of the crista ampullaris and macula of the utricle of the internal ear. a. This low-

magnification view of a horizontal section of the temporal bone reveals several regions of the internal ear. The prominent *cochlea* contains a well-preserved cochlear duct with a *cochlear nerve* emerging from the base of the modiolus. Note the cross section of the *stapedius muscle* and *facial nerve*. The central cavity of the slide represents the vestibule that contains three parts of the membranous labyrinth: the *utricle*, *sacculle*, and *ampulla of the anterior semicircular canal*. The locations of sensory receptors (macula of utricle, macula of sacculle, and crista ampullaris) are enclosed within the rectangles. ×20. b. This high-magnification view of the crista ampullaris from the anterior semicircular canal shows a thick *sensory epithelium* that contains two types of cells: the *hair cells* in the upper layer and the *supporting cells* in the basal layer. Note that the sensory hair processes of the cells are barely discernable and are covered by the *cupula*. The underlying loose *connective tissue* extends to the wall of the bony labyrinth and contains nerve fibers with associated Schwann cells, fibroblasts, capillaries, and other connective tissue cells. ×380. c. This high-magnification view of the macula of the utricle shows *sensory epithelium* similar to that of the crista ampullaris. The sensory epithelium is overlaid by the *otolithic membrane* containing a darker stained layer of *otoconia* (otoliths) on its surface. ×380. (Copyright 2010 Regents of the University of Michigan. Reprinted with permission.)

A gelatinous protein-polysaccharide mass, known as the **cupula**, is attached to the hair cells of each crista (see Fig. 25.13). The cupula projects into the lumen and is surrounded by endolymph. During rotational movement of the head, the walls of the semicircular canal and the membranous semicircular ducts move, but the endolymph contained within the ducts tends to lag behind because of inertia. The cupula, projecting into the endolymph, is swayed by the movement differential between the crista fixed to the wall of the duct and the endolymph. Deflection of the stereocilia in the narrow space between the hair cells and the cupula generates nerve impulses in the associated nerve endings.

The maculae of the sacculle and utricle are sensors of gravity and linear acceleration.

The **maculae** of the sacculle and utricle are innervated sensory thickenings of the epithelium that face the endolymph of the sacculle and utricle (see Figs. 25.14 and 25.15). As in the cristae, each macula consists of **type I** and **type II hair**

cells, supporting cells, and nerve endings associated with the hair cells. The maculae of the utricle and saccule are oriented at right angles to each another. When a person is standing, the macula of the utricle is in a horizontal plane and the macula of the saccule is in a vertical plane.

FIGURE 25.15. Diagram of function and structure of the macula within the utricle. **a.** As shown in this drawing, the macula of the utricle (as well as macula of the saccule) functions as a sensor for gravity and linear acceleration. For example, when the head of the individual shown in this diagram is tilted forward, tiny crystals of calcium carbonate called *otoconia* are shifted on the surface of the otolithic membrane. This movement is detected by the underlying hair cells. **b.** The macula is composed of a sensory epithelium containing both type I and type II hair cells. The hair cell processes are embedded in the gelatinous polysaccharide otolithic membrane. The luminal surface of the membrane is covered by otoconia that are heavier than endolymph. **c.** As visible on the map below the macula, the hair cells are polarized with respect to the striola, an imaginary plane that curves through the center of each macula. Note that on each side of the striola, the kinocilia of the hair cells are oriented in opposite directions facing toward the striola (see direction of the *blue* and *green* arrows on the polarization map of the utricle). This arrangement is only seen in the utricle because in the macula of the saccule, the kinocilia of the hair cells are turned away from the striola.

Hair cells are polarized with respect to the **striola**, an imaginary plane that curves through the center of each macula (see Fig. 25.15). On each side of the striola, the kinocilia of the hair cells are oriented in opposite directions, facing toward the striola in the utricle and turning away from the striola in the saccule. Owing to polarization of the hair cells, the maculae of the saccule and utricle are sensitive to multiple directions of linear accelerations.

The gelatinous polysaccharide material that overlies the maculae is called the **otolith membrane** (see Fig. 25.15). Its outer surface contains 3- to 5- μm crystalline bodies of calcium carbonate and a protein (Fig. 25.16). **Otoliths**, also called **otoconia**, are heavier than endolymph. The outer surface of the otolith membrane lies opposite the surface in which the stereocilia of the hair cells are embedded. The otolith membrane moves on the macula in a manner analogous to that by which the cupula moves on the crista. Stereocilia of the hair cells are deflected by gravity in the stationary individual when the otolith membrane and its otoliths pull on the stereocilia. They are also displaced during linear movement when the individual is moving in a straight line and the otolith membrane drags on the stereocilia because of inertia. In both cases, movement of the otolith membrane causes the stereocilia to move toward the kinocilium, activating MET channels. This depolarizes hair cells and generates an action potential. Displacement of stereocilia in the opposite direction away from the kinocilium causes hyperpolarization of hair cells and inhibits the generation of the action potential.

FIGURE 25.16. Scanning electron micrograph of human otoconia. Each otoconium has a long cylindrical body with a three-headed facet on each end. $\times 5,000$.

The spiral organ of Corti is the sensor of sound vibrations.

The **cochlear duct** divides the cochlear canal into three parallel compartments or *scalae*:

- **Scala media**, the middle compartment in the cochlear canal
- **Scala vestibule**
- **Scala tympani**

The **cochlear duct** itself is the **scala media** (Fig. 25.17). The scala vestibuli and scala tympani are the spaces above and below, respectively, the scala media. The scala media is an

endolymph-containing space that is continuous with the lumen of the saccule and contains the spiral organ of Corti, which rests on its lower wall (see Fig. 25.17).

FIGURE 25.17. Schematic diagram and photomicrograph of the cochlear canal. **a.** Cross section of the basal turn of the cochlear duct is shown in the *box* on the smaller orientation view. This view of a midmodiolar section of the cochlea illustrates the position of the cochlear duct within the 2.75 turns of the bony cochlea. Observe that at the top of the cochlea, the scala vestibuli and scala tympani communicate with each other at the helicotrema. The scala media and the osseous spiral lamina divide the cochlea into the scala vestibuli and the scala tympani, which are filled with perilymph. The scala media (the space within the cochlear duct) is filled with endolymph and contains the organ of Corti. **b.** This photomicrograph shows a section of the basal turn of the cochlear canal. The osseous spiral lamina (*OSL*) and its membranous continuation, the basilar membrane (*BM*) as well as the vestibular membrane (*VM*) are visible. Note the location of the *scala vestibuli*, the scala media (*SM*) or cochlear duct, and the *scala tympani*. The three walls of the scala media are

formed by the basilar membrane inferiorly, the stria vascularis (*SV*) and underlying spiral ligament (*SL*) laterally, and the vestibular membrane superiorly. The spiral organ of Corti resides on the inferior wall of the cochlear duct. Dendrites of the cochlear nerve (*CN*) that originate in the spiral ganglion (*SG*) enter the spiral organ of Corti. The axons of the spiral ganglion cells form the cochlear part of the vestibulocochlear nerve. $\times 65$.

The **scala vestibuli** and the **scala tympani** are **perilymph-containing spaces** that communicate with each other at the apex of the cochlea through a small channel called the **helicotrema** (see Fig. 25.17b). The scala vestibuli begins at the **oval window**, and the scala tympani ends at the **round window**.

The scala media is a triangular space with its acute angle attached to the modiolus.

In transverse section, the **scala media** appears as a triangular space with its most acute angle attached to a bony extension of the modiolus, the **osseous spiral lamina** (see Fig. 25.17). The upper wall of the scala media, which separates it from the scala vestibuli, is the **vestibular (Reissner) membrane** (Fig. 25.18). The lateral or outer wall of the scala media is bordered by a unique epithelium, the **stria vascularis**. It is responsible for the production and maintenance of endolymph. The stria vascularis encloses a complex capillary network and contains three types of cells (Fig. 25.19). The marginal cells, primarily involved in K^+ transport, line the endolymphatic space of the scala media. Intermediate pigment-containing cells are scattered among capillaries. The basal cells separate stria vascularis from the underlying spiral ligament. The lower wall or floor of the scala media is formed by a relatively flaccid **basilar membrane** that increases in width and decreases in stiffness as it coils from the base to apex of the cochlea. The spiral organ of Corti rests on the basilar membrane and is overlain by the **tectorial membrane**.

FIGURE 25.18. Transmission electron micrograph of the vestibular (Reissner) membrane. Two cell types can be observed: a mesothelial cell, which faces the scala vestibuli and is bathed by perilymph, and an epithelial cell, which faces the scala media and is bathed by endolymph. $\times 8,400$.

FIGURE 25.19. Transmission electron micrograph of the stria vascularis. The apical surfaces of the marginal cells (*M*) of the stria are bathed by endolymph (*E*) of the scala media. Intermediate cells (*I*) are positioned between the marginal cells and the basal

cells (*B*). The basal cells separate the other cells of the stria vascularis from the spiral ligament (*SpL*). $\times 4,700$.

The spiral organ of Corti is composed of hair cells, phalangeal cells, and pillar cells.

The **spiral organ of Corti** is a complex epithelial layer on the floor of the scala media (Fig. 25.20 and Plate 25.2, page 1044). It is formed by the following:

FIGURE 25.20. Photomicrograph of the vestibular duct and spiral organ of Corti. This higher magnification photomicrograph of the cochlear duct shows the structure of the spiral organ of Corti. Relate this structure to the *inset*, which labels the structural features of the spiral organ. $\times 180$. *Inset*. Diagram of the sensory and supporting cells of the spiral organ of Corti. The sensory cells are divided into an inner row of sensory hair cells and three rows of outer sensory hair cells. The supporting cells are the inner and outer pillar cells, inner and outer (Deiters) phalangeal cells, outer border cells (Hensen cells), inner border cells, Claudius cells, and Böttcher cells.

- **Inner hair cells** (close to the spiral lamina) and **outer hair cells** (farther from the spiral lamina)
- **Inner phalangeal (supporting) cells** and **outer phalangeal cells**
- **Pillar cells**

Several other named cell types of unknown function are also present in the spiral organ.

The hair cells are arranged in inner and outer rows of cells.

The **inner hair cells** form a single row of cells throughout all 2.75 turns of the cochlear duct. The number of cells forming the width of the continuous row of **outer hair cells** is variable. Three ranks of hair cells are found in the basal part of the coil (Fig. 25.21). The width of the row gradually increases to five ranks of cells at the apex of the cochlea.

FIGURE 25.21. Scanning electron micrograph of the spiral organ of Corti. This electron micrograph illustrates the configuration of stereocilia on the apical surfaces of the inner row and three outer rows of the cochlear sensory hair cells. $\times 3,250$.

The phalangeal and pillar cells provide support for the hair cells.

Phalangeal cells are supporting cells for both rows of hair cells. The phalangeal cells associated with the inner hair cells surround the cells completely (Fig. 25.22a). The phalangeal cells associated with the outer hair cells surround only the basal portion of the hair cell completely and send apical processes toward the endolymphatic space (Fig. 25.22b). These processes flatten near the apical ends of the hair cells and collectively form a complete plate surrounding each hair cell (Fig. 25.23).

FIGURE 25.22. Electron micrograph of an inner and outer hair cell. a. Observe the rounded base and constricted neck of the inner hair cell. Nerve endings (*NE*) from afferent nerve fibers (*AF*) to the inner hair cells are seen basally. *IP*, inner pillar cell; *IPH*, inner phalangeal cell. $\times 6,300$. b. Afferent (*AF*) and efferent (*EF*) nerve

fiber endings on the base of an outer sensory hair cell are evident. Outer phalangeal cells (*OPH*) surround the outer hair cells basally. Their apical projections form the apical cuticular plate (*ACP*). Note that the lateral domains in the middle third of the outer hair cells are not surrounded by supporting cells. $\times 6,300$. (Reprinted with permission from Kimura RS. Sensory and accessory epithelia of the cochlea. In: Friedmann I, Ballantyne J, eds. *Ultrastructural Atlas of the Inner Ear*. Butterworth; 1984.)

FIGURE 25.23. Structure of the outer phalangeal cell. **a.** This scanning electron micrograph illustrates the architecture of the outer phalangeal (Deiters) cells. Each phalangeal cell cups the basal surface of an outer hair cell and extends its phalangeal process apically to form an apical cuticular plate that supports the outer sensory hair cells. $\times 2,400$. **b.** Schematic drawing showing the relationship of an outer phalangeal cell to an outer hair cell.

The apical ends of the phalangeal cells are tightly bound to one another and to the hair cells by elaborate tight junctions. These junctions form the **reticular lamina** that separates the endolymphatic compartment from the true intercellular spaces of the organ of Corti (see Figs. 25.20 and 25.22b). The extracellular fluid in this intercellular space is **cortilymph**. Its composition is similar to that of other extracellular fluids and to perilymph.

Pillar cells have broad apical and basal surfaces that form plates and a narrowed cytoplasm. The inner pillar cells rest on the tympanic lip of the spiral lamina; the outer pillar cells

rest on the basilar membrane. Between them, they form a triangular tunnel, the **inner spiral tunnel** (see Fig. 25.20).

The tectorial membrane extends from the spiral limbus over the cells of the spiral organ of Corti.

The **tectorial membrane** is attached medially to the modiolus. Its lateral free edge projects over and attaches to the organ of Corti by the stereocilia of the hair cells. It is formed from the radially oriented bundles of collagen types II, V, and IX embedded in a dense amorphous ground substance. Glycoproteins unique to the internal ear, called **otogelin** and **tectorin**, are associated with the collagen bundles. These proteins are also present in the otolithic membranes overlying the maculae of the utricle and saccule as well as in the cupulae of the cristae in the semicircular canals.

Sound Perception

As described on pages 1018–1019, sound waves striking the tympanic membrane are translated into simple mechanical vibrations. The ossicles of the middle ear convey these vibrations to the cochlea.

In the internal ear, the vibrations of the ossicles are transformed into waves in the perilymph.

Movement of the stapes in the oval window of the vestibule sets up vibrations or traveling waves in the perilymph of the scala vestibuli. The vibrations are transmitted through the vestibular membrane to the scala media (cochlear duct), which contains endolymph, and are also propagated to the perilymph of the scala tympani. Pressure changes in this closed perilymphatic–endolymphatic system are reflected in movements of the membrane that covers the round window in the base of the cochlea.

As a result of **sound vibrations** entering the internal ear, a traveling wave is set up in the basilar membrane (Fig. 25.24). A sound of a specified frequency causes displacement of a relatively long segment of the basilar membrane, but the region

of maximal displacement is narrow. The point of maximal displacement of the basilar membrane is specified for a given frequency of sound and is the morphologic basis of frequency discrimination. High-frequency sounds cause maximal vibration of the basilar membrane near the base of the cochlea; low-frequency sounds cause maximal displacement nearer the apex. Amplitude discrimination (i.e., perception of sound intensity or loudness) depends on the degree of displacement of the basilar membrane at any given frequency range. Thus, coding acoustic information into nerve impulses depends on the vibratory pattern of the basilar membrane.

FIGURE 25.24. Schematic diagram illustrating the dynamics of the three divisions of the ear. The cochlear duct is shown here as if straightened. Sound waves are collected and transmitted from the external ear to the middle ear, where they are converted into mechanical vibrations. The mechanical vibrations are then converted at the oval window into fluid vibrations within the internal ear. Fluid vibrations cause displacement of the basilar membrane (traveling wave) on which rest the auditory sensory hair cells. Such displacement leads to stimulation of the hair cells and a discharge of neural impulses from them. Note that high-frequency sounds cause vibrations of the narrow, thick portion of the basilar membrane at the base of the cochlea, whereas low-frequency sounds displace basilar membrane toward the apex of the cochlea near its helicotrema.

Movement of the stereocilia of the hair cells in the cochlea initiates neuronal transduction.

Hair cells are attached through the **phalangeal cells** to the basilar membrane, which vibrates during sound reception. The **stereocilia** of these hair cells are, in turn, attached to the tectorial membrane, which also vibrates. However, the **tectorial membrane** and the **basilar membrane** are hinged at different points. Thus, a shearing effect occurs between the basilar membrane (and the cells attached to it) and the tectorial membrane when sound vibrations impinge on the internal ear.

Because they are inserted into the tectorial membrane, the stereocilia of the hair cells are the only structures that connect the basilar membrane and its complex epithelial layer to the tectorial membrane. The shearing effect between the basilar membrane and the tectorial membrane deflects the stereocilia and thus the apical portion of the hair cells. This deflection activates **MET channels** located at the tips of stereocilia and generates action potentials that are conveyed to the brain via the **cochlear nerve** (cochlear division of the vestibulocochlear nerve, cranial nerve VIII).

Innervation of the Internal Ear

The vestibular nerve originates from the sensory receptors associated with the vestibular labyrinth.

The **vestibulocochlear nerve (cranial nerve VIII)** is a special sensory nerve and is composed of two divisions: a vestibular division called the *vestibular nerve* and a cochlear division called the *cochlear nerve*. The **vestibular nerve** is associated with equilibrium and carries impulses from the sensory receptors located within the vestibular labyrinth. The **cochlear nerve** is associated with hearing and conveys impulses from the sensory receptors within the cochlear labyrinth (Fig. 25.25).

FIGURE 25.25. Diagram illustrating the innervation of the sensory regions of the membranous labyrinth. Note that cochlear and vestibular nerves form the vestibulocochlear nerve (cranial nerve VIII). The cochlear nerve carries the sound impulses from the spiral organ of Corti located within the cochlear duct; the vestibular nerve carries balance information from the three cristae ampullares of the semicircular canals, utricle, and saccule. The cell bodies of these sensory fibers are located in the spiral ganglion (for hearing) and vestibular ganglion (for equilibrium).

The cell bodies of the bipolar neurons of the **vestibular nerve** are located in the **vestibular ganglion (of Scarpa)** in the internal acoustic meatus. Dendritic processes of the vestibular ganglion cells originate in the cristae ampullares of the three semicircular ducts, the macula of the utricle, and the macula of the saccule. They synapse at the base of the vestibular sensory hair cells, either as a chalice around a type I hair cell or as a bouton associated with a type II hair cell. The axons of the vestibular nerve originate from the vestibular ganglion, enter the brainstem, and terminate in four vestibular nuclei. Some secondary neuronal fibers travel to the

cerebellum and to the nuclei of cranial nerves III, IV, and VI, which innervate the muscles of the eye.

The cochlear nerve originates from the sensory receptors of the spiral organ of Corti.

Neurons of the **cochlear nerve** are also bipolar, and their cell bodies are located in the **spiral ganglion of Corti** within the modiolus. Dendritic processes of spiral ganglion cells exit the modiolus through the small openings in the bony spiral lamina and enter the spiral organ. Approximately 90% of dendrites originating from the spiral ganglion cells synapse with the inner hair cells; the remaining 10% of dendrites synapse with the outer hair cells of the spiral ganglion. The axons of the spiral ganglion cells form the cochlear nerve, which enters the bony cochlea through the modiolus to appear in the internal acoustic meatus (see Fig. 25.25). From the internal acoustic meatus, the cochlear nerve enters the brainstem and terminates in the cochlear nuclei of the medulla. Nerve fibers from these nuclei pass to the geniculate nucleus of the thalamus and then to the auditory cortex of the temporal lobe.

The organ of Corti also receives a small number of efferent fibers conveying impulses from the brain that pass parallel to the afferent nerve fibers of the vestibulocochlear nerve (olivocochlear tract, cochlear efferents of Rasmussen). Efferent nerve fibers from the brainstem pass through the vestibular nerve. They synapse either on afferent endings of the inner hair cell or on the basal aspect of an outer hair cell. Efferent fibers are thought to affect the control of auditory and vestibular input to the central nervous system, presumably by enhancing some afferent signals while suppressing other signals. **Damage to the organ of Corti, cochlear nerve, nerve pathways, or auditory cortex is responsible for sensorineural hearing loss (see Folder 25.2).**

FOLDER 25.3

CLINICAL CORRELATION: VERTIGO

The sensation of rotation without equilibrium (**dizziness, vertigo**) signifies dysfunction of the vestibular system. Causes of

vertigo include viral infections, certain drugs, and tumors such as **acoustic neuroma**. Acoustic neuromas develop in or near the internal acoustic meatus and exert pressure on the vestibular division of cranial nerve VIII or branches of the labyrinthine artery. Vertigo can also be produced normally in individuals by excessively stimulating the semicircular ducts. Similarly, excessive stimulation of the utricle can produce motion sickness (seasickness, carsickness, or airsickness) in some individuals.

The most common vestibular disorder is **benign paroxysmal positional vertigo (BPPV)**. In this condition, otoconia become detached from the macula of the utricle and lodge in one of the three cristae ampullares. The anatomic position of the posterior semicircular canal (it has an opening inferior to the macula) makes it the most common site for the detached otoconia to enter (81% - 90%). The otoconia remain either free floating within the canal (**canalithiasis**) or are attached to the cupula (**cupulolithiasis**), causing inappropriate movement of the stereocilia at the apical surface of the receptor hair cells. Individuals with BPPV report episodes of an erroneous sensation of spinning evoked by certain movements of the head. Otoconia may detach following trauma or viral infections, but in many instances, it occurs idiopathically.

Some diseases of the internal ear affect both hearing and equilibrium. For example, people with **Ménière disease** initially complain of episodes of dizziness and tinnitus (ringing in the ears) and later develop low-frequency hearing loss. The causes of Ménière disease are related to blockage of the cochlear aqueduct, which drains excess endolymph from the membranous labyrinth. Blockage of this duct causes an increase in endolymphatic pressure and distension of the membranous labyrinth (endolymphatic hydrops).

Blood Vessels of the Membranous Labyrinth

Arterial blood is supplied to the membranous labyrinth by the labyrinthine artery; venous blood drainage is to the venous dural sinuses.

The blood supply to the external ear, middle ear, and bony labyrinth of the internal ear is from vessels associated with the external carotid arteries. The **arterial blood supply** to tissues of the membranous labyrinth of the internal ear is from the intracranial **labyrinthine artery**, a common branch of the anterior inferior cerebellar or basilar artery. The labyrinthine artery is a terminal artery: It has no anastomoses

with other surrounding arteries. Branches of this artery are exactly parallel to the distribution of the superior and inferior parts of the vestibular nerve.

Venous drainage from the cochlear labyrinth is via the posterior and anterior spiral modiolar veins that form the **common modiolar vein**. The common modiolar vein and the vestibulocochlear vein form the vein of the cochlear aqueduct, which empties into the inferior petrosal sinus. Venous drainage from the vestibular labyrinth is via **vestibular veins** that join the vein of the cochlear aqueduct and by the vein of vestibular aqueduct, which drains into the sigmoid sinus.

EAR

OVERVIEW OF THE EAR

- The **ear** is a paired specialized sensory organ that is responsible for sound perception and balance.
- Tissues of the ear are derived from **surface ectoderm** (epithelia lining of the membranous labyrinth) and components of the **first pharyngeal pouch** (auditory tube and middle ear cavity), **first pharyngeal groove** (external acoustic meatus), **first pharyngeal arch** (malleus, incus, and anterior part of the auricle), and **second pharyngeal arch** (stapes and posterior part of the auricle).

EXTERNAL EAR

- The **auricle** is the external component of the ear that collects and amplifies sound.

- The **external acoustic meatus** extends from the auricle to the tympanic membrane. It is lined by skin that contains hair follicles as well as sebaceous and ceruminous glands (which produce **cerumen**, or **earwax**).

MIDDLE EAR

- The **middle ear** is an air-filled space lined by a mucous membrane that contains three **auditory ossicles** (malleus, incus, and stapes). It is separated from the external acoustic meatus by the tympanic membrane and is connected by the **auditory (Eustachian) tube** to the nasopharynx.
- The middle ear **amplifies mechanical forces** generated by the vibration of the tympanic membrane.
- The **tympanic membrane** is composed of skin of the external auditory meatus, a thin core of connective tissue, and mucous membrane of the middle ear.
- The auditory ossicles (**malleus**, **incus**, and **stapes**) cross the space of the middle ear in series and connect the tympanic membrane to the oval window. Movement of the ossicles is modulated by the **tensor tympani muscle** that inserts to the malleus and the **stapedius muscle** that inserts to the stapes.

COMPARTMENTS OF THE INTERNAL EAR

- The **internal ear** consists of two compartments within the temporal bone: the **bony labyrinth** and the **membranous labyrinth**, which is contained within the bony labyrinth.
- The internal ear has three fluid-filled spaces: the **endolymphatic space** within the membranous labyrinth (which has a high K^+ and a low Na^+ concentration), the **perilymphatic space** between the wall of the bony and membranous labyrinth (which has a low K^+ and a high Na^+

concentration), and the **cortilymphatic space** that lies within the tunnels of the organ of Corti of the cochlea.

- The **bony labyrinth** consists of three connected spaces: **semicircular canals**, **vestibule**, and **cochlea**, each containing different parts of the membranous labyrinth.
- The **membranous labyrinth** consists of a series of communicating sacs (**utricle**, **saccule**, and **endolymphatic sac**) and ducts (**three semicircular ducts**, **cochlear duct**, **utricleosaccular duct**, **endolymphatic duct**, and **ductus reuniens**) that contain **endolymph**.

SENSORY RECEPTORS OF THE MEMBRANOUS LABYRINTH

- Specialized sensory cells are located in six regions in the membranous labyrinth: three **cristae ampullares** in the ampullae of the semicircular ducts (receptors for angular acceleration of the head), two **maculae** in the utricle and saccule (receptors for position of the head and its linear movements), and the **spiral organ of Corti** (receptors for sound).
- Utricle and saccule maculae contain **hair cells** that are epithelial mechanoreceptors. These hair cells contain **hair bundles** on their apical surfaces (formed by rows of stereocilia with a single kinocilium) and are overlaid with a gelatin-like **otolithic membrane** that contains otoliths (otoconia).
- Movement of the **otoliths** is detected by the hair bundles, which activate **mechanically gated ion channels** to generate an action potential.
- Sensory receptors in the **crista ampullaris** are also covered by a gelatin-like mass without otoliths called the **cupula**. The cupula is deflected during the flow of endolymph through the semicircular canal. Movement of the cupula stimulates **mechanically gated ion channels** to generate an action potential.
- The **cochlear canal** is divided into three parallel compartments: **scala media** or **cochlear duct** (the middle

compartment filled with endolymph that contains the spiral organ of Corti), **scala vestibuli**, and **scala tympani** (both containing perilymph).

- The **scala media** is a triangular space with its lower wall forming the **basilar membrane** on which the spiral organ of Corti resides. The upper wall (**vestibular membrane**) separates the scala media from scala vestibuli, and the lateral wall contains the **stria vascularis** that produces endolymph.
- The **spiral organ of Corti** is composed of **hair cells** (arranged in inner and outer rows), supportive **phalangeal cells**, and **pillar cells**. Movement of the stereocilia on hair cells during interaction with the overlying **tectorial membrane** generates electrical impulses that are transmitted to the cochlear nerve.
- **Sound waves** are transmitted from the vibrating tympanic membrane by the ossicles to the oval window, where they produce movement (waves) of the perilymph in the scala vestibule. This movement deflects the basilar membrane and spiral organ of Corti to generate electrical nerve impulses, which are perceived by the brain as sounds.
- Nerve impulses from the cristae ampullares and maculae travel with the **vestibular nerve**, and the impulses from the spiral organ of Corti travel with the **cochlear nerve**. These two nerves join together in the internal acoustic meatus to form the **vestibulocochlear nerve** (cranial nerve VIII).

PLATE 25.1 ■ EAR

The internal ear, located in the temporal bone, consists of a system of chambers and canals that contain a network of membranous channels. These are referred to, respectively, as the **bony labyrinth** and **membranous labyrinth**. In some areas, the membranous labyrinth forms the lining of the bony labyrinth; in others, they are separated. Within the space lined by the membranous labyrinth is a watery fluid called **endolymph**. External to the membranous labyrinth, that is, between the

membranous and bony labyrinths, is an additional fluid called perilymph.

The bony labyrinth is divided into three parts: **cochlea**, **semicircular canals**, and **vestibule**. The cochlea and semicircular canals contain membranous counterparts of the same shape; however, the membranous components of the vestibule are more complex in form, being composed of ducts and two chambers, the **utricle** and **sacculle**. The cochlea contains the receptors for hearing (the **organ of Corti**); the semicircular canals contain the receptors for movement of the head; and the utricle and sacculle contain receptors for position of the head.

Internal ear, ear, guinea pig, hematoxylin and eosin (H&E) $\times 20$.

In this section through the **internal ear**, bone surrounds the entire internal ear cavity. Because of its labyrinthine character, sections of the internal ear appear as a number of separate chambers and ducts.

However, these structures are all interconnected (except for the perilymphatic and endolymphatic spaces, which remain separate). The largest chamber is the **vestibule** (*V*). The left side of this chamber (*black arrow*) leads into the **cochlea** (*C*). Just below the *black arrow* and to the right is the oval ligament (*OL*) surrounding the base of the stapes (*S*). Both structures have been cut obliquely and are not seen in their entirety. The facial nerve (*FN*) is in an osseous tunnel to the left of the oval ligament. The communication of the vestibule with one of the semicircular canals is marked by the *white arrow*. Note the crista ampullaris (*CA*) that is projecting into the lumen of the semicircular canal. At the *upper right* are cross sections of the membranous labyrinth passing through components of the semicircular duct system (*DS*).

The cochlea is a spiral, cone-shaped structure. The specimen illustrated here makes $3\frac{1}{2}$ turns (in humans, there are $2\frac{3}{4}$ turns). The section goes through the central axis of the cochlea. This consists of a bony stem called the **modiolus** (*M*). It contains the beginning of the cochlear nerve (*CN*) and the spiral ganglion (*SG*). Because of the plane of section and the spiral arrangement of the cochlear tunnel, the tunnel is cut crosswise in seven places (note $3\frac{1}{2}$ turns). A more detailed examination of the cochlea and the organ of Corti is provided in Plate 25.2 (page 1044).

Semicircular canal, ear, guinea pig, H&E $\times 85$; inset $\times 380$.

A higher magnification of one of the semicircular canals and of the **crista ampullaris** (*CA*) within the canal seen in the *lower right* corner of the previous figure is provided here. The receptor for movement, the crista ampullaris (note its relationships in the previous figure), is present in each of the semicircular canals. The epithelial (*EP*) surface of the crista consists of two cell types, supporting cells and receptor hair cells. (Two types of hair cells are distinguished with the electron microscope.) It is difficult to identify the hair and supporting cells on the basis of specific characteristics; they can, however, be distinguished on the basis of location (see *inset*), as the **hair cells** (*HC*) are situated in a more superficial location than the supporting cells (*SC*). A gelatinous mass, the cupula (*Cu*), surmounts the epithelium of the crista ampullaris. Each receptor cell sends a hair-like projection deep into the substance of the cupula.

The epithelium rests on a loose, cellular connective tissue (*CT*) that also contains the nerve fibers associated with the receptor cells. The nerve fibers are difficult to identify because they are not organized into a discrete bundle.

C, cochlea
CA, crista ampullaris
CN, cochlear nerve
CT, connective tissue
Cu, cupula
DS, duct system (of membranous labyrinth)
EP, epithelium
FN, facial nerve
HC, hair cell
M, modiolus
OL, oval ligament
S, stapes
SC, supporting cell
SG, spiral ganglion
V, vestibule
black arrow, entry to cochlea
white arrow, entry to semicircular canal

PLATE 25.2 ■ COCHLEAR CANAL AND ORGAN OF CORTI

The hair cell, a nonneuronal mechanoreceptor, is the common receptor cell of the vestibulocochlear system. Hair cells are epithelial cells that possess numerous stereocilia, modified microvilli also called sensory hairs. They convert mechanical energy to electrical energy that is transmitted via the vestibulocochlear nerve (cranial nerve VIII) to the brain. Hair cells are associated with afferent, as well as efferent, nerve endings. All hair cells have a common basis of receptor cell function that involves bending or flexing of their stereocilia. The specific means by which the stereocilia are bent varies from receptor to receptor, but in each case, stretching of the plasma membrane caused by the bending of the stereocilia generates transmembrane potential changes that are transmitted to the afferent nerve endings associated with each cell. Efferent nerve endings on the hair cells serve to regulate their sensitivity.

Cochlear canal, ear, guinea pig, hematoxylin and eosin (H&E) $\times 65$; inset $\times 380$.

A section through one of the turns of the cochlea is shown here. The most important functional component of the cochlea is the organ of Corti, enclosed by the *rectangle* and shown at higher magnification in the next figure. Other structures are included in this figure.

The spiral ligament (*SL*) is a thickening of the periosteum on the outer part of the tunnel. Two membranes, the basilar membrane (*BM*) and the vestibular membrane (*VM*), join with the spiral ligament and divide the cochlear tunnel into three parallel canals, namely, the **scala vestibuli** (*SV*), the **scala tympani** (*ST*), and the **cochlear duct** (*CD*). Both the scala vestibuli and the scala tympani are perilymphatic spaces; these communicate at the apex of the cochlea. The cochlear duct is the space of the membranous labyrinth and is filled with endolymph. It is thought that the endolymph is formed by the portion of the spiral ligament that faces the cochlear duct, the stria vascularis (*StV*). This is highly vascularized and contains specialized “secretory” cells.

A shelf of bone, the osseous spiral lamina (*OSL*), extends from the modiolus to the basilar membrane. Branches of the cochlear nerve (*CN*) travel along the spiral lamina to the modiolus, where the main trunk of the nerve is formed. The components of the cochlear nerve are bipolar neurons whose cell bodies constitute the spiral ganglion (*SG*). These cell bodies are shown at higher magnification in the *inset* (*upper right*). The spiral lamina supports an elevation of cells, the

limbus spiralis (*LS*). The surface of the limbus is composed of columnar cells.

**Organ of Corti, ear, guinea pig, H&E $\times 180$;
inset $\times 380$.**

The cross section of the **cochlear canal** (*CD*) visible in this image appears as a triangular space. The upper wall (roof) of this canal is formed by the vestibular membrane (*VM*) that separates it from the scala vestibuli (*SV*). The lateral (outer) wall of the cochlear canal is bordered the stria vascularis (*StV*) and underlying spiral ligament (*SL*). The lower wall (or floor) is formed by the basilar membrane, an extension of the osseous spiral lamina with visible branches of the cochlear nerve (*CN*). The basilar membrane supports the spiral **organ of Corti**. The components of the organ of Corti, beginning at the limbus spiralis (*LS*), are as follows: inner border cells (*IBC*), inner phalangeal and hair cells (*IP&HC*), and inner pillar cells (*IPC*). The sequence continues, repeating itself in reverse as follows: outer pillar cells (*OPC*), hair cells (*HC*) and outer phalangeal cells (*OP*), and outer border cells or cells of Hensen (*CH*). Hair cells are receptor cells; the other cells are collectively referred to as *supporting cells*. The hair and outer phalangeal cells can be distinguished in this figure by their location (see *inset*) and because their nuclei are well aligned. Because the hair cells rest on the phalangeal cells, it can be concluded that the upper three nuclei belong to outer hair cells, whereas the lower three nuclei belong to outer phalangeal cells.

The supporting cells extend from the basilar membrane (*BM*) to the surface of the organ of Corti (this is not evident here but can be seen in the *inset*), where they form a reticular membrane (*RM*). The free surface of the receptor cells fits into openings in the reticular membrane, and the “hairs” of these cells project toward, and make contact with, the tectorial membrane (*TM*). The latter is a cuticular extension from the columnar cells of the limbus spiralis. In ideal preparations, nerve fibers can be traced from the hair cells to the cochlear nerve (*CN*).

In their course from the basilar membrane to the reticular membrane, groups of supporting cells are separated from other groups by spaces that form spiral tunnels. These tunnels are named the inner tunnel (*IT*), the outer tunnel (*OT*), and the internal spiral tunnel (*IST*). Beyond the supporting cells are two additional groups of cells, the cells of Claudius (*CC*) and the cells of Böttcher (*CB*).

BM, basilar membrane

CB, cells of Böttcher
CC, cells of Claudius
CD, cochlear duct
CH, cells of Hensen
CN, cochlear nerve
HC, hair cells
IBC, inner border cells
IPC, inner pillar cells
IP&HC, inner phalangeal and hair cells
IST, internal spiral tunnel
IT, inner tunnel
LS, limbus spiralis
OP, outer phalangeal cells
OPC, outer pillar cells
OSL, osseous spiral lamina
OT, outer tunnel
RM, reticular membrane
SG, spiral ganglion
SL, spiral ligament
ST, scala tympani
StV, stria vascularis
SV, scala vestibule
TM, tectorial membrane
VM, vestibular membrane

- classification of, 113 - 114, 123 - 124, 125 *t*
- columnar, 113, 113, 123, 125 *t*, 172*p* - 175*p*
- crevicular, 608
- cuboidal, 113, 113, 123, 125 *t*, 170*p* - 175*p*
- distribution of, 122, 125 *t*
- enamel, 600, 601 - 602, 603
- functions of, 123, 124, 125 *t*
- glandular, 163 - 164, 389
- histogenesis of, 117
- junctional or attachment, 608
- keratinized, 113, 589 - 590, 590, 620*p* - 621*p*
- in membrane functional unit, 167 *f*
- mesodermal, 863, 864
- mucosal, 633, 661
- nonkeratinized, 113
- parakeratinized, 590, 620*p* - 621*p*
- as pathogenic target, 148 *f*
- primary cilia of, 136 *t*
- pseudostratified, 124, 125 *t*, 172*p* - 173*p*
- renewal of, 166 - 167
- as selective barrier, 123
- simple, 113, 113, 123 - 124, 125 *t*, 170*p* - 175*p*
- squamous, 113, 113, 123, 125 *t*, 170*p* - 175*p*
- stratified, 113 - 114, 113, 123 - 124, 125 *t*, 172*p* - 175*p*
- structure of, 122 - 123
- surface modifications of, 113
- transitional, 124, 125 *t*, 174*p* - 175*p*, 795 - 796, 796, 810*p* - 813*p*
- transport across, 124, 144 - 145, 144
- of urothelium, 810*p* - 811*p*
- Epithelium, olfactory, 733, 734, 735
- Eponychium, 565, 567, 586*p* - 587*p*
- Epoxy resin, 21
- Epsilon cell, of pancreas, 717 *t*
- ϵ -Tubulin, in MTOC, 77
- Equatorial division (meiosis II), 102, 103
- Erbin, 160, 161, 162
- Erectile dysfunction (ED), 892 *f*
- Erectile tissue, 890, 890, 892 *f*, 940, 941, 942, 943
- Erection of penis, 890, 892 *f*
- Ergastoplasm, 54, 57, 58
- Ergocalciferol, 769 *f*
- Erythroblast(s), 324, 325 - 326, 325, 326, 329 *t*, 340*p* - 341*p*
- Erythroblastosis fetalis, 304 *f*
- Erythrocyte(s)
 - on blood smear, 336*p* - 337*p*
 - on bone marrow smear, 338*p* - 339*p*
 - chromatin of, 326

- development of, 321, 322, 323 - 326, 324, 325, 329 *t*, 340*p* - 341*p*

 endothelial cell maintenance of, 456*t*
 fibrocartilage, 224
 functions of, 192
 ground substance of, 193-194
 junctions anchoring cells to, 153
 photoaging and, 193*f*
 production of, 219-220
 Extracellular matrix adhesion molecules, 250
 Extrahepatic bile ducts, 707-708
 Extramural digestive gland epithelium, 117
 Extramural glands, 633, 634
 Extraocular muscles, 1007
 Extremities, autonomic innervation of, 421
 Extrinsic laryngeal muscles, 736
 Extrinsic muscles of eye, 1007
 Eye(s), 980-1017, 1010*p*-1018*p*
 accessory structures of, 1004-1007
 anterior segment of, 1014*p*-1015*p*
 barriers protecting, 989, 990-991, 994
 chambers of, 982, 982
 color of, 988
 corneoscleral coat of, 980-981, 981, 983-987
 development of, 116, 982-983, 983, 984*t*
 general structure of, 980-983
 innervation of, 980-981, 981-983, 988, 993, 994, 1002, 1010*p*
 layers of, 980-981, 981
 microscopic structure of, 983-1004, 988
 movements of, 1007
 muscles of, 981, 987-989, 987-989, 1004, 1004, 1007, 1014*p*-1015*p*
 ophthalmoscopic examination of, 989, 1002
 overview of, 980
 pressure in (intraocular pressure), 990*f*, 991
 refractile (dioptric) media of, 982
 vascular coat of, 981, 981, 987-992
 Eyelash glands, 1005, 1006

Eyelashes, 1006
Eyelids, 163, 1004 - 1006, *1005*
Ezrin, 128

F

F-actin (filamentous actin), 69, 344
F cell, of pancreas, 717*t*
Facial expression, muscles of, 555
Facial nerve (CN VII), 592, 614
Factor VIII, (coagulating), 457
Facultative heterochromatin, 88, 91
False vocal cords, 737 - 738
Fas signaling pathway, 109
Fascia
 deep investing, 345 - 346
 subcutaneous (superficial), 281, 538, 555
Fascia adherens, 148 - 149, *148*, 362, *364*
Fascicle, muscle, 345, *346*, *347*, 376*p* - 377*p*
Fascicle, nerve, 417
Fascin, 70, 127, *128*
Fast anterograde transport, 396 - 397
Fast oxidative glycolytic muscle fibers, 347
Fast retrograde transport, 397
Fast-twitch, 347
Fast-twitch muscle fibers, 347
Fat absorption, 708
Fat droplets (lipid inclusions), 30*t*, 31*t*, 81 - 82
Fatigue-prone muscle units, 347
Fatigue-resistant motor units, 347
Fatty acid(s), 32, *33*, 285, 350*f*, 544, 844 - 845
Fatty acid β -oxidation, 62, 64, 695, 713
Fatty liver disease, 693
Fatty streak, 452*f*
F_c receptors, 200, 204, 309, 313, 495, 521, 550
¹⁸F-FDG (radioactive glucose isotope), 293*f*
Feedback mechanisms, 818, 827
Female gametes. *See* Oogenesis; Ova

 blood supply to, 719
 endocrine, 712, 715 - 719, 726*p* - 727*p*
 epithelial tissue of, 113, 170*p* - 175*p*
 exocrine, 712 - 713, 726*p* - 727*p*

- hormonal and neural regulation of, 714 - 715
- innervation of, 718
- islet cells of, 716, 716*t*, 717, 717*t*, 719*f*, 726*p* - 727*p*
- islets of, 174*p* - 175*p*, 644*f*, 712, 715 - 718, 715, 716, 726*p* - 727*p*
- secretions of, 589
- Pancreatic ducts, 707, 708, 711 - 715, 711, 712
- Pancreatic enzymes, 648*f*, 713
- Pancreatic hormones, 715 - 718, 718*t*
- Pancreatic polypeptide, 647*t*, 717*t*, 718*t*, 719
- Paneth cells, 166, 652, 656 - 657, 656, 661
- Panniculus adiposus, 280, 555
- Panniculus carnosus, 555
- Papanicolaou (Pap) test, 933, 945*f*
- Papillary cells of enamel, 603
- Papillary ducts (of Bellini), 773, 775
- Papillary layer, of dermis, 551 - 552, 578*p* - 579*p*
- Papillary layer, of enamel (tooth), 603
- Papillary muscles, of heart, 443, 446, 447, 447
- Paracellular diffusion barrier, 141
- Paracellular gap, 308
- Paracellular pathway, 144, 145, 308, 453
- Paracetamol, 700*f*
- Paracortex (deep cortex), of lymph nodes, 507, 508, 510
- Paracrine control, 815, 815
- Paracrine hormones, 644*f*, 647*t*, 656, 819*f*
- Paracrine luteotropins, 921
- Paracrine secretion, 402
- Paracrine signaling, 163, 163
- Paraffin, 2
- Parafollicular cells (C cells), 831, 831
- Paragangliomas, 844*f*
- Parakeratinized epithelium, 50, 590, 620*p* - 621*p*
- Paranasal sinuses, 731, 736
- Paranemin, 74*t*, 75
- Paraptosis, 108
- Parasitic infections, 148*f*, 207, 313
- Parasternal lymph nodes, 951
- Parasympathetic division, of ANS, 389, 418 - 420, 419
 - cardiac regulation by, 449
 - liver innervation by, 708
 - pancreatic innervation by, 718
 - penis innervation by, 891, 892*f*
 - tongue innervation by, 596
 - urinary bladder innervation by, 798
- Parasympathetic ganglia, 415*t*, 432*p*
- Parathyroid glands, 117, 815, 837 - 839, 837, 856*p* - 857*p*
- Parathyroid hormone (PTH), 251, 261 - 262, 769, 769*f*, 787, 837 - 839, 837*t*

- Parathyroid hormone receptors, 251
- Paraurethral ducts, 799
- Paraurethral glands, 799
- Paraventricular nuclei, of hypothalamus, 820, 824
- Paravertebral ganglia, 418, 432*p*
- Parenchyma, 122
 - of liver, 696, 697 - 698
 - of lung, 743
 - of lymph node, 508
 - of prostate gland, 885 - 886
 - of thymus, 512 - 513
- Parenchymal cells
 - of adrenal glands, 839
 - of pineal gland, 828 - 829
- Parietal cells, 640 - 644, 640, 643, 649 - 650, 674*p* - 677*p*
- Parietal epithelial cells, of Bowman capsule, 780, 781
- Parietal layer, of Bowman capsule, 775, 780, 806*p* - 807*p*
- Parietal layer of serous pericardium, 445, 445
- Parkinson disease, 396, 398*f*, 420
- Parkinsonism, secondary, 398*f*
- Parotid (Stensen) duct, 589
- Parotid gland, 164, 609
- Parotid gland tumors, 617*f*
- Parotid glands, 589, 608, 614, 615, 628*p* - 629*p*
- Parotid papilla, 589
- Pars distalis, of adenohypophysis, 819, 820, 821 - 824, 822, 850*p* - 853*p*
- Pars fibrosa, of nucleolus, 91
- Pars flaccida, of tympanic membrane, 1020
- Pars granulosa, of nucleolus, 91
- Pars intermedia, of pituitary gland, 819, 820, 824, 824, 850*p* - 851*p*
- Pars nervosa, of neurohypophysis, 819, 820, 824, 850*p* - 853*p*
- Pars tensa, of tympanic membrane, 1020
- Pars tuberalis, of pituitary gland, 819, 820, 824, 850*p* - 851*p*
- PAS cells (microphages in thymus), 512
- PAS staining, 6, 6, 154, 154, 155, 187
- Passive (simple) diffusion, 37 - 38, 38
- Passive transport, 38, 38
- Pathogen-associated molecular patterns (PAMPs), 40, 309
- Pathology
 - expansion, 13
 - telepathology, 25
- Pattern recognition receptors (PRRs), 309, 483 - 484
- Pax3* gene, 544
- Pax5* transcription factor, 331
- Pax7*, 361
- Paxillin, 161, 161
- PDZ-domain proteins, of zonula occludens, 144

Pectinate ligament, 986
 Pedicels, of podocytes, 774, 775, 776, 781
 Pedicle, of cone, 1001
 Peg cells, of uterine tubes, 924
 Pellicle, acquired, 617
 Pelvis, autonomic innervation of, 421
 Pendrin, 833, 833
 Penicillar arterioles, of spleen, 518, 521
 Penile urethra, 799
 Penis, 862, 891, 892*f*
 Pentose phosphate pathway (pentose shunt), 310 - 311
 Pepsin, 641
 Pepsinogen, 641, 642
 Peptic ulcer disease (PUD), 641*f*
 Peptide hormones, 45, 816, 937 - 938
 Peptide neurotransmitters, 402, 402*t*
 Peptide YY (PYY), 284, 647*t*

- appendages of, 559 - 572, 560, 586*p* - 587*p*
- cell renewal in, 167, 539 - 540, 544
- cells of, 541 - 550
- chronological aging of, 193*f*
- connective tissue of, 179
- dark, 548, 548
- epidermal derivatives of, 538
- epithelial tissue of, 124, 167, 174*p* - 175*p*
- excretion by, 539
- functions of, 538 - 539
- layers of, 539 - 541, 539
- light, 548, 548
- mechanical stress on, 551
- nerve supply of, 555 - 559, 556, 584*p* - 585*p*
- photoaging of, 193*f*
- primary cilia of, 136*t*
- repair of, 572*f*
- secretion by, 539
- stem cells in, 539, 564, 564
- thick or thin, 539, 539, 540, 576*p* - 577*p*
- vitamin D production in, 769*f*

Skin aging, 572 - 573

Skin cancer, 551*f* - 552*f*, 556*f* - 558*f*

Skin color (pigmentation), 548, 561*f*, 578*p* - 579*p*

Sliding movement, ciliary, 132 - 134

Slow anterograde transport system, 396

Slow oxidative fibers, 346 - 347

Slow-twitch muscle fibers, 346 - 347

Slowly renewing cell populations, 97

SMAC/DIABLO, 105

Small arteries, 451*t*, 456, 461 - 462
 Small granule cells
 of nasal cavity, 732
 of trachea, 740 - 741
 Small intestine, 633, 651 - 660, 680*p* - 685*p*
 absorptive cells (enterocytes) of, 630, 648*f* - 649*f*, 652 - 655, 680*p* - 683*p*
 bile flow to, 707 - 708
 cells of, 652 - 658
 contractions of, 660
 digestive and absorptive functions of, 589, 651 - 652
 divisions of, 651, 678*p* - 685*p*
 epithelial cell renewal in, 659
 glands of, 652, 653, 678*p* - 681*p*
 immune functions of, 652, 657*f*, 658 - 659
 lamina propria of, 652, 658, 680*p* - 683*p*
 lymphatic nodules of, 505, 506, 634, 652, 653, 658, 684*p* - 685*p*
 mucosa of, 651 - 659, 653, 678*p* - 685*p*
 muscularis externa of, 386*p* - 387*p*, 660, 680*p* - 685*p*
 muscularis mucosae of, 652, 653, 680*p* - 685*p*
 plicae circulares of, 633, 651, 680*p* - 683*p*
 secretions of, 589
 serosa of, 660, 680*p* - 683*p*
 smooth muscle of, 386*p* - 387*p*
 stem cells in, 166 - 167, 205, 659
 submucosa of, 659, 680*p* - 685*p*
 tight junctions in, 654
 villi of, 633, 652, 653, 680*p* - 685*p*
 Small leucine-rich proteoglycans (SLRPs), 985
 Small nucleolar RNAs (snoRNAs), 91
 Small peptides, as neurotransmitters, 402, 402*t*
 Small proline-rich (SPR) proteins, 543, 544
 Small pyramidal cell layer, of cerebrum, 436*p* - 437*p*
 Small veins, 451*t*, 465 - 466
 Smooth border, of ameloblasts, 601
 Smooth endoplasmic reticulum (sER), 29, 57 - 58
 detoxification in, 57 - 58
 functions and pathologies of, 31*t*
 hepatocyte, 703, 704
 of Leydig cell, 868
 lipid metabolism in, 57
 microscopic features of, 30*t*, 57, 58
 of Sertoli cell, 877, 878
 Smooth muscle, 115, 115, 344 - 345, 366 - 372, 386*p* - 387*p*
 actin filaments in, 198, 202, 202*f*
 autonomic regulation of, 372*f*, 389, 418
 basal lamina in, 155, 155
 bronchial, 743

Visceral layer of serous pericardium, 445, 445
Visceral motor (efferent) neurons, 390, 418, 418
Visceral pleura, 754, 764*p* - 765*p*
Visceral sensory (afferent) neurons, 390, 416, 418
Visceral striated muscle, 344 - 345
Visfatin, 281, 286*t*
Visible mucus, 639
Vision
 accommodation in, 981, 982, 1003
 adaptation in, 981
 color sensitivity in, 995, 1000*f*
 light sensitivity in, 995
 process of, 998 - 999, 999
 stereopsis in, 980
 vitamin A and, 693, 702, 998
Visual fields, 980, 992*f*, 993
Visual pigment/purple (rhodopsin), 702, 998
Visual processing, 998 - 999, 999
Vitamin A, 693, 702, 998
Vitamin B₁₂, 644
Vitamin B₁₂ deficiency, 306*f*, 641, 641*f*, 644
Vitamin B₂ (riboflavin), 488
Vitamin C, 185, 265*f*
Vitamin D, 693, 695, 769, 769*f*, 839
 deficiency of (rickets), 265*f*, 693, 769*f*
 regulation of, 839
 renal regulation of, 769, 769*f*
Vitamin E, 693

Vitamin K, 693
 Vitamin K - dependent proteins, bone-specific, 239
 Vitamin(s), hepatic storage and metabolism of, 693, 702
 Vitreous body, 982, 982, 983, 1004
 Vitreous chamber, 982, 982, 1010*p* - 1011*p*
 Vitreous humor, 982
 Vocal folds, 189, 732, 736 - 737, 737, 738, 760*p* - 761*p*
 Vocalis muscle, 736, 738
 Voice production, 736 - 738
 Volkmann canals, 242, 242, 245, 270*p* - 271*p*
 Voltage-dependent anion channels, 62, 63, 63
 Voltage-gated Ca²⁺ channels, 399, 594, 595
 Voltage-gated ion channels, 38
 Voltage-gated K⁺ channels, 414
 Voltage-gated Na⁺ channels, 356, 359, 400, 414
 Voltage-sensitive Ca²⁺ channels, 596
 Voltage-sensitive Na⁺ channels, 595, 596
 Voltage-sensor proteins, 356, 359, 359, 365
 Volume receptors, 450
 von Ebner (lingual salivary) glands, 592, 608, 624*p* - 625*p*
 von Willebrand factor, 457
 Vulva, 908, 939 - 941
 Vulvovaginitis, 945*f*

W

Waldeyer tonsillar ring, 589
 Wallerian degeneration, in nerve injury, 426 - 429
 Wandering cell population, of connective tissue, 197
 Warts, genital, 950*f*
 Washing, of tissue specimen, 2
 Water barrier, of epidermis, 541, 542, 543, 544
 Water channels (aquaporins), 785, 791*f*
 ADH action on, 791, 791*f*, 825
 in gallbladder, 711
 in glomerular capillaries, 775
 in high endothelial venules, 509 - 510
 in water homeostasis of brain, 425
 Water homeostasis, 425, 542, 825
 Water reabsorption, 660, 784 - 786
 Wave of mineralization, 261, 606
 "Wear and tear" pigment, 82
 Weibel - Palade bodies, 457, 466
 Weight regulation, 283 - 285
 Wet age-related macular degeneration, 992*f*
 Wharton (submandibular) duct, 589
 Wharton's jelly, 177, 178

Wharton's jelly mesenchymal stem cells, 177
 White adipocytes, 281 - 285, 282, 292 - 293
 White adipose tissue, 281 - 285, 296*p* - 297*p*
 features of, 292*t*
 function of, 281
 regulation of, 283 - 285
 structure of, 283, 283
 transdifferentiation of, 292 - 293
 White blood cells (WBCs). *See* Leukocyte(s)
 White matter
 brain, 421, 436*p* - 437*p*
 spinal cord, 422, 423, 440*p* - 441*p*
 White muscle fibers, 346
 White pulp, of spleen, 516, 532*p* - 533*p*
 White-to-brown transdifferentiation, in adipocytes, 291
 Wilms tumor 1 gene (*WT-1*), 863
 Wilms tumor, familial, 863
 Wilson ATPase, 694
 Wilson disease, 694
 Wirsung, duct of, 707, 711 - 712, 711, 713
 Wisdom teeth, 597
 Wolffian duct, 880 - 882, 881, 885
 Wolfring, glands of, 1005, 1007
 Wolman disease, 51*f*
 Wound repair (healing), 99, 197, 200, 202*f*, 206, 312, 572*f*
 Woven bone, 242, 254, 254
WT-1 gene, 863

X

X91 disease, 311*f*
 X chromosome, 90, 91, 91, 865
 Xanthomatosis, familial, 51*f*
 Xenobiotics, 694
 XY female embryo with gonadal dysgenesis, (Swyer syndrome), 863

Y

Y chromosome, 90, 865
 Yellow bone marrow, 241, 333
 Yolk-sac phase, of hemopoiesis, 321, 323
 Young's syndrome, 139*f*

Z

Z line (Z disc)
 cardiac muscle, 363, 364

skeletal muscle, 347, 348 - 349, 349, 352, 355
 Z matrix, 349
 Zeis glands, 566, 1005, 1006
 Zellweger syndrome, 66
 ζ -Tubulin, in MTOC, 77
 ZO-1 protein, 143 *t*, 144, 149
 ZO-2 protein, 143 *t*, 144
 ZO-3 protein, 143 *t*, 144
 Zollinger-Ellison syndrome, 642 *f*, 716
 Zona glomerulosa, 781, 843 - 844, 844, 858*p* - 859*p*
 Zona pellucida, 911, 912, 913, 920 - 921, 957*p* - 958*p*
 Zona reaction, 921
 Zona reticularis, 811, 843, 846, 858*p* - 859*p*
 Zone 1, of liver acinus, 697
 Zone 2, of liver acinus, 697
 Zone 3, of liver acinus, 697
 Zone of calcified cartilage, 257, 258, 276*p* - 277*p*
 Zone of hypertrophy, 257, 258, 276*p* - 277*p*
 Zone of proliferation, 257, 258, 276*p* - 277*p*
 Zone of reserve cartilage, 257, 258, 276*p* - 277*p*
 Zone of resorption, 257, 258, 276*p* - 277*p*
 Zonula adherens, 140, 145 - 149, 147, 152 *t*
 composition of, 146 - 148
 electron microscopy of, 147, 148
 function of, 146
 Zonula occludens, 140, 141 - 145, 143, 152 *t*
 bicellular, 142
 permeability of, 145
 proteins of, 142 - 144, 143 *t*
 strand formation, 142 - 144
 transport across, 144 - 145, 144
 tricellular, 142, 142, 145
 viruses exploiting, 142 - 144, 148 *f*
 Zonular fibers, of eye, 987, 988, 990 - 991, 1003, 1003
 Zonule of Zinn, 982
 ZP (zona pellucida) glycoproteins, 911
 Zygote, 102, 917, 920 - 921, 930
 Zygotene, 100, 102
 Zymogen(s), 648 *f*, 659
 Zymogen granules, 40, 610, 642, 642, 712, 713
